Proof. If $\mathsf{Beaut}(B) = \mathsf{Ful}(B) \wedge \mathsf{Sur}(B)$ is designated, then both $\mathsf{Ful}(B)$ and $\mathsf{Sur}(B)$ have designated truth components, hence $\mathsf{Ful}_m(B; I) \geq \theta_F$ and (after rescaling) $\mathsf{Sur}_m(B; I) \geq \theta_S$ for suitable corresponding numeric thresholds. By assumptions (1) and (2) and $\mathsf{Self}C(m; I) \geq \theta_C$, we get $G_I > 0$ and $G_T > 0$. Thus $\mathsf{Rep}_m(B; I)$ is OEI-active by Definition 409. In other words, the designated status of $\mathsf{Beaut}(B)$ forces *both* constituents—fulfillment and surprise—to be present to a model-dependent but nontrivial degree (captured by θ_F, θ_S), and the OEI-activity condition is triggered precisely because the growth terms G_I, G_T are required to be strictly positive rather than merely nonnegative. The "after rescaling" clause is included to emphasize that $\mathsf{Sur}_m(\cdot)$ may be measured on a different natural scale than $\mathsf{Ful}_m(\cdot)$ (e.g. entropic novelty versus reward-like satisfaction), yet the designatedness constraint can still be pushed down to a single inequality by choosing a monotone calibration map and an appropriate θ_S. □

Remark 1350. *This theorem is intentionally a "sanity theorem": it shows that the ontology can formalize Hyperseed's claim that beauty is tied to open-ended intelligence (individuation + self-transcendence) without requiring a single reductionist scalar. Stronger results can be obtained once specific models of $G_I, G_T, \mathsf{Self}C$ are chosen. In particular, the point is not that* Beaut equals *any one quantitative score, but that the logical structure of beauty-as-"surprising fulfillment" can be made to entail (via thresholding) the activation of a representation subnetwork with both individuative and transcendent growth directions. Accordingly, the theorem isolates the minimal commitments needed for the implication $\mathsf{Beaut}(B) \Rightarrow$ "OEI-active representation": designatedness of the conjunction, and positivity of the growth terms under adequate self-coherence.*

24.9 Archetypes, art, and religion as communion technologies

Hyperseed treats archetypes as patterns that occur surprisingly often across a collection of systems but with diverse instantiations, and treats art as something with strong aesthetic effect. A natural ontology-level synthesis is: *artifacts and rituals are pattern carriers that can induce cross-mind patterns, thus facilitating communion.* Here "pattern carrier" is intended broadly: it includes not only static objects (images, texts, buildings) but also repeatable procedures (chants, dances, liturgies) whose execution can synchronize attention, affect, and interpretation across a group. The central technical idea is that such carriers can be analyzed in the same language as other representational substrates, by tracking how they change cross-supported intensities and thereby shift communion margins.

Definition 410 (Archetype as a cross-context pattern template)**.** *Fix a class of systems (minds, texts, cultures, etc.) indexed by J. An* archetype *is a template τ together with an instantiation map sending each $j \in J$ to a (possibly empty) set of instantiations $\mathsf{Inst}_j(\tau)$, such that:*

1. *τ has high support across J (many j have $\mathsf{Inst}_j(\tau) \neq \emptyset$), and*
2. *the typical instantiations are diverse (not near-copies), and*
3. *the support is "surprising" relative to the description complexity of τ (e.g. high occurrence despite nontrivial $\kappa(\tau)$).*

Intuitively, (1) captures the "recurrence" aspect of archetypes, (2) rules out trivial replication effects (e.g. a single meme copied verbatim), and (3) is the anti-tautology constraint ensuring that τ is neither so vague that it matches anything nor so simple that high frequency is automatically expected. Depending on application, "diverse" can be operationalized via a distance on instantiations (semantic, structural, stylistic), and "surprising" can be operationalized via deviation from a null model on J in which occurrences are generated independently of τ's internal structure.

Remark 1351. *A useful way to read Definition 410 is as a three-way tension: increasing $\kappa(\tau)$ typically decreases baseline occurrence under simple generative priors, so an archetype is precisely a template whose empirical support remains high despite that penalty. This aligns the informal "archetypal" notion (recurring forms that feel deeper than coincidence) with a quantitative perspective in which recurrence is evaluated against compressibility and expected frequency.*

Definition 411 (Art as an intersubjective pattern carrier)**.** *Fix a class of experiencers $\mathcal{X} \subseteq \mathsf{Mind}$. An* art object *$A$ (relative to $\mathcal{X}$) is any entity such that, for many $m \in \mathcal{X}$, encountering A induces a designated beauty proposition $\mathsf{Beaut}(A)$ in m's valuation. Equivalently, it induces a high rate of beauty episodes in the population $\mathcal{X}$. Because $\mathsf{Beaut}(\cdot)$ lives in a paraconsistent setting, this criterion allows that some experiencers may also (simultaneously) assign non-designated or even conflicting evaluations to A without preventing A from counting as an art object relative to $\mathcal{X}$, so long as the designated-beauty response is sufficiently widespread. The explicit relativization to $\mathcal{X}$ is meant to capture the familiar phenomenon that what functions as art for one community may not function as art for another, not merely due to preference but due to differences in learned perceptual and interpretive repertoires.*

Definition 412 (Communion capacity of an artifact)**.** *Fix a community C and interval I, and let A be an artifact jointly attended to by the community on I. Define the* communion capacity *of A for (C, I) as the expected change in communion margin:*

$$\Gamma_{\mathsf{Comm}}(A; C, I) := \mathbb{E}\Big[\Delta_{\mathsf{Comm}}(C, I; \mathbf{w}^A) - \Delta_{\mathsf{Comm}}(C, I; \mathbf{w})\Big],$$

where $\mathbf{w}$ *is the baseline intensity datum and* $\mathbf{w}^A$ *is the datum after (or during) joint participation in* A*, and the expectation is over relevant internal stochasticity and contextual variation. The quantity* Γ_{Comm} *is therefore an* intervention effect*: it isolates the marginal contribution of adding joint participation in* A *to the community's dynamics, holding fixed (in expectation) other sources of fluctuation. In particular,* $\Gamma_{\mathsf{Comm}}(A; C, I)$ *may be negative for artifacts that fragment interpretation or intensify within-mind idiosyncrasy more than cross-mind alignment, so the sign of* Γ_{Comm} *functions as a formal separator between communion-promoting and communion-eroding interventions.*

Proposition 40 (Broadly beautiful artifacts tend to have positive communion capacity)**.** *Assume:*

1. *Joint attention to an artifact* A *creates at least one cross-supported pattern (a shared representation, shared affective response, shared narrative token, etc.) with intensity increasing in the number of participants who undergo a beauty episode with* A*.*

2. *Within-mind intensities are not increased by joint attention to* A *faster than cross-mind intensities (i.e. the dominant new patterns created by joint participation are cross-supported).*

Then for communities drawn from a population in which A *is an art object (Definition 411), we have* $\Gamma_{\mathsf{Comm}}(A; C, I) > 0$ *for a substantial measure of* (C, I)*. The "substantial measure" clause is meant to exclude degenerate cases (e.g. communities of size one, or intervals too short for any shared pattern to form) while not requiring universality across all possible* C *and* I*; it is enough that the positive effect persists across a non-negligible region of typical group compositions and engagement durations.*

Proof. Under assumption (1), the probability that multiple members of C undergo beauty episodes with A implies creation of cross-supported patterns with positive intensity, increasing W_{cross}. Assumption (2) ensures the within-mind total does not outgrow the cross-supported total under this intervention. Therefore Δ_{Comm} increases in expectation, giving $\Gamma_{\mathsf{Comm}}(A; C, I) > 0$. More explicitly, when A is an art object for the ambient population, draws of (C, I) from that population have a nontrivial chance that several members of C will instantiate designated $\mathsf{Beaut}(A)$ during I; by (1) this increases at least one cross-supported component of the intensity datum, so $\mathbf{w}^A$ differs from $\mathbf{w}$ by adding (or amplifying) cross-linked structure. Condition (2) prevents this amplification from being offset by a larger (or faster) growth in purely within-mind intensities, so the net effect on the communion margin remains positive on average under the stated expectation. □

Remark 1352. *This proposition is the formal core of a qualitative Hyperseed theme: art and ritual can function as reliable methods for inducing communion, hence as social technologies for shaping intersubjective realities. In this framing, the reliability is not mystical but statistical: if an artifact robustly elicits designated beauty episodes across a class of experiencers, then joint exposure predictably increases the weight of cross-supported patterns (shared interpretations, shared affect, shared narrative anchors), which is exactly the structural move required for communion as measured by* Δ_{Comm}*. This also clarifies why the same artifact can fail to produce communion in some settings: if the induced increments concentrate in within-mind idiosyncratic elaborations rather than in shared tokens, assumption (2) can fail and* Γ_{Comm} *can be small or negative.*

24.10 Religion, ritual, and state-dependent science

Hyperseed treats religion as a system of cultural beliefs and social roles associated with spirituality within a society, and treats "state-dependent science" as science relative to observation-sets accepted broadly within a community while they are in particular states of consciousness. In this framing, "religion" is not reduced to propositional doctrine alone; it also includes institutional roles, pedagogies, calendars, and shared interpretive practices that shape how spiritual episodes are recognized, narrated, and transmitted. Likewise, "state-dependent" is meant in a precise epistemic sense: it marks a restriction of the evidential interface (what counts as an observation) and of the community's background constraints (what counts as a permissible inference) to those intervals in which the relevant state predicate is satisfied. The intent is not to grant automatic authority to any such state, but to make explicit that many communities already operate with tacit state-conditions (e.g. prayer, meditation, fasting, liturgical participation) that filter both experience and evaluation.

The ontology-level reading is that:

- Religions are persistent, socially stabilized pattern systems that (among other things) scaffold repeated access to spiritual communion (Definition 402), making such episodes more frequent and more explicit (Definition 400). This includes stabilizing a repertoire of symbols, narratives, and practices that lower the activation threshold for communion-relevant patterns and provide socially shared "handles" for interpreting them. In particular, the persistence of a religion can be understood as a kind of cultural memory that preserves the conditions under which communion has been historically attainable, even when individuals' private access is intermittent.

- Rituals are repeated procedures that reliably increase cross-supported pattern intensity, thereby tending to push a community toward Comm and sometimes $\mathsf{ExplComm}$. Here "procedure" is meant broadly: bodily synchrony, chanting, call-and-response, incense, architectural acoustics, and coordinated attention can all function as controllable parameters that increase mutual predictability and shared salience. On the present ontology, a ritual's efficacy is therefore not primarily a matter of private belief, but of interlocking supports that raise the intensity of patterns that are jointly tracked, jointly enacted, and jointly reinforced.

- State-dependent science is an epistemic practice internal to an intersubjective reality-system that is conditioned on particular community states; formally, it is ordinary science carried out on a restricted subdomain of intervals I satisfying a state predicate $\Sigma(I)$. The restriction to $\Sigma(I)$ should be read as a domain restriction rather than a suspension of ordinary epistemic norms: within the selected intervals one still compares models, checks predictiveness, and negotiates intersubjective agreement, but one does so using the observation-sets and inferential affordances that are actually available in those states. In this sense, the proposal parallels familiar cases where instruments or training open new observation channels, except that the "instrument" is partly constituted by communal state and practice.

Definition 413 (State-dependent science schema)**.** *Fix a community C and a state predicate Σ selecting intervals I (e.g. "oceanic state", "I-Thou state", "high compassion resonance"). A* state-dependent science *for (C, Σ) is a family of model-building procedures that, restricted to intervals I with $\Sigma(I)$, produces predictive/causal models of observation-sets that are accepted broadly by members of C in those states.*

The schema is intentionally permissive about what counts as a "model-building procedure." In some cases the procedures may look like familiar experimental cycles (induction, controlled variation, replication, and error analysis), while in others they may be closer to disciplined phenomenological reporting with structured elicitation protocols and inter-rater calibration. The key constraints are (i) the restriction to Σ-intervals is explicit, (ii) the outputs are not merely idiosyncratic but admit communal uptake, and (iii) there is some articulated sense in which the resulting models succeed or fail relative to the observation-sets available under Σ. In particular, the acceptance clause is meant to exclude purely private revelation from counting as "science" in this narrow technical sense, unless it is embedded in practices that render its contents intersubjectively assessable within C.

Remark 1353. *This definition is intentionally schematic; it exists to locate the concept inside the ontology. Filling it out requires specifying: the observation algebra, the acceptance criterion, and how altered states modify the available observation channels and inference biases.*

A useful way to read "observation algebra" in this setting is as the community's formal or informal account of which experiential discriminations are admissible as stable observables under Σ, and which combinations, comparisons, and transformations of those observables preserve meaning. For example, a tradition might treat certain affective contours, attentional unifications, or relational gestalts as reliably reportable only after training; that training then functions analogously to calibration in laboratory practice. Similarly, altered-state inference biases need not be understood only as sources of error; they may also function as structured priors that are appropriate to the restricted domain (though they can mislead when exported outside it). On the present view, the main methodological risk is equivocation between domains: treating claims stabilized under Σ as if they were validated over all intervals, or conversely dismissing Σ-restricted regularities simply because they do not appear in the complement domain.

24.11 Summary and forward links

We have given:

- a community pattern-system definition of intersubjective reality (Definition 395);
- a quantitative criterion for intersubjective communion via cross-supported pattern dominance (Definition 397);
- a formalization of explicit communion via self-model recognition using uncertain paraconsistent truth values (Definition 400);
- a scope-based definition of spiritual communion and an intervention-based definition of entheogen (Definitions 401–403);
- emotion and compassion as mind-body-and-community patterns (Definitions 404–405);
- beauty as paraconsistent conjunction of fulfillment and surprise and a non-explosion theorem explaining why this is coherent (Theorem 21);
- a minimal theorem linking beauty episodes to OEI-activity of the representing subnetwork (Theorem 22);
- archetypes, art, and ritual as cross-mind pattern carriers with positive communion capacity (Definitions 410–412, Proposition 40);
- a schema locating religion and state-dependent science as persistent community-level pattern practices (Definition 413).

Taken together, these items supply a single "ladder" from ontology to practice. At the base, intersubjective reality is treated as neither a private mental construction nor an observer-independent substrate, but as what is stabilized when multiple agents participate in and reinforce a shared pattern system. The communion criteria then provide a way to distinguish mere agreement (e.g., coincidental similarity of reports) from structural coupling in which patterns become mutually sustaining across minds and media.

The progression from intersubjective communion to explicit communion clarifies the role of reflexivity: explicit communion is not only that agents co-enact compatible patterns, but that their self-models (and their models of others) register this co-enactment under truth values that may be incomplete or even locally inconsistent. The use of uncertain paraconsistent valuations is thus not a stylistic choice but a technical mechanism for allowing realistic cognitive states—where agents can partially endorse and partially reject the same proposition—without trivializing the overall inferential system.

The scope-based definition of spiritual communion and the intervention-based definition of entheogen can be read as a controlled extension of the communion framework to cases where (i) the relevant pattern web extends beyond ordinary interpersonal exchange (scope enlargement), and (ii) there exist interventions that systematically alter the salience, accessibility, or binding of patterns in $\mathbf{w}$ and in the agent valuations. This framing makes it possible to compare "spiritual" episodes to other kinds of high-scope communal episodes (scientific, artistic, political) using the same underlying vocabulary while still marking where special interventions or altered state dynamics are doing explanatory work.

Emotion and compassion enter as patterns precisely because they mediate between internal valuation updates and outwardly observable coordination. In this setting, emotions are not merely "inner feelings" but structured, learnable, and socially conditioned pattern complexes that affect attention, memory, and action selection; compassion is then a special case with characteristic coupling properties (e.g., tendencies to align the welfare-related evaluations of self and other), which makes it directly relevant to communion as a stabilizing or destabilizing force depending on context.

The aesthetic items connect evaluation to coherence under contradiction. Defining beauty as a paraconsistent conjunction of fulfillment and surprise formalizes an everyday phenomenology—that the beautiful often both "fits" and "exceeds" expectation—while the non-explosion theorem guarantees that allowing such conjunctions does not collapse the logic into triviality. The OEI link then supplies a minimal dynamical bridge: beauty episodes are not only definitional artifacts of a valuation scheme, but correlate with identifiable activity of the representing subnetwork, which is the sort of claim needed for later empirical contact (e.g., computational or neurocognitive modeling).

Archetypes, art, and ritual are positioned as portable pattern carriers that can propagate and synchronize across individuals, timescales, and media. Their "communion capacity" is the key functional notion: it identifies when a carrier does not merely transmit content but tends to increase cross-support among participants' patterns (including affective and normative patterns), thereby enhancing the conditions under which communion predicates are satisfied. Finally, the schema for religion and state-dependent science frames both as persistent community-level pattern practices: each involves stabilized methods of generating, selecting, legitimating, and teaching patterns, and each can be analyzed in terms of the same underlying machinery while differing in their typical interventions, scopes, and validation dynamics.

In later sections, these constructions can be specialized by: (i) choosing concrete pattern languages and complexity measures (linking to weakness/MDL formalisms), (ii) choosing explicit dynamical models for how artifacts and rituals modify $\mathbf{w}$ and the valuations v_m, and (iii) connecting repeated communal practice to habit formation (morphic resonance) as a long-run stabilizer of intersubjective pattern webs.

Concretely, item (i) determines what counts as a "pattern" in the first place and how competing descriptions are penalized or preferred; this is where the abstract pattern-system talk acquires operational bite, since the same empirical stream can admit multiple encodings with different complexity profiles. The MDL/weakness link is especially important here because it yields a principled way to trade off expressivity and generalization, making intersubjective stabilization a matter of converging on pattern sets that are jointly compressive under shared constraints.

Item (ii) then fixes the time-evolution story: the definitions above specify relational and logical conditions, but dynamical models specify mechanisms by which those conditions arise, persist, or fail. In particular, modeling how artifacts and rituals modify $\mathbf{w}$ and the valuations v_m makes it possible to distinguish (a) mere informational transmission from (b) systematic reweighting of saliences, priorities, and inferential pathways. This also clarifies how the same ritual form can have different communion outcomes depending on parameter regimes (e.g., strength of coupling, noise levels, or the degree of paraconsistent tolerance in participants' valuation dynamics).

Item (iii) provides the long-horizon glue: repeated practice does not only reinforce explicit beliefs but also trains priors, attentional habits, and default interpretive moves, thereby shaping the background conditions under which future communion is more or less likely. Casting this as habit formation (morphic resonance) supplies a way to model persistence at the community timescale without requiring that every episode of communion be re-constructed from scratch; instead, stabilized pattern webs can be treated as attractors that new participants enter and that existing participants revisit, with the possibility of drift, bifurcation, or sudden reconfiguration under strong interventions.

25 Reality-systems, cosmos, multiverse, and eurycosm

This section scales Hyperseed's observer-relative ontology outward. Earlier sections developed the formal core (paraconsistent evidence, quantale weakness, and compositional model/process structure) and used it to formalize patterns, habits, and resonance (cf. [1, 5, 3]). Here we use the same primitives to define:

(i) *empirical reality* as predictive usefulness to a mind over an interval;
(ii) *reality-systems* as stabilized networks of mutually predictive entities/patterns;
(iii) *physical reality and body* as a particular reality-system with a privileged sensorimotor interface;
(iv) *cosmos/universe* as an observer- and signal-class-indexed reachability notion;
(v) *multiverse* and *guidable multiverse* as (controlled) stochastic evolution on universes;
(vi) the *Yverse* as a recursive limit of multiverse towers (best treated paraconsistently);
(vii) the *eurycosm* and *near eurycosm* as the "wider world" beyond any single well-defined mind or universe; and
(viii) optional speculative anchors: the anthropic principle and big-bounce cosmology.

To motivate the ordering of (i)–(viii), it is helpful to view the constructs as successive closures of the same operational loop: a mind conditions on evidence, makes predictions, and adjusts its internal models/processes; "reality" is then whichever parts of this loop remain stable enough to support compression and counterfactual reliability across time. In this sense, the section does not introduce new metaphysical primitives so much as new *scales* at which the same inferential machinery is applied: from short-horizon usefulness (empirical reality) to long-horizon mutual stabilization (reality-systems), then to reachability under constraints (cosmos/universe), then to stochastic families of such reachability structures (multiverse towers), and finally to limiting constructions intended to capture what remains when no single observer-indexed universe is taken as final (Yverse, eurycosm).

A practical reading is that each definition below will be paired with an "operational test" of the form: what evidence is admissible, what predictions are counted, what closure operator is being used, and what is treated as a fixed point or attractor. This makes the terminology functional: for instance, whether some entity belongs to a reality-system is not a binary metaphysical decree, but a question about whether it participates in sufficiently strong mutual predictability with other entities (relative to the mind, the time interval, and the permitted evidence transformations).

Remark 1354. *Conceptually, the aim is to keep the metaphysical vocabulary honest by tethering it to explicit operations: conditioning, prediction, closure, reachability, and fixed points. One may read this as a Russell-style attempt to replace vague nouns ("the real," "the universe") by precise relations between a mind and its prospective experience, without thereby denying that there can be a world that exceeds any one mind. In Hyperseed's idiom, the exceeding is captured not by a single absolute set, but by a family of observer-indexed constructions and their limits.*

The emphasis on reachability and fixed points is not accidental: many of the objects named in this section can be presented as solutions to recursive equations (e.g., "the smallest closed structure containing what the mind can stably track," or "the maximal set of states reachable given a class of signals and updates"). When the recursion is well-founded and convergent, classical set-based reasoning can suffice; when the recursion is open-ended (as in multiverse towers or the Yverse), paraconsistent treatment is advocated so that one can work with partially specified limits without trivializing the theory in the presence of inevitable self-reference and boundary ambiguities.

Hyperseed concepts covered here. Empirical reality / reality-systems (**??**, 149); physical reality and body (135); algebraically asymmetric physical reality (55); cosmos/eurycosmos (89, **??**); universe, multiverse, guidable multiverse, Yverse (116, 209); eurycosm and near -eurycosm (**??**); anthropic principle (57); big bounce (66).

For orientation, "signal-class-indexed" in (iv) anticipates that a mind's accessible universe may depend not only on its internal inferential capacities but also on which channels of interaction are counted as legitimate interventions or observations (e.g., a restricted sensor suite versus an augmented one, or a narrower versus richer class of admissible measurements). Likewise, the "privileged sensorimotor interface" in (iii) should be read as a structural asymmetry: the body is not merely another predicted object, but the particular interface through which prediction errors arrive and actions are issued, thereby shaping the update dynamics that define empirical reality and reality-systems in the first place.

Finally, the "optional speculative anchors" in (viii) are included as interpretive touchpoints rather than as load-bearing axioms: they indicate how Hyperseed-style definitions might interface with familiar cosmological and selection-effect discussions without presupposing that any single cosmological narrative exhausts the eurycosm. In particular, the near eurycosm is intended to name those aspects of the "wider world" that remain robust across a broad range of observer-indexed constructions, even when the full eurycosm is treated only via partial, limit-like characterizations.

25.1 Empirical reality as predictive usefulness

Hyperseed characterizes "empirically real" in explicitly operational terms: roughly, something is empirically real to a mind over a time interval insofar as perceiving it improves that mind's predictions about its future. To formalize this, we separate (a) *entities/patterns* that may be perceived and (b) the *prediction task* induced by the mind's ongoing coupling to its environment. This framing treats "reality" as a role played inside an inferential control-loop: what matters is whether incorporating a candidate distinction measurably improves forward-looking performance, not whether the distinction is metaphysically primitive or phenomenologically forceful.

Definition 414 (Entities and perceptions)**.** *Fix a mind (or observer) M and an interval of (proto-)time I. Let $\mathcal{U}$ be a set of entities, situations, or patterns that M may treat as objects of perception. We represent "perceiving $x \in \mathcal{U}$" over the interval I by an observation token $\mathsf{obs}_I(x)$.*

Remark 1355. *The notation here is deliberately spare. The set $\mathcal{U}$ is not assumed to be "the set of all things that exist"; it is merely the repertoire of candidate distinctions available to the mind M in the context at hand. Likewise $\mathsf{obs}_I(x)$ is a token standing for the event "M has (somehow) taken in x during I," not a claim that x is thereby known with certainty. The proto-time interval I is the minimal temporal scaffolding needed to speak of "future observations"; it matches the Hyperseed emphasis that time may be mind- and process-relative (see Hyperseed-Concept 142).*

Remark 1356. *A useful way to read $\mathsf{obs}_I(x)$ is as an* interface variable *rather than a raw datum: it stands for whatever internal representation M actually makes available to its predictor. Thus, two minds may share the same external stimulus while having different x-tokens (different feature sets, categorizations, or attention policies), and consequently different empirical realness scores for "the same" ostensible thing. This observer-indexing is not a bug in the framework; it is the intended mechanism by which Hyperseed makes "empirical reality" a property of mind–world coupling rather than a view-from-nowhere.*

Remark 1357. *A simple example is to let $\mathcal{U}$ contain items like "the traffic light is red," "the stove is hot," "my colleague looks annoyed," or "this symbol-string has the form of a proof." Then $\mathsf{obs}_I(x)$ is an abstract placeholder for whichever perceptual/interpretive process produces that classification. The definition is useful because it lets us discuss reality in terms of what changes in the mind's predictive situation when such a token is available, without taking a stand on whether the token came from a retina, a dream, a telescope, or a theorem-prover.*

Definition 415 (Observer-indexed prediction loss)**.** *Let $\mathcal{F}_I$ denote a space of future observation streams relevant to M on the next interval (e.g. I^+). A* predictor *for M is a map Π_M that assigns to each current informational state a predictive distribution over $\mathcal{F}_I$. Let L be a bounded loss function comparing predicted to realized futures. Define the expected prediction error of Π_M on I by*

$$\mathsf{Err}_I(\Pi_M) := \mathbb{E}\big[L(\Pi_M, \mathsf{future})\big]. \tag{1}$$

If M conditions on perceiving x, write $\Pi_M \mid \mathsf{obs}_I(x)$ and $\mathsf{Err}_I(\Pi_M \mid \mathsf{obs}_I(x))$.

Remark 1358. *The symbol $\mathcal{F}_I$ is a space of possible "next-step" futures as M encodes them: e.g., strings of sensor readings, sequences of internal thoughts, or higher-level events. The predictor Π_M is left abstract on purpose: it may be Bayesian, neural, symbolic, hybrid, or something else. The expectation $\mathbb{E}[\cdot]$ is taken with respect to the distribution over futures that actually governs M's coupling to the world (whatever that means in the model). Boundedness of L is a technical convenience ensuring the expectation exists and that normalizations below behave well.*

Remark 1359. *The phrase "current informational state" can be understood broadly to include: memory traces, latent beliefs, currently attended features, and any background context that persists through I. In this sense, conditioning on $\mathsf{obs}_I(x)$ does not assert that x is the* only *input to prediction; it isolates the marginal contribution of having x available on top of whatever else M already carries. One can therefore interpret $\mathsf{Err}_I(\Pi_M) - \mathsf{Err}_I(\Pi_M \mid \mathsf{obs}_I(x))$ as an operational proxy for "how much x helps, given the rest of M."*

Remark 1360. *As an example, suppose L is log loss and Π_M outputs a probability distribution over the next sensory frame; then $\mathsf{Err}_I(\Pi_M)$ is a cross-entropy-like quantity measuring how surprised M*

is, on average, by what happens next. Conditioning on $\mathsf{obs}_I(x)$ corresponds to giving the predictor access to a feature x ("I see smoke"), and the resulting change in error formalizes the pragmatic sense in which perceiving x makes the world more navigable. This is precisely the Hyperseed-Concept **??** *cast in a predictive mold.*

Remark 1361. *In the special (idealized) case where Π_M is the Bayes-optimal predictor for M's true generative coupling and L is log loss, the expected reduction in loss from conditioning on x admits an information-theoretic reading: it coincides with an expected log-likelihood ratio and is closely related to the mutual information between $\mathsf{obs}_I(x)$ and the next-step future in $\mathcal{F}_I$. This highlights an intended interpretation of "empirically real" as "carries compressive, future-relevant information for this mind," while still allowing non-log-loss settings where other operational desiderata (calibration, squared error, asymmetric costs, safety margins) matter more than pure information gain.*

Definition 416 (Empirical realness score)**.** *Fix a small constant $\delta > 0$. The* empirical realness *of $x \in \mathcal{U}$ to mind M on interval I (relative to predictor Π_M and loss L) is*

$$\rho_{M,I}(x) := \frac{\mathsf{Err}_I(\Pi_M) - \mathsf{Err}_I(\Pi_M \mid \mathsf{obs}_I(x))}{\mathsf{Err}_I(\Pi_M) + \delta}. \tag{2}$$

Thus $\rho_{M,I}(x)$ is high when conditioning on x yields a large relative reduction in prediction loss.

Remark 1362. *The fraction defining $\rho_{M,I}(x)$ is a normalized error reduction. The numerator is the improvement in expected predictive performance when x is perceived; the denominator $\mathsf{Err}_I(\Pi_M)+\delta$ prevents division by zero and makes the score scale-comparable across regimes where overall prediction is easy or hard. In particular, $\rho_{M,I}(x)$ can be negative: an observation token that systematically misleads the predictor (say, due to illusion, biased interpretation, or adversarial manipulation) will increase error rather than decrease it.*

Remark 1363. *Because L is bounded, $\rho_{M,I}(x)$ is also controlled in magnitude (though not necessarily confined to $[-1,1]$ under this particular normalization). Concretely, if $0 \le L \le L_{\max}$, then $0 \le \mathsf{Err}_I(\Pi_M) \le L_{\max}$ and the numerator lies in $[-L_{\max}, L_{\max}]$, giving the crude bound*

$$-\frac{L_{\max}}{\mathsf{Err}_I(\Pi_M) + \delta} \;\le\; \rho_{M,I}(x) \;\le\; \frac{L_{\max}}{\mathsf{Err}_I(\Pi_M) + \delta}. \tag{3}$$

This makes explicit the role of δ as more than a division-by-zero patch: it also prevents extreme blow-ups when $\mathsf{Err}_I(\Pi_M)$ is very small (i.e., when the mind is already in an easy-to-predict regime). In applications, δ may be chosen to reflect a minimum meaningful scale of predictive error (a noise floor) below which additional "improvement" should not count as large empirical realness.

Remark 1364. *The score $\rho_{M,I}(x)$ is explicitly relative to a predictor Π_M. This is intentional: if M uses a systematically mis-specified predictor, then even perfectly reliable cues may fail to improve its forecasts, yielding low measured realness in practice. In that sense, empirical realness here is not only about the environment; it is also about the competence and inductive biases of the mind. This matches the Hyperseed stance that "world" and "knower" cannot be fully separated when reality is cashed out operationally.*

Remark 1365. *Two instructive examples:*

(a) If x is "the kettle is whistling" and the future includes "steam will appear," then conditioning on x can sharply reduce error, giving $\rho_{M,I}(x) > 0$.

(b) *If x is "I am certain this random sequence has a hidden message" but this belief leads to consistently wrong anticipations, then $\rho_{M,I}(x)$ may be < 0 even though the experience feels compelling.*

This illustrates why Hyperseed refuses to identify the real with the merely vivid: empirical realness is tied to the predictive economy of the mind-world coupling, not to a phenomenological intensity taken in isolation (cf. Hyperseed-Concept **??***).*

Remark 1366. *The time-indexing by I matters. Some tokens x can be locally predictive (high $\rho_{M,I}(x)$) while degrading longer-horizon performance if they incentivize brittle policies or overfitting to short-lived regularities. Conversely, some distinctions may appear useless on a single step but become empirically real over extended horizons (e.g., slow variables, latent traits, stable causal mechanisms). A natural extension is therefore to consider multi-interval aggregates such as $\rho_{M,[I_1:I_T]}(x)$ defined by replacing Err_I with an averaged or discounted error across a sequence of proto-time steps, which better captures the pragmatic persistence often associated with "real objects."*

Remark 1367. *Finally, nothing in the setup restricts x to being atomic. In many cognitive and scientific settings, empirical traction comes from* bundles *of cues (joint features, models, or hypotheses) that are only predictive together. One may therefore treat x as a structured object (e.g., a tuple, a submodel, or a learned representation) or generalize the conditioning event to a set $S \subseteq \mathcal{U}$ by writing $\Pi_M \mid \mathsf{obs}_I(S)$ for "M has access to all tokens in S on I," enabling a notion of incremental realness (marginal contribution) and synergy (non-additive gains) within the same operational framework.*

Remark 1368 (Paraconsistent evidence)**.** *The scalar $\rho_{M,I}(x)$ measures predictive utility, not logical certainty. If one wishes, one may lift ρ to a* p-bit *value by tracking (i) evidence that conditioning on x improves prediction and (ii) evidence that conditioning on x worsens or destabilizes prediction. This is compatible with Hyperseed's tolerance for borderline and inconsistent boundaries, and connects naturally to paraconsistent valuation frameworks such as Constructible Duality Logic [23] and resonance-based paraconsistent semantics [24].*

25.2 Reality-systems as stabilized mutually predictive pattern complexes

Hyperseed motivates "reality" as a property of *systems of entities* rather than isolated objects. The circularity in the slogan "x is real if perceiving it helps predict real things" is not a bug; it indicates a fixed-point structure. We now package this via a closure operator on subsets of $\mathcal{U}$.

Definition 417 (Predictive adjacency at threshold)**.** *Fix M, I and a threshold $\theta \in (0,1)$. Define a directed relation $\to_\theta$ on $\mathcal{U}$ by setting*

$$x \to_\theta y \quad \textit{iff} \quad \rho_{M,I}(x \to y) \geq \theta, \tag{4}$$

where $\rho_{M,I}(x \to y)$ is a chosen score measuring how much conditioning on $\mathsf{obs}_I(x)$ improves prediction of observation tokens associated with y. (Concrete choices include conditional loss reduction restricted to features belonging to y.)

Remark 1369. *The symbol $\to_\theta$ is a thresholded "predicts" relation: $x \to_\theta y$ means that, at the selected confidence level θ, access to x makes y more predictable. The auxiliary score $\rho_{M,I}(x \to y)$ is intentionally underspecified; it should be read as a* directed *version of the earlier $\rho_{M,I}(x)$ that focuses on the part of the future stream attributable to y. In a feature-based setting, one may take y to denote a subset of coordinates of the future observation stream and compute loss reduction on those coordinates only.*

Remark 1370. *A simple example: let $\mathcal{U}$ include weather-relevant tokens, and suppose x is "dark clouds" and y is "rain within 10 minutes." Then $x \to_\theta y$ holds for a fairly high θ in many climates. By contrast, if x is "I had a particular dream" and y is "rain within 10 minutes," the relation may fail for typical observers, even if some observers attribute meaning to the dream. The definition is useful because it turns "seems to go with" into a directed graph that can be closed and iterated, preparing the ground for fixed-point constructions of reality-systems (Hyperseed-Concept 149).*

Definition 418 (Forward/backward predictive closure)**.** *For $R \subseteq \mathcal{U}$, define*

$$\mathsf{Pred}^{\to}(R) := \{y \in \mathcal{U} : \exists x \in R \text{ s.t. } x \to_\theta y\}, \tag{5}$$

$$\mathsf{Pred}^{\leftarrow}(R) := \{y \in \mathcal{U} : \exists x \in R \text{ s.t. } y \to_\theta x\}. \tag{6}$$

Define the mutual predictive closure operator

$$F(R) := \mathsf{Pred}^{\to}(R) \cap \mathsf{Pred}^{\leftarrow}(R). \tag{7}$$

Remark 1371. *The operators $\mathsf{Pred}^{\to}$ and $\mathsf{Pred}^{\leftarrow}$ are the one-step out- and in-neighborhood operators in the directed graph given by $\to_\theta$. Thus:*

- $\mathsf{Pred}^{\to}(R)$ *collects what R predicts;*
- $\mathsf{Pred}^{\leftarrow}(R)$ *collects what predicts R; and*
- $F(R)$ *keeps only those nodes that stand in both relations to R.*

The intersection is where the circularity enters: a candidate real set should not merely emit predictions, nor merely be predicted; it should participate in a mutually supporting web.

Remark 1372. *As a toy example, suppose $\mathcal{U} = \{a, b, c, d\}$ with edges $a \to b$, $b \to a$, $b \to c$, $c \to b$, and d isolated. Then the mutually predictive closure of $\{a\}$ yields $\{a, b\}$ (and may further expand to include c depending on the thresholded edges), while d never enters any nontrivial fixed point. This makes vivid the intended metaphysical moral: isolated tokens that do not participate in stable mutual prediction are, by this operational criterion, not part of a well-formed reality-system.*

Lemma 5 (Monotonicity)**.** *The operator $F : 2^{\mathcal{U}} \to 2^{\mathcal{U}}$ is monotone: if $R \subseteq R'$ then $F(R) \subseteq F(R')$.*

Remark 1373. *Intuitively, monotonicity says: if you start with more candidate "real" items (a larger seed set), then the set of things that are mutually predictively adjacent to it cannot shrink. This is a minimal sanity condition for any closure-like operator and is precisely what we need to invoke general fixed-point theorems later. In the logic of the development, this lemma is the hinge connecting the empirical/predictive notions above to lattice-theoretic existence results below.*

Proof. If $R \subseteq R'$, then any witness $x \in R$ for membership in $\mathsf{Pred}^{\to}(R)$ or $\mathsf{Pred}^{\leftarrow}(R)$ is also in R'. Thus $\mathsf{Pred}^{\to}(R) \subseteq \mathsf{Pred}^{\to}(R')$ and $\mathsf{Pred}^{\leftarrow}(R) \subseteq \mathsf{Pred}^{\leftarrow}(R')$, hence their intersection is monotone. □

Remark 1374. *At a high level, the proof uses only the existential nature of the definitions: membership in $\mathsf{Pred}^{\to}(R)$ is witnessed by the existence of some $x \in R$ with an edge $x \to_\theta y$. If R grows to R', every old witness remains available, so the image can only expand. Geometrically, enlarging a set of nodes in a directed graph cannot reduce its one-step neighborhoods.*

Proof sketch. Unpack the definitions: both $\mathsf{Pred}^{\to}$ and $\mathsf{Pred}^{\leftarrow}$ are built from an $\exists x \in R$ condition. Replacing R by a superset R' preserves all witnesses, so each of the two neighborhood operators is monotone, hence so is their intersection. □

Definition 419 (Reality-system (fixed-point form)). *A* reality-system *for mind M on interval I (at threshold θ) is a nonempty set $R \subseteq \mathcal{U}$ such that*

$$F(R) = R. \tag{8}$$

Elements of R are then "real relative to R" in the sense that they are both predicted by and predictive of the rest of R (at least along some edges at the chosen threshold).

Remark 1375. *The definition is intentionally parameterized by M, I, and θ to make explicit that "what counts as mutually predictive" can depend on the observer, the temporal or contextual window, and the granularity at which predictive links are deemed strong enough to count. In particular, changing θ changes the edge set of $\to_\theta$ and therefore changes the fixed points of F; one can view θ as controlling the tradeoff between permissive "reality-systems" (low θ, many weak links) and conservative ones (high θ, only robust links survive).*

Remark 1376. *The fixed-point condition can also be read as a closure principle: R contains exactly those tokens that survive the operator F when applied to R itself. Equivalently, if one starts from R and applies the "mutual predictability filter" encoded by F, nothing is gained and nothing is lost. This makes $F(R) = R$ a formal way to say that R is self-maintaining under the inferential norms induced by $\to_\theta$ (for the chosen mind and interval).*

Remark 1377. *The fixed-point equation $F(R) = R$ is the formal expression of the earlier circular slogan. Rather than attempting to define "the real" by a one-directional reduction (from world to mind or from mind to world), we define it as a* stabilized relation *between tokens inside a predictive web. The requirement that R be nonempty prevents the trivial solution in which nothing is real because nothing predicts anything.*

Remark 1378. *Nonemptiness also forces "reality" to pick out at least one informationally anchored token, which matters when $\to_\theta$ is sparse or when the mind is in a regime where predictive links degrade (e.g. noise, novelty, or adversarial inputs). Without the nonemptiness clause, the empty set would always be a fixed point for many natural choices of F, and the theory would risk collapsing into the claim that vacuity is always an available "reality-system". The clause therefore functions like a minimal coherence constraint: there must be at least some token(s) that participate in the mutual-support structure.*

Remark 1379. *A practical example: in ordinary perception, the set R might include "solid objects," "my hand," "gravity," "sound sources," and so on, because these tokens support a dense network of mutual predictability (touch predicts proprioception; object permanence predicts future visual input; etc.). In a scientific sub-community, R might also include theoretical entities (fields, genes, curvature) insofar as conditioning on them improves predictions of experimental outcomes. This is a conceptual bridge to Hyperseed's view of science as observer- and community-relative model selection [20].*

Remark 1380. *This example can be sharpened by observing that the same underlying sensory stream can support different stabilized sets depending on which auxiliary tokens the community treats as eligible members of $\mathcal{U}$ (measurement conventions, inferential schemas, instrument readouts, and mathematical constructs). On this view, disagreements about "what exists" often reduce to disagreements about which tokens belong in the shared candidate universe and which predictive relations clear the threshold θ under the community's modeling practices. The fixed-point framing makes those dependencies explicit without implying that reality is arbitrary: fixed points are still constrained by the actual pattern of predictive relations.*

Theorem 23 (Existence of minimal and maximal reality-systems)**.** *For any mind M and interval I, the monotone operator F has a complete lattice of fixed points (ordered by inclusion). In particular there exist:*

(a) a least fixed point $\mathsf{lfp}(F)$ (possibly empty),

(b) a greatest fixed point $\mathsf{gfp}(F)$ (possibly all of $\mathcal{U}$), and

(c) for any seed set $R_0 \subseteq \mathcal{U}$, a least fixed point containing R_0 given by iterating F from R_0 until convergence.

Remark 1381. *The "least" and "greatest" qualifiers are with respect to inclusion, so $\mathsf{lfp}(F)$ is the smallest reality-system (if any) that satisfies the fixed-point constraint, while $\mathsf{gfp}(F)$ is the largest stabilized predictive web compatible with F. Interpreting fixed points as possible "worlds-as-modeled," the theorem guarantees both an extremal minimal commitment (take as real only what must be in any fixed point) and an extremal maximal commitment (take as real everything that can be stably included without breaking mutual predictive closure). This is useful later when comparing conservative and expansive ontologies inside the same formal framework.*

Remark 1382. *Part (c) can be read as a procedure for "ontological bootstrapping": begin with some tokens treated as nonnegotiable (e.g. immediate experiences, measurement outcomes, or postulated primitives), then repeatedly close under the mutual predictability operator until the process stops changing the set. The resulting fixed point is the smallest stabilized reality-system that honors the initial commitments R_0. This provides a clean way to formalize how different starting assumptions can lead to different self-consistent stabilized webs even when F is held fixed.*

Remark 1383. *In plain terms, the theorem says that once we define "mutual predictive closure" in a monotone way, reality-systems exist automatically: there is always a smallest self-consistent predictive web and a largest one, and any initial guess can be iteratively refined to a stabilized web. This is important because it shows that the fixed-point approach is not merely poetic; it is supported by general order-theoretic machinery (Knaster–Tarski) rather than by ad hoc assumptions. It also connects directly with later uses of fixed points in Hyperseed to study self-stabilizing systems, including goal systems of self-modifying agents [10].*

Remark 1384. *The lattice-of-fixed-points perspective also highlights that reality-systems need not be unique: there can be many distinct fixed points, partially ordered by inclusion. When multiple fixed points exist, the formalism separates two questions: (i) which stabilized webs are* possible *under the predictive relations encoded by F, and (ii) which one(s) are* selected *by a particular mind or community, perhaps via pragmatic criteria (compression, robustness, intervention success) not contained in the bare fixed-point equation. Thus, the existence theorem supplies the space of candidates, while selection principles (if any) determine where within that lattice an actual observer tends to land.*

Proof. The powerset $2^{\mathcal{U}}$ is a complete lattice under inclusion. By Lemma 5, F is monotone, so the Knaster–Tarski theorem implies that the set of fixed points of F is a complete lattice and that least/greatest fixed points exist. If $\mathcal{U}$ is finite, then the ascending chain $R_0 \subseteq F(R_0) \subseteq F^2(R_0) \subseteq \cdots$ stabilizes in at most $|\mathcal{U}|$ steps at the least fixed point above R_0. In the infinite case, one may use transfinite iteration or (under mild continuity assumptions) Scott-continuous fixed-point theory. $\square$

Remark 1385. *The proof is a direct application of a general theorem: monotone endomaps on complete lattices have fixed points, and in fact their fixed points themselves form a complete lattice.*

The finite case adds a computational intuition: iterating F from a seed set is like repeatedly expanding to the mutually predictive neighborhood until no new nodes appear. Visually, one is "growing" a subgraph until it becomes closed under the relevant in- and out-neighborhood operators.

Remark 1386. *In the finite case, the bound of $|\mathcal{U}|$ steps is a worst-case guarantee; in typical sparse predictive graphs convergence can be much faster because each application of F only adds tokens supported by the existing predictive structure. Conversely, if one begins from a large R_0, iteration may also* remove *tokens depending on the exact definition of F (e.g. if F enforces mutuality rather than one-way reachability), so the intuitive picture is not only "expansion" but "pruning toward stability." This clarifies why the fixed-point condition is aptly described as stabilization: it is the point at which neither expansion nor pruning changes the set.*

Remark 1387. *The reference to Scott-continuity is not essential for the existence of fixed points (which is already guaranteed by Knaster–Tarski) but becomes relevant if one wants the iterative procedure to converge by taking countable limits rather than transfinite stages. In applications where $\mathcal{U}$ is effectively enumerable and F has suitable continuity properties, this can justify practical approximation schemes: compute $F^n(R_0)$ for increasing n and interpret the limit (when it stabilizes) as the induced reality-system.*

Proof sketch. Show the ambient space $2^{\mathcal{U}}$ is a complete lattice. Verify F is monotone (Lemma 5). Invoke Knaster–Tarski to obtain existence of $\mathsf{lfp}(F)$ and $\mathsf{gfp}(F)$ and completeness of the fixed-point set. For finite $\mathcal{U}$, use the fact that a strictly increasing chain of subsets cannot exceed length $|\mathcal{U}|$, so iteration stabilizes. □

Remark 1388. *The sketch can be operationalized as follows: one chooses an explicit representation for $\mathcal{U}$ (tokens), an explicit rule for the predictive relation $\to_\theta$ at the chosen threshold, and then defines F as the induced closure (or mutuality) operator. At that point, the abstract order-theoretic argument guarantees that the resulting computation is not chasing a mirage: there really are stabilized sets to be found, even if one later adds additional criteria for preferring one fixed point over another.*

Remark 1389 ("Stabilized pattern complex")**.** *Interpreting $\to_\theta$ as a weighted directed graph, a reality-system is a subgraph that is closed under taking one-step predictive in- and out-neighborhoods. If we refine F to use multi-step reachability rather than one-step edges, fixed points coincide more closely with unions of strongly connected components. Either way, the fixed-point condition captures the intended circularity: reality is attributed to collections of entities that mutually support predictive coherence.*

Remark 1390. *The phrase "pattern complex" is meant to stress that membership in R is not an intrinsic label attached to a token in isolation, but a property of a* configuration *of tokens linked by reliable predictive constraints. Graph-theoretically, the closure requirement ensures that once a token is admitted, the local predictive dependencies that sustain it (incoming support) and that it sustains (outgoing support) are also represented within the same subgraph, at least to the degree enforced by F. This turns "being real relative to R" into a coherence notion: reality is the stable core of a mutual-modeling relation rather than a primitive unary predicate.*

Remark 1391. *When F is strengthened from one-step to multi-step conditions, the strong connectivity analogy helps explain why reality-systems tend to behave like "modules" of inference: within a strongly connected predictive module, information can circulate and reinforce itself, supporting robust counterfactual and temporal predictions. At the same time, the threshold θ controls whether weak long-range links suffice to merge modules into larger fixed points or whether they remain separate, yielding multiple coexisting stabilized pattern complexes inside the same $\mathcal{U}$.*

25.3 Physical reality and body as an interface-mediated reality-system

Hyperseed defines *physical reality* (relative to an embodied mind) as a reality-system containing the body, with the additional property that the mind's causal impact on that reality is mostly mediated through the body-channel. We formalize this by adding a factorization condition on causal/process morphisms.

Definition 420 (Embodied mind and body)**.** *Let M be a mind modeled as a dynamical subsystem with internal states* Mind*, percept tokens* $\mathsf{Percepts}$*, and action tokens* Acts*. A* body *for M is a pattern-system B together with a distinguished interface map*

$$\iota : (\mathsf{Percepts}, \mathsf{Acts}) \longrightarrow B \tag{9}$$

such that there is a highly significant mutual causal relationship between M and B. (In enriched categorical terms: the coupling morphisms $M \leftrightarrow B$ have large weight and are stable under refinement.)

Remark 1392. *The typing of ι encodes a simple but crucial idea: percepts and actions are not free-floating; they are anchored in some structured subsystem B that mediates between inner and outer. Here* Mind*,* $\mathsf{Percepts}$*, and* Acts *are names for state/token sets internal to the model of M; B is a pattern-system (in the sense developed earlier, cf. [5]) that carries stable regularities over time. The parenthetical enriched-categorical phrasing points to the earlier "weights" (weakness/residuals) that quantify coupling strength (Hyperseed-Concept 202, 143; see [3, 2]).*

Remark 1393. *A concrete example is an animal body:* $\mathsf{Percepts}$ *may include retinotopic arrays and proprioceptive signals, while* Acts *includes muscle activations. Then ι maps these tokens to bodily subsystems (eyes, joints, muscles) whose dynamics couple to the environment. For a software agent, B could be a robot platform, a server interface, or even a stable toolchain. The definition is necessary because later notions of "physical reality" depend on which causal paths are privileged, and those privileges are expressed by factorization through B.*

Definition 421 (Physical reality)**.** *A* physical reality *for an embodied mind M is a reality-system R such that:*

(a) the body B is largely contained in R (i.e. $B \subseteq R$ as a pattern-subsystem);

(b) most percepts and actions of M are perceptions/actions of entities in R;

(c) ***body-channel mediation:*** *for any action-effect morphism $f : M \to R$ there exist morphisms $g : M \to B$ and $h : B \to R$ with*

$$f \approx h \circ g, \tag{10}$$

where "$\approx$" denotes approximation in the enrichment (e.g. bounded residual weakness or bounded prediction-error increase when replacing f by $h \circ g$).

Remark 1394. *Clause (c) is the formal core: the mind's effective influence on R must (up to controlled error) factor through the body. In symbols, $f : M \to R$ is any causal/process morphism capturing an action-to-effect link; then $g : M \to B$ is the "issue a bodily action" component, and $h : B \to R$ is the downstream physical influence of the body on the larger reality-system. The approximation relation $\approx$ is where the enrichment matters: one may measure the deviation between f and $h \circ g$ by weakness residuals, by increased prediction loss, or by any compatible metric-like structure supplied by the formal core.*

Remark 1395. *An example: if M is you, B includes your vocal tract and hands, and R includes your room, then speaking to move air molecules and thereby alter another person's beliefs is still mediated through B. By contrast, if one posits a mind that can directly alter far-away objects without any intervening bodily channel, then (in this framework) its "physicalness" relative to that R would be lower. This provides a mathematically expressible sense in which "physical reality and body" (Hyperseed-Concept 135) are intertwined.*

Remark 1396 (Degree of "physicalness")**.** *One can define a graded physicalness score by measuring how well action-effect morphisms factor through B. For example, if the enrichment provides a distance d, define*

$$\mathsf{phys}(M, R; B) := 1 - \sup_{f:M\to R} \inf_{g,h} d\big(f, h \circ g\big). \tag{11}$$

If M can significantly impact R without using the body-channel, this score decreases.

Remark 1397 (Laws of physics)**.** *Within this ontology, the "laws of physics" relative to a physical reality R are simply a system of effective hypotheses (models) for predicting and explaining what happens in R. Formally, this can be cast as selecting a model class $\mathcal{H}_R$ that minimizes prediction error subject to simplicity/weakness constraints (a Minimum Description Length or weakness-regularized choice).*

Remark 1398. *The last parenthetical points to a convergence of ideas: Minimum Description Length is a way of expressing that models should be predictive yet parsimonious, often formalized using description lengths related to algorithmic information [16]. Hyperseed's weakness-regularized variants reinterpret this parsimony as a representational/effort constraint (Hyperseed-Concept 82, 202), anticipating the Wu Wei control formalism developed later [21].*

25.4 Algebraically asymmetric physical reality

Hyperseed stresses an *algebraic asymmetry* between physical reality (often low-dimensional and "vector-space-like") and mental/intersubjective realities (typically weaker, more topological, and only approximately projectable into low-dimensional coordinates). We can express this without committing to a particular physical theory by treating "algebraic structure" as additional operations/axioms on the state space. In particular, the asymmetry is not meant to assert that mental reality is "vague" in every respect, but that the kinds of structure that make physical systems rigid (e.g. smoothness, metrics, conservation laws, differential constraints, compatibility conditions) are not, in general, fully present in intersubjective representations. Thus "algebraic weakness" here is a statement about *recoverability of structure*: the mental/intersubjective level typically underdetermines many physically distinct realizations.

Definition 422 (Structure strength and forgetful maps)**.** *Let $\mathcal{R}_{\text{phys}}$ be a category (or enriched category) of models of physical reality, whose objects carry some strong algebraic structure (e.g. smooth manifold, metric space, vector bundle, etc.). Let $\mathcal{R}_{\text{ment}}$ be a category of models of mental and intersubjective reality (e.g. topological or relational pattern spaces). An* algebraic asymmetry *is the presence of a structure-forgetting functor*

$$U : \mathcal{R}_{\text{phys}} \longrightarrow \mathcal{R}_{\text{ment}} \tag{12}$$

that is not (even approximately) invertible on the images relevant to a given community of minds. In this case we say that mental reality is algebraically weaker *than physical reality.*

Remark 1399. *The phrase "category (or enriched category)" allows one to treat morphisms as carrying graded costs, probabilities, or fidelities when needed. For example, in an enriched setting one can measure how well a mental representation matches an underlying physical state, rather than treating representation as all-or-nothing. This is useful for articulating the "approximately projectable" clause: minds may track some physical degrees of freedom with high fidelity while collapsing or ignoring others.*

Remark 1400. *The functor U is called "forgetful" because it discards structure: it takes an object with rich operations/axioms (say, a differentiable manifold with metric) and remembers only whatever mental/intersubjective representation retains (say, adjacency relations, coarse regions, or pattern links). The non-invertibility condition encodes the asymmetry: from the weaker description alone one generally cannot reconstruct the full physical structure. This is the categorical way to articulate the Hyperseed-Concept 55.*

Remark 1401. *One can make the non-invertibility intuition more concrete by considering the* fibers *of U. For an object $m \in \mathrm{Ob}(\mathcal{R}_{\mathrm{ment}})$, the preimage (informally) $U^{-1}(m)$ consists of all physically structured objects that "look like" m under the forgetting process. Algebraic asymmetry asserts that these fibers are typically large: many distinct physical configurations collapse to the same mental/intersubjective pattern. The inability to choose a canonical element of the fiber (even approximately, for the relevant class of observers) is exactly the sense in which U fails to be invertible where it matters.*

Remark 1402. *A simple example is the ordinary map/territory gap: the same topological graph of "places connected by roads" can be embedded in many different geometries with different distances and curvatures. If mental reality records mostly graph-like relations, then lifting it to a physical geometry requires extra choices. This is useful because it explains, without mysticism, why physical reality feels "hard" or "constraining": the constraint is precisely the missing information needed to select one physical refinement among many mental descriptions that collapse under U.*

Remark 1403. *The same pattern appears in familiar mathematical forgetful functors. For instance, forgetting a metric yields a topological space; forgetting a topology yields a set; forgetting a smooth structure yields a topological manifold; forgetting phase information yields an intensity pattern. In each case, the weaker object retains certain invariants (e.g. continuity properties, adjacency relations, cardinality, qualitative connectivity), but it does not determine the stronger object without additional data. The point of stating this categorically is that one can swap in different notions of "physical" and "mental" models while keeping the same asymmetry schema.*

Remark 1404 (Why asymmetry "feels like constraint")**.** *If U discards operations/constraints present in physical reality, then many distinct physical states become indistinguishable in the weaker mental description. From the mind's perspective, trying to realize a mentally-specified pattern physically requires choosing (or discovering) additional structure to lift it back into $\mathcal{R}_{\mathrm{phys}}$. This lifting typically incurs effort and may be impossible, producing the phenomenology that physical reality "constrains" mind.*

Remark 1405. *The "may be impossible" clause has two distinct readings that can coexist. First, there may be no object in $\mathcal{R}_{\mathrm{phys}}$ that maps (even approximately) to the desired m under U, meaning the mental pattern is not physically instantiable in that reality-system. Second, there may be many such objects, but the agent may lack access to the additional structure needed to select and stabilize one. In either case, the mental specification underdetermines the physical implementation, and that underdetermination shows up phenomenologically as friction, failed attempts, or the need for iterative refinement.*

Proposition 41 (Free lift as a source of effort)**.** *Suppose U has a left adjoint F (a "free" structure-adding functor), so $F \dashv U$. Then any mental description $m \in \mathrm{Ob}(\mathcal{R}_{\mathrm{ment}})$ has a canonical lift $F(m)$ into physical-structured form. If a mind's goal pattern is specified in $\mathcal{R}_{\mathrm{ment}}$, then realizing it physically requires at least the "free" lift plus additional constraint satisfaction (selecting a morphism out of $F(m)$ compatible with the actual physical reality-system). This separates* conceptual feasibility *from* physical realizability*.*

Remark 1406. *Intuitively, an adjunction $F \dashv U$ formalizes the idea of "adding structure in the cheapest possible way." The proposition says that even the cheapest lift $F(m)$ already introduces commitments not present in m, and that making the lifted structure* actually occur *in a given physical reality-system is an additional step. This is important because it lets us speak rigorously about effort: effort is not only about searching a space of possibilities, but about bridging a categorical gap between levels of structure.*

Remark 1407. *The word "free" should be read in the technical sense, not as implying physical ease. In many settings, $F(m)$ is a large object: it can represent the space of all minimally constrained implementations of m consistent with the algebraic axioms of $\mathcal{R}_{\mathrm{phys}}$. As a result, the agent's labor is not removed by having F; rather, the adjunction clarifies* what kind *of labor is required: selecting, constraining, and stabilizing a specific physical realization within the degrees of freedom left open by $F(m)$.*

Proof. An adjunction $F \dashv U$ provides, for each m, a unit map $\eta_m : m \to U(F(m))$ that is universal among maps from m into U-images. Thus $F(m)$ is the least additional structure needed to represent m in the physical category. Any further realization must factor through $F(m)$ and so must satisfy additional physical constraints not present in the mental description. $\square$

Remark 1408. *The key step is the universality of the unit η_m. It ensures that every attempt to interpret the mental description m as something physically structured must pass through $F(m)$, so the free lift acts as a bottleneck: it is the common interface between the weak and strong worlds. Geometrically, one may picture $F(m)$ as the "bundle of all minimal physical implementations" of a mental specification, and "physical realizability" as the further act of selecting a section compatible with the actual physics. The proof works because adjunctions are precisely the machinery that captures "best approximation" across categories.*

Remark 1409. *There is also a useful dynamical reading. The composite $T := U \circ F$ is a monad on $\mathcal{R}_{\mathrm{ment}}$, meaning it is an endofunctor that takes a mental description and returns its "freely physically-coherent" enrichment as seen back in the mental category. In this language, iterating T can be interpreted as repeatedly applying a coherence-imposing closure: the agent refines a pattern until it becomes stable under the constraints implicitly imported from $\mathcal{R}_{\mathrm{phys}}$. This does not add a new assumption beyond $F \dashv U$; it only spells out a standard categorical consequence that often matches how agents learn to respect physical constraints through repeated feedback.*

Proof sketch. Use the unit $\eta_m : m \to U(F(m))$ provided by $F \dashv U$. By the adjunction's universal property, any map from m into an underlying physical object factors uniquely through η_m, showing that $F(m)$ is the canonical minimal-structure lift. Realizing m physically then necessarily involves (at least) choosing and satisfying additional constraints beyond those encoded in m. $\square$

25.5 Signals and observer-indexed universes

Hyperseed defines a "universe" relative to a system and a signal class. Intuitively: what counts as "in the universe" depends on what kinds of signal exchanges the system believes are possible.

This usage is intentionally operational: it tracks what is *reachable for interaction* (in the sense of potential bidirectional coordination, observation, or control), rather than what is "out there" in a mind-independent inventory.

Definition 423 (Signals and signal classes)**.** *Let $\mathcal{S}$ be a category (or enriched category) whose objects are systems/entities. A* signal *from A to B is a pair of patterns $(p_{\rm tx}, p_{\rm rx})$ (transmission, receipt) together with a causal interpretation that the transmission pattern is causal for the receipt pattern. A* signal class *C is a specified family of signals (morphisms) in $\mathcal{S}$. Because these are observer-indexed, we allow a mind M to assign a* p-bit *evidence value $E_M(s) \in [0,1]^2$ to the proposition "signal s is usable."*

Remark 1410. *The category $\mathcal{S}$ supplies the ambient "systems and interactions" universe in which we talk about signaling. A signal $s : A \to B$ is not merely a physical disturbance; it is a disturbance together with an interpretation that it transmits information in a usable way. The pair $(p_{\rm tx}, p_{\rm rx})$ emphasizes that the same underlying process may be encoded one way at the transmitter and decoded another way at the receiver; this matches the earlier emphasis that "pattern" is observer-relative [5]. Allowing $E_M(s) \in [0,1]^2$ makes the epistemic status of "usability" paraconsistent: a mind can have simultaneous evidence for and against the usability of a purported channel [23, 24].*

Remark 1411. *It is helpful to separate three layers that are bundled in ordinary language: (i) a dynamical coupling in the substrate (some causal influence from A toward B), (ii) a* coding/decoding *convention that makes that coupling function as information transfer, and (iii) a* pragmatic *constraint that the transfer is reliable enough (or controllable enough) to count as usable for the mind's current purposes. The definition of "signal" packages (i) and (ii) into a morphism-like object, while the evidence value $E_M(s)$ records (iii) in a way that can accommodate ambiguity, adversarial environments, deception, and internal uncertainty.*

Remark 1412. *When $\mathcal{S}$ is taken as an enriched category, the enrichment can encode graded notions of interaction (e.g. costs, capacities, fidelities, probabilities, or resource bounds). In that case, "a specified family of signals" may mean "morphisms satisfying a constraint in the enriching structure" (for example, only channels above a minimum capacity, or only interactions within a given energy budget). The present development does not require fixing an enrichment, but it is useful to keep in mind that many physically relevant restrictions on communication are naturally expressed in enriched-categorical terms.*

Remark 1413. *Example: in an embodied physical cosmos, C might be electromagnetic signals detectable by the body's sensors (light, radio) or mechanical signals (sound, touch). In a social/intersubjective cosmos, C might include linguistic utterances and symbolic artifacts. The definition is useful because it makes "what exists for me" depend on the reachability structure induced by which signals are taken seriously, which is exactly the sort of observer-relativity Hyperseed intends.*

Remark 1414. *The same underlying interaction may fall into different signal classes depending on the mind's model. For instance, the same acoustic wave can be treated as "noise" (excluded from C), as a generic mechanical disturbance (included in a broad C), or as a linguistic utterance with semantic content (included in a narrower but more structured C that presupposes shared conventions). In this way, choosing C captures not only physical modality but also interpretive commitment.*

Definition 424 (Observable universe relative to a signal class)**.** *Fix a system S (typically including a mind and its current reality-system model) and a signal class C. For a threshold $\eta \in (0,1)$, define the* observable universe *of S relative to C as*

$$\mathsf{Univ}_{C,\eta}(S) := \{X \in \mathrm{Ob}(\mathcal{S}) : \exists \text{ a finite } C\text{-signal path } S \rightsquigarrow X \text{ with } E_M^+ \geq \eta\}. \tag{13}$$

In words: X is in the universe if S believes it can (now or eventually) send/receive a C-class signal to/from X.

Remark 1415. *Here* $\mathrm{Ob}(\mathcal{S})$ *denotes the objects of the category* $\mathcal{S}$*. The notation* $S \rightsquigarrow X$ *indicates a finite composable chain of signals in the class* C *from* S *to* X*. The condition "with* $E_M^+ \geq \eta$*" means that along the relevant path(s), the mind's* positive *evidence component for usability exceeds the chosen threshold. (One may similarly incorporate negative evidence, for instance by requiring high positive and low negative evidence, but the present definition keeps the reachability notion uncluttered.)*

Remark 1416. *Concretely, if* $E_M(s) = (E_M^+(s), E_M^-(s)) \in [0,1]^2$*, then* E_M^+ *refers to the first coordinate, interpreted as evidence-for-usability. The definition leaves implicit how evidence is aggregated across a multi-step path; the intended minimal reading is existential: there exists at least one finite path* $s_1, \ldots, s_n$ *of* C*-signals for which each step is usable to degree* $\geq \eta$ *(or, more generally, for which the mind judges the* path as a whole *to clear the threshold under its preferred aggregation rule). This keeps the reachability predicate flexible enough to model different epistemic policies (e.g. "weakest-link" aggregation via* $\min_i E_M^+(s_i)$ *versus Bayesian-like compounding), without changing the surrounding categorical picture.*

Remark 1417. *The phrase "now or eventually" is meant to include mediated reachability:* S *may not directly signal to* X*, but may be able to do so via relays, intermediaries, or composed protocols. The use of a* finite *path matches the operational idea that interaction proceeds through finitely many steps that the mind can in principle represent as a procedure, even if the intermediate systems are not themselves salient in ordinary description.*

Remark 1418. *As an example, if* C *is "radio transmission" and* S *is an Earth-based civilization, then* $\mathsf{Univ}_{C,\eta}(S)$ *includes objects that are radio-reachable in principle (satellites, nearby spacecraft), but excludes galaxies beyond any plausible ability to send/receive radio signals at the required strength. Changing* C *changes the universe: if* C *expands to include hypothetical faster-than-light signals, the universe expands accordingly. This formalizes Hyperseed's distinction between cosmos/universe talk and absolute ontology (Hyperseed-Concept 89).*

Remark 1419. *The threshold* η *plays a normative role: it encodes how demanding the system is about what counts as a usable channel. A cautious scientific instrument may require a high* η *(only high-confidence channels are admitted), whereas an exploratory or imaginative cognition may use a lower* η *(allowing tenuous, speculative, or weakly supported channels to count as potential links). Thus* $\mathsf{Univ}_{C,\eta}(S)$ *is sensitive not only to physics and infrastructure, but also to epistemic temperament and context.*

Proposition 42 (Monotonicity in signal class)**.** *If* $C \subseteq C'$ *then* $\mathsf{Univ}_{C,\eta}(S) \subseteq \mathsf{Univ}_{C',\eta}(S)$*.*

Remark 1420. *This proposition states the obvious but important structural fact: allowing more kinds of signals cannot reduce what you can reach. It mirrors Lemma 5 at a different level: both are monotonicity principles ensuring that subsequent closure/fixed-point constructions behave well.*

Proof. Any C-signal path is also a C'-signal path. Thus reachability using C implies reachability using C'. □

Remark 1421. *The proof is immediate because the definition of universe membership is existential: it suffices that there* exists *a path of allowed signals. Enlarging the allowed set preserves existing paths. Visually, if one adds more edge-types to a graph, the set of vertices reachable from a fixed start vertex can only increase.*

Remark 1422. *Operationally, this monotonicity is a sanity check for model revision: if a mind updates its reality-system model by admitting a previously disallowed channel type into C (e.g. it learns a new protocol, discovers a new sensor modality, or accepts testimony it previously discounted), then previously reachable entities remain reachable, while additional entities may become reachable. This aligns the formalism with ordinary learning dynamics.*

Proof sketch. Universe membership is witnessed by a finite path using signals in C. If $C \subseteq C'$, the same path is valid in C', so reachability (and hence membership) is preserved. □

Proposition 43 (Monotonicity in threshold)**.** *If $\eta \leq \eta'$ then $\mathsf{Univ}_{C,\eta'}(S) \subseteq \mathsf{Univ}_{C,\eta}(S)$.*

Proof. If $X \in \mathsf{Univ}_{C,\eta'}(S)$ then there exists a finite C-signal path $S \rightsquigarrow X$ whose positive evidence satisfies $E_M^+ \geq \eta'$. Since $\eta \leq \eta'$, the same path also satisfies $E_M^+ \geq \eta$, hence $X \in \mathsf{Univ}_{C,\eta}(S)$. □

Remark 1423. *This captures the dual way in which the "observer-indexed universe" can grow: either by broadening C (new modalities of interaction) or by lowering η (relaxing standards of usability). Conversely, a stricter evidential policy (raising η) can shrink the operational universe even if the underlying substrate and signal class remain unchanged.*

Remark 1424 (Cosmos vs universe)**.** *We use* cosmos *informally for a privileged or stabilized universe notion, often induced by a canonical signal class (e.g. "physical" signals mediated through the body-channel for embodied minds). Different minds or different coupling regimes may induce different cosmos notions.*

Remark 1425. *In this terminology, a "cosmos" is typically what remains after a process of convergence: shared measurement conventions, stable instrumentation, and negotiated intersubjective standards produce a relatively fixed C and an implicit threshold policy η. By contrast, "universe" here is deliberately parameterized, so that shifts in embodiment, interface, language-game, or trust policy are represented as explicit parameter changes rather than as contradictions about what exists.*

25.6 Multiverse and guidable multiverse

In Hyperseed, a multiverse is not introduced as a purely metaphysical postulate. Rather, it is an observer-relative construct: a multiverse is a class of possible universes such that (from the observer's perspective) stochastic events determine which universe the observer will inhabit after the event. In this sense, "universe" should be read as a structured world-hypothesis or world-state at the level of description available to the observer's modeling interface, rather than as a commitment to a specific cosmological ontology. The same underlying reality-system may admit many such universe-descriptions depending on which signal classes are available and which variables the observer can stably track.

Definition 425 (Stochastic events relative to an observer)**.** *Fix an observer O. An event e is* stochastic relative to *O if O cannot predict its outcome. An* event class *is stochastic relative to O if O cannot predict the outcome of any particular event in the class, but can predict some features of the outcome distribution over many instances.*

Remark 1426. *This definition is epistemic rather than metaphysical: "stochastic" means "unpredictable to the observer," not "uncaused." One may read this in a Peircean spirit: chance is a name for a limit of habit, a region where regularities have not yet been formed or recognized (cf. the emphasis on habit and Thirdness in [14]). In Hyperseed's operational language, the mind lacks a model that reduces prediction error for the outcomes of e. A practical consequence is that* *"stochastic" depends on the observer's representational capacity, data access, and computational limits; it can therefore change when the observer learns, upgrades instrumentation, or acquires a new signal class.*

Remark 1427. *Example: a fair coin flip is stochastic relative to a typical human observer. But the same physical process may be non-stochastic relative to an idealized observer with complete microstate information and unlimited computation (if one adopts a deterministic underlying model). The definition is useful because it lets multiverse talk arise naturally from limits of prediction and control, rather than requiring an ontological proclamation that "all possibilities exist." More generally, what matters is not whether the microphysics is deterministic, but whether the observer can compress the relevant causal details into a predictive habit at the scale of interaction; when the required compression is unavailable, the observer is forced into a distributional (rather than point) forecast.*

Definition 426 (Multiverse (controlled Markov form))**.** *Fix an observer O and a base universe U_0 (itself observer- and signal-class-indexed). A* multiverse *associated with (U_0, O) is:*

(a) a set (or measurable space) $\mathcal{U}$ of candidate universes consistent with O's model class;

(b) a transition kernel $P(\cdot \mid U, e)$ giving a distribution over next universes after a stochastic event e occurring while in universe U.

Thus, the observer's universe evolves as a stochastic process on $\mathcal{U}$.

Remark 1428. *The kernel $P(\cdot \mid U, e)$ is a Markov-style update rule on the space of universes: given that the observer is currently in universe U and event e occurs, the observer assigns a distribution over which universe comes next. The measurable-space option is included because $\mathcal{U}$ may be infinite or continuous in realistic modeling. The point is not that universes are literally "jumped between" in a physical sense, but that the observer's* self-location *among competing world-hypotheses changes stochastically as unpredictable events unfold. This formalizes Hyperseed-Concept 116 in a way compatible with decision/control extensions. One can also read U as an information-state (e.g., a hypothesis index, a parameter setting, or a latent regime label), in which case $P(\cdot \mid U, e)$ expresses how surprises and updates move the observer among regimes.*

Remark 1429. *A simple example is Bayesian model selection over a hypothesis class of "which underlying dynamics governs my environment." After a surprising observation, probability mass shifts among hypotheses, which can be read as transitioning among "universes" in $\mathcal{U}$. The definition is useful because it makes multiverse structure available wherever there is irreducible uncertainty and competing world-models, including mundane settings like partial observability and nonstationarity. In this Bayesian reading, the "state" of the multiverse can equivalently be taken as a belief distribution over $\mathcal{U}$; the present definition instead treats the realized (self-located) universe as the stochastic variable and keeps the belief implicit in O's kernel assignment. Both viewpoints are compatible: the former emphasizes inference dynamics, while the latter emphasizes experienced branch-selection.*

Remark 1430. *The "event" label e may be instantiated at different granularities. At one extreme, e can be a single measurement or observation; at the other, e can stand for an extended episode whose internal microstructure is not modeled by O. The Markov form should then be read as a modeling commitment that whatever details of the past matter for predicting the next universe are encoded in the current U (as represented by O), which is exactly the usual sufficiency intuition behind state variables in stochastic process modeling.*

Definition 427 (Guidable multiverse). *Let S_1 and S_2 be two signal classes and let O be an observer. A* guidable multiverse *(relative to S_1, S_2, O) is a multiverse $\mathcal{U}$ defined using S_1-reachability such that, in universe U as modeled by O, signals in class S_2 can systematically influence which element of $\mathcal{U}$ the observer will be in after a transition. Formally, this means there is an action set A (implementing S_2 signals) and a controlled transition kernel*

$$P(\cdot \mid U, a) \tag{14}$$

on $\mathcal{U}$.

Remark 1431. *The only new ingredient is control: $a \in A$ indexes interventions available to the observer (or to an agent coupled to the observer) and the kernel $P(\cdot \mid U, a)$ replaces the purely event-driven kernel. This is the same structural move that turns an uncontrolled Markov chain into a Markov decision process. The definition is useful because it makes room for the Hyperseed idea that broader or subtler signal classes could enlarge not only what is reachable, but what is steerable. In particular, if S_2 is weak or noisy, then distinct actions may induce nearly identical kernels $P(\cdot \mid U, a)$, making the multiverse effectively unguidable at the level of $\mathcal{U}$ even if many universes are in principle possible.*

Remark 1432. *Example: in ordinary life, S_1 might be "sensory signals that define my everyday physical universe," while S_2 might be "actions I can take using tools and institutions." Then $P(\cdot \mid U, a)$ encodes how my choices alter which future regimes ("universes" in the hypothesis/experience space) become actual for me. This connects to Hyperseed's general emphasis on action as selection among futures, later formalized variationally in Wu Wei dynamics [21]. In a more explicitly decision-theoretic register, one can introduce a policy $\pi(a \mid U)$ and consider the induced (uncontrolled) kernel $P_\pi(\cdot \mid U) = \int_A P(\cdot \mid U, a)\, \pi(da \mid U)$, which makes clear that guidance is realized through a choice rule that couples the observer's current universe-description to action selection.*

Remark 1433 (Interpretation). *A guidable multiverse is simply a multiverse equipped with controllable degrees of freedom. In conventional physical modeling, "guidance" is limited by the causal structure of the physical reality-system. Hyperseed allows (as a conceptual possibility) that broader signal classes may exist, which would make the multiverse "more guidable" relative to a mind. One concrete way to interpret "more guidable" (still at the level of modeling, not metaphysics) is that different actions a induce more distinguishable outcome distributions over $\mathcal{U}$ (e.g., larger separations between $P(\cdot \mid U, a)$ across a), thereby increasing the set of achievable transitions and decreasing the entropy of the next-universe distribution under well-chosen interventions.*

Remark 1434. *The guidable multiverse definition deliberately remains neutral about whether the observer has direct access to U (full observability) or only to signals generated by U (partial observability). In the latter case, U may be treated as latent and the effective control problem lives on a belief state over $\mathcal{U}$, but the intuitive claim remains: certain signal classes (S_2) can act as handles that reshape which world-hypothesis becomes experientially realized next. This preserves the Hyperseed motif that expansion of signal classes is simultaneously an expansion of both epistemic discrimination and practical steering capacity.*

25.7 The Yverse as a recursive limit of multiverse towers

Hyperseed introduces the *Yverse* as the limit of iterating the "multi" construction:

$$\texttt{universe} \to \texttt{multiverse} \to \texttt{multimultiverse} \to \cdots$$

In this view, signals that appear random at one level may become predictable at a higher level, and in the limit a signal may be paraconsistently both random and predictable. The name "Yverse" references the Y-combinator from combinatory logic, which makes its argument recursive. One can read the informal "$\to \cdots$" not merely as an unending sequence, but as a prompt to replace indefinite iteration with a stabilization principle: rather than asking for the tower at stage n, one asks for a description that is already closed under the "make it multi" operation. This is the sense in which the Yverse is a *recursive limit*: it is characterized by an equation rather than by an external indexing set of stages.

Remark 1435. *The "random vs. predictable" slogan can be understood in a coarse-graining sense: at a given level of description, a signal may be effectively unpredictable because relevant hidden variables are not represented. A higher-level description may add latent structure (e.g. by turning a single-world description into a distribution over refinements), making the same signal conditionally predictable relative to the expanded information state. In the limit, if the description is self-referentially closed under such expansions, it becomes coherent (in a paraconsistent sense) to treat the signal as both "random" (under a projection or forgetting map back down to a lower level) and "predictable" (under the enriched viewpoint that retains the higher-order structure).*

Definition 428 (Abstract multi-operator)**.** *Let $\mathcal{D}$ be a complete lattice of "world-descriptions" (these may encode universes, multiverses, and higher-level constructions). A* multi-operator *is a monotone map*

$$\mathsf{Multi} : \mathcal{D} \to \mathcal{D} \tag{15}$$

that sends a description to the corresponding "multi" description.

Remark 1436. *The lattice $\mathcal{D}$ is an abstract container for levels of description: an element might be a single universe model, a probability distribution over universe models, a distribution over such distributions, and so on. The order structure (making $\mathcal{D}$ a complete lattice) is what permits fixed-point reasoning: it provides suprema/infima needed by general theorems. Monotonicity of* Multi *means that refining a description cannot yield a strictly coarser multi-level description; it is the analog, at the "tower of worlds" level, of the earlier monotonicity lemmas. It is often helpful to read the order $\leq$ on $\mathcal{D}$ epistemically: $d_1 \leq d_2$ may mean "d_2 contains at least as much information/constraint as d_1," or "d_2 is at least as strong a theory as d_1." Under such readings, monotonicity of* Multi *expresses the idea that adding constraints at the base level should not reduce the constraints (or information) available after passing to the multi-level wrapper.*

Remark 1437. *A concrete mental picture is to let $\mathcal{D}$ be a powerset lattice of admissible meta-descriptions, or a lattice of theories ordered by entailment/strength. Then* Multi *wraps a description into a "distribution over refinements" object. The definition is useful because it isolates the recursion in a single operator, making the Yverse a fixed point rather than an indefinitely postponed iteration. Another concrete picture (compatible with the same formalism) is to treat elements of $\mathcal{D}$ as* state spaces with semantics*: a description might specify both (i) a space of possible world-histories and (ii) an interpretation map telling us which signals are observable. Then* Multi *can be understood as lifting a description to a meta-space in which the previous space appears as one component among many alternatives, together with a weighting or selection mechanism. The formal abstraction deliberately does not commit to whether this lifting is probabilistic, possibilistic, or logical; it only commits to the order-theoretic property needed for fixed-point existence.*

Definition 429 (Yverse as a fixed point)**.** *A* Yverse *is a fixed point $Y \in \mathcal{D}$ of* Multi*:*

$$Y = \mathsf{Multi}(Y). \tag{16}$$

When multiple fixed points exist, one may select $Y := \mathsf{lfp}(\mathsf{Multi})$ (the least fixed point) or $Y := \mathsf{gfp}(\mathsf{Multi})$ (the greatest fixed point) depending on the intended semantics.

Remark 1438. *The equation $Y = \mathsf{Multi}(Y)$ is the formal signature of self-reference: the Yverse is a world-description that, when "multiversed," yields itself. Philosophically, this is the point where classical insistence on well-founded constructions begins to strain: the object is defined by its own image. Hyperseed treats this not as a defect but as a clue that paraconsistent and/or non-well-founded semantics may be appropriate when discussing ultimate "wider world" notions (Hyperseed-Concept 209). In analogy with the Y-combinator, the role of Multi is that of a functional F for which one seeks a fixed point satisfying $Y = F(Y)$. The combinatory-logic analogy is not meant to collapse set-theoretic and computational fixed points, but to highlight a shared structural theme: self-application is not an anomaly to be eliminated, but a generative mechanism that produces objects characterized by closure or invariance under a transformation.*

Remark 1439. *One may think of $\mathsf{lfp}(\mathsf{Multi})$ as the most conservative fixed point: the smallest self-consistent Yverse description compatible with the multi-operator. Conversely, the greatest fixed point can be read as the most expansive closure under "multi." The availability of both mirrors familiar least/greatest fixed point choices in semantics (induction vs. coinduction), which in turn mirrors Hyperseed's willingness to keep multiple, potentially tensioned, but useful perspectives in play. In semantic terms, least fixed points are typically associated with "generated" structures (what must be true if one starts from nothing and repeatedly closes under the operator), whereas greatest fixed points are associated with "allowed" structures (what can be true if one permits any consistent completion that remains closed under the operator). Under a "tower of worlds" interpretation, these correspond to two different attitudes: building up the multi-tower from a minimal base versus admitting any sufficiently rich background and requiring only that it be stable under further multiversing.*

Remark 1440. *When $\mathcal{D}$ has a least element $\perp$ and greatest element $\top$ (as every complete lattice does), one may form the ascending chain*

$$\perp \;\le\; \mathsf{Multi}(\perp) \;\le\; \mathsf{Multi}^2(\perp) \;\le\; \cdots \tag{17}$$

and the descending chain

$$\top \;\ge\; \mathsf{Multi}(\top) \;\ge\; \mathsf{Multi}^2(\top) \;\ge\; \cdots, \tag{18}$$

where Multi^n denotes n-fold iteration. In many familiar settings these chains stabilize at $\mathsf{lfp}(\mathsf{Multi})$ and $\mathsf{gfp}(\mathsf{Multi})$ respectively; in full generality, one can require transfinite iteration and take suprema/infima at limit ordinals. This makes precise the earlier informal idea of "iterating the multi construction and taking a limit," with the lattice operations providing the needed notion of limit.

Proposition 44 (Existence of Yverse fixed points)**.** *If Multi is monotone on a complete lattice $\mathcal{D}$, then fixed points exist and the set of fixed points forms a complete lattice.*

Remark 1441. *This proposition says that the Yverse is not a merely aspirational infinity: under the same minimal hypotheses used earlier (complete lattice + monotone operator), fixed points exist by purely mathematical necessity. In the narrative of the paper, this repeats the structural motif of Section 25.2: wherever Hyperseed defines something by a stabilization condition, it also provides the monotonicity needed to guarantee existence. This is a recurring theme in the broader Hyperseed program [1]. A further useful consequence (often taken as part of the Knaster–Tarski package) is that least and greatest fixed points admit order-theoretic characterizations:*

$$\mathsf{lfp}(\mathsf{Multi}) \;=\; \bigwedge\{d \in \mathcal{D} : \mathsf{Multi}(d) \le d\}, \qquad \mathsf{gfp}(\mathsf{Multi}) \;=\; \bigvee\{d \in \mathcal{D} : d \le \mathsf{Multi}(d)\}. \tag{19}$$

Here the meet ranges over pre-fixed points *and the join ranges over* post-fixed points*. This connects the fixed-point selection question to a semantics question: choosing the least fixed point amounts to intersecting all descriptions that are "closed downward" under multiversing, whereas choosing the greatest fixed point amounts to uniting all descriptions that can be extended in a way preserved by multiversing.*

Proof. This is again Knaster–Tarski. ☐

Remark 1442. *The proof deliberately does not add detail because it is identical in structure to Theorem 23: Knaster–Tarski applies to any monotone operator on a complete lattice. The visual intuition is again closure under iteration, except that the objects being iterated are now themselves "world towers." One may imagine repeatedly applying* Multi *and taking a limit in the lattice order; fixed points are precisely where the process stabilizes. It is also worth noting what is* not *assumed: no continuity, no contractiveness, and no metric or topological structure is required. The cost of this generality is that the fixed point need not be reached in finitely many steps or even in countably many steps by naive iteration; the benefit is that the existence of a stabilized "recursive limit" does not depend on a particular implementation of multiversing, only on its monotone behavior with respect to refinement/strength.*

Proof sketch. Invoke Knaster–Tarski on the complete lattice $\mathcal{D}$ and the monotone endomap Multi. Conclude existence of least and greatest fixed points and completeness of the fixed-point set. ☐

Remark 1443 (Why paraconsistent logic helps)**.** *If the "multi" tower diverges or leads to self-referential definitions, classical well-founded reasoning may fail. Paraconsistent logic and non-well-founded set-like constructions (used elsewhere in Hyperseed to model self-reference) provide principled semantics in which such recursive limits can be discussed without trivialization [23, 24]. Concretely, if one tries to force a strict stratification in which level* $n+1$ *must be built only from level* n*, then the equation* $Y = \mathsf{Multi}(Y)$ *appears illicit, because the right-hand side mentions* Y *"from above." Paraconsistent and non-well-founded approaches relax the demand that definitions be grounded in a well-founded hierarchy, allowing circularity while controlling explosion (the principle that from a contradiction everything follows). This aligns with the intended reading of the Yverse as a stable closure of the multiverse-building act itself, rather than as a final object obtained only after completing an impossible traversal of all stages.*

25.8 Eurycosm and near eurycosm

Hyperseed's *eurycosm* ("wider world") is the scope of distinctions, entities, and experiences beyond any single well-defined mind or physical universe. The intent is to capture, in one term, the idea that what is "out there" may not be exhausted by any one internally coherent physics, ontology, or observer-interface; different observers and different admissible channels of interaction can carve the wider world into different operational "worlds" that may partially overlap, partially disagree, or be mutually incommensurable. The *near eurycosm* relative to a given mind is the portion of the eurycosm that the mind can at least partially comprehend. In particular, "comprehend" here does not require full simulation or perfect prediction; it can mean any stable representational handle, such as a compressive model, a useful analogy, or a reliable decision-relevant summary. Universe, multiverse, and Yverse are then different ways of conceptualizing aspects of the eurycosm. One can think of these as different lenses: "universe" emphasizes a single consistent context, "multiverse" emphasizes families of related contexts, and "Yverse" emphasizes structures that remain meaningful across diverse contexts (e.g. cross-context invariants and correspondences).

Definition 430 (Eurycosm)**.** *Let* Mind *be a class of minds/observers and let* $\mathsf{SigClass}$ *be a class of signal classes. The* eurycosm *is the (typically large) union of observer-indexed universes across signal classes:*

$$\mathsf{Eury} := \bigcup_{M \in \mathsf{Mind}} \bigcup_{C \in \mathsf{SigClass}} \mathsf{Univ}_{C,\eta}(M). \tag{20}$$

Here $\mathsf{Univ}_{C,\eta}(M)$ *should be understood as the "universe" induced for observer* M *when* M *treats signals of class* C *as admissible and reliable up to the tolerance parameter* η *(e.g. a coarse-graining or error bar that determines which distinctions count as stable). This makes the union sensitive not only to* what *channels are allowed but also to* how finely *the mind is able or willing to discriminate structure within those channels. This definition is schematic; formally one may treat* Eury *as a large category of contexts with morphisms given by admissible signals and cross-context pattern correspondences. In that categorical picture, objects are contexts (observer-relative worlds), and morphisms represent structured ways of carrying information, models, or identifications from one context to another without insisting on literal identity of ontology.*

Remark 1444. *The formula for* Eury *should be read with a logician's caution: it is not claiming that all such unions form a small set. Rather, it expresses an* organizing principle*: the wider world is what you get when you range over minds and over the classes of signals they treat as real. The suggestion that* Eury *may be treated as a large category emphasizes that relations between contexts (translations, analogies, correspondences of patterns) matter at least as much as the contexts themselves. This aligns with the euryphysics framing [18]. Concretely, depending on ones foundational stance,* Eury *may be a proper class, or it may be internalized by working inside a Grothendieck universe or a type-theoretic hierarchy; the mathematical bookkeeping is secondary to the intended invariant: do not privilege one observer-context as* the *unique container of reality. The categorical emphasis also helps separate two kinds of questions: questions about the internal laws of a context (object-level structure) and questions about how patterns recognized in one context can be transported or matched to patterns in another (morphism-level structure).*

Remark 1445. *A helpful example is to consider* $\mathsf{SigClass}$ *ranging from ordinary physical channels to social-symbolic channels and to any hypothetical channels contemplated by a community. Then* Eury *contains, in a single schematic envelope, the diverse "universes" induced by those different signal regimes. The definition is necessary because Hyperseed wishes to speak about "beyond any one universe" while retaining operational content: the beyond is not a mysterious elsewhere, but a quantified range over observer-indexed reachability structures (Hyperseed-Concept* **??***). In practice,* $\mathsf{SigClass}$ *can also include formal channels such as mathematical proof systems, computational experiment, and mediated instrumentation; these are not "mere language" in this framing, but structured ways of making distinctions and establishing constraints that can stabilize parts of the eurycosm for a community of minds. On this view, "physical" and "social-symbolic" are not competing substances but different signal-mediated interfaces, each with its own notions of invariance, noise, and admissible intervention.*

Definition 431 (Near eurycosm)**.** *Fix a mind* M*. Let* $\mathsf{Comp}_M(X) \in [0, \infty]$ *be a complexity/effort cost for* M *to represent or comprehend* X *(e.g. a weakness-regularized description length). For a budget* B*, define the* near eurycosm *of* M *at budget* B *by*

$$\mathsf{NearEury}_B(M) := \{X \in \mathsf{Eury} : \mathsf{Comp}_M(X) \le B\}. \tag{21}$$

The parameter B *is intentionally abstract: it may stand for compute, time, memory, training data, attention, or any mixture of resources that constrain the minds modeling capacity. One* *natural consistency condition (not required but often convenient) is monotonicity: if $B_1 \leq B_2$ then $\mathsf{NearEury}_{B_1}(M) \subseteq \mathsf{NearEury}_{B_2}(M)$, expressing that additional resources weakly expand what the mind can stably grasp.*

Remark 1446. *The function Comp_M is where resource-boundedness enters explicitly. It may be defined via description length (algorithmic complexity [16]), via weakness in the sense of quantale-enriched representational limitation [3], or by any other effort-like cost compatible with the formal core. The budget B turns that cost into a boundary: what the mind can grasp without exceeding its representational and computational means. Depending on the application, Comp_M may include (i) the cost to* learn *a representation from data, (ii) the cost to* use *the representation for inference or action, and (iii) the cost to* communicate *the representation to other minds; these can diverge sharply even when the underlying object X is the same. It is also useful to allow $\mathsf{Comp}_M(X) = \infty$ for objects that are, for that mind, effectively unrepresentable (for example, because no stable interface exists within its available signal classes).*

Remark 1447. *Example: for a human mind M, parts of Eury corresponding to high-dimensional microscopic dynamics may be outside $\mathsf{NearEury}_B(M)$ for any realistic B, while coarse statistical laws fall inside. For a rich-resource mind (Hyperseed-Concept 162) with the ability to simulate vast portions of the cosmos (as discussed in [11]), the boundary may be dramatically farther out. The definition is useful because it makes "the wider world that is in principle there" distinct from "the portion of it that this mind can meaningfully engage." This distinction also clarifies why scientific progress can look like an outward motion of the near eurycosm: new instruments, mathematical languages, and training regimes can decrease $\mathsf{Comp}_M(X)$ for previously inaccessible X, thereby pulling additional structure into $\mathsf{NearEury}_B(M)$ without changing Eury itself. Conversely, the same underlying region of Eury may be "near" for one mind and "far" for another because Comp_M is observer-relative: what is a direct percept for one agent can be an exotic hypothesis for another.*

Remark 1448 (Operational meaning)**.** *The near eurycosm depends on the mind's representational resources. This makes "beyond our universe" precise in the same observer-relative style as the rest of Hyperseed: it means "outside the portion of the wider world that the mind can currently model with bounded effort." Operationally, a claim that some phenomenon lies outside $\mathsf{NearEury}_B(M)$ can be read as a prediction about failure modes: the mind will lack stable compressions, will be forced into brittle ad hoc models, or will be unable to maintain cross-context correspondences robustly under noise and limited data. Likewise, bridging work (new signal channels, new representational formalisms, or better translations between contexts) can be understood as constructing morphisms that effectively lower Comp_M for relevant targets, thereby making parts of the wider world newly actionable.*

25.9 Anthropic principle as self-locating evidence

Hyperseed treats the anthropic principle as a straightforward statistical point: one's own existence is data, and should be conditioned on when reasoning about the universe. In this sense, "anthropic" updates are not a special-purpose loophole in inference, but an ordinary application of Bayesian reasoning in the presence of indexical (self-locating) information: not only do we learn facts about the world, we also learn that we are located in a world-history compatible with our being here to observe it.

Definition 432 (Anthropic conditioning)**.** *Let Θ be a parameter space of universe models (physical constants, laws, initial conditions, etc.). Let $\pi(\theta)$ be a prior distribution over Θ. Let A be an* *"anthropic" event such as "observers of type $\mathcal{O}$ exist." The anthropic posterior is*

$$\pi(\theta \mid A) \propto \pi(\theta)\,\mathbb{P}(A \mid \theta). \tag{22}$$

Remark 1449. *The notation is standard Bayesian conditioning: $\pi(\theta)$ is a prior over models $\theta \in \Theta$, and $\mathbb{P}(A \mid \theta)$ is the probability that observers exist under model θ. The proportionality indicates normalization by the marginal $\mathbb{P}(A)$. The definition is useful because it demystifies anthropic arguments: they are, at their core, conditioning on self-location information.*

Remark 1450. *In many applications, $\mathbb{P}(A \mid \theta)$ is understood as an "observer-weight" or "selection" factor: models in which observers are common receive greater posterior support after conditioning on the fact that an observer is making the inference. More explicitly, the omitted normalization constant is*

$$\mathbb{P}(A) = \int_{\Theta} \pi(\theta)\,\mathbb{P}(A \mid \theta)\,d\theta, \tag{23}$$

so that the posterior is a reweighted version of the prior in which the weight is precisely the model-dependent chance (or frequency, or measure) of producing observers of the relevant kind.

Remark 1451. *The event A can be defined at different levels of granularity depending on the question. A coarse-grained choice is "there exists at least one observer somewhere in the universe," while a more fine-grained choice might be "there exists an observer with my evidence-state" (including, for example, being in a galaxy of roughly the Milky Way's age, observing a low-entropy past, and so on). Hyperseed's usage emphasizes that such choices are not arbitrary decorations: they encode what information is actually being conditioned on, and therefore what hypotheses are being compared.*

Remark 1452. *A simple example: if some models predict sterile universes with essentially zero probability of observers, then conditioning on A will suppress those models regardless of their prior weight. This aligns with Hyperseed's insistence that epistemology is observer-indexed: what is rational to believe depends on what kind of observer you are and that you are one at all (Hyperseed-Concept 57).*

Remark 1453. *It is also useful to distinguish "possibility" from "probability" in $\mathbb{P}(A \mid \theta)$. A model might permit observers in principle but only in an exceedingly small region of its parameter-realization space (or along an exceedingly narrow subset of histories), making $\mathbb{P}(A \mid \theta)$ tiny. In that case, anthropic conditioning treats the model as strongly disfavored, not because it is logically inconsistent with observers, but because observers are atypical under it. This captures the intuition that "compatible with our existence" is weaker than "makes our existence probable."*

Remark 1454 (Selection effects are not "explanations")**.** *Anthropic conditioning does not explain why a parameter choice is "likely" in some absolute sense. Rather, it formalizes a constraint on what an observer should expect to see given that the observer exists. This is fully compatible with Hyperseed's emphasis on observer-relativity.*

Remark 1455. *In particular, anthropic conditioning separates two questions that are often conflated: (i) what the universe is like (encoded by θ), and (ii) what an observer should expect to see given that they are sampling from the subset of world-histories containing observers. The latter is a statement about conditional expectation, not about a teleological "purpose" of the universe. On this reading, anthropic arguments do not compete with dynamical or microphysical explanations; they specify how observational evidence is filtered by the fact that only certain worlds contain observers capable of gathering that evidence.*

Remark 1456. *Finally, the anthropic event A is a minimal form of self-locating evidence, but it is not the only one. One may also condition on additional indexical data such as "I am an observer at a cosmic time when heavy elements are abundant" or "I find myself in a region with a particular coarse-grained environment." In Bayesian terms, these are further events E to be conditioned on, leading to $\pi(\theta \mid A, E) \propto \pi(\theta)\mathbb{P}(A, E \mid \theta)$, which makes explicit that anthropic reasoning is continuous with ordinary scientific updating: the only novelty is that some components of E describe the observer's location within the model rather than only the model itself.*

25.10 Big bounce as two-ended boundary coupling (speculative)

Hyperseed suggests a "big bounce" picture as an optional speculative anchor: if the large-scale cosmos is modeled by a least-contrivance (Wu Wei) principle between boundary conditions, then one may ask where those boundary conditions come from. A big-bounce hypothesis replaces a strict "beginning" and "end" with a coupled pair of boundaries, potentially allowing certain patterns to "pass through" from a previous cycle.

A further motivation for writing the hypothesis in a two-ended form is that, in many inferential and variational settings, specifying *both* endpoints is a compact way to encode constraints that would otherwise appear as time-dependent "forces" or finely tuned initial microstates. In cosmological language, this also echoes the idea that macroscopic regularities (including low-entropy constraints or special smoothness conditions) may be more naturally stated as boundary information than as ad hoc midstream interventions. In this register, the "bounce" is not only a geometric picture (contraction followed by expansion) but also an informational coupling between terminal and subsequent initial data.

Definition 433 (Two-ended cosmic boundary model)**.** *Let $\mathcal{X}$ be a space of coarse cosmic states (or state distributions), and let $T > 0$ be a cosmic timescale. A two-ended model specifies boundary data (μ_0, μ_T) and selects a history distribution $\{\mu_t\}_{t\in[0,T]}$ by minimizing a contrivance functional (e.g. a KL divergence relative to a reference dynamics), subject to these boundary constraints. This is the same mathematical idiom used for Schrödinger bridges and Wu Wei dynamics.*

Remark 1457. *The objects μ_0 and μ_T are boundary distributions on $\mathcal{X}$, and $\{\mu_t\}$ is a path (in distribution space) connecting them. The "contrivance functional" is meant to quantify how much the selected history deviates from a reference, "natural" dynamics; KL divergence is a canonical choice in Schrödinger bridge theory. Hyperseed uses this idiom to formalize Wu Wei as least forcing [21]; the present definition merely transposes the same mathematics to a cosmic scale (Hyperseed-Concept 66, 207).*

Remark 1458. *For readers who prefer a slightly more explicit bridge to standard formulations: one common setup places a reference path measure P_0 on trajectories (induced, for instance, by a Markov kernel or stochastic differential equation regarded as "baseline physics" at the chosen coarse-graining), and then selects a constrained path measure P whose time-marginals are $\{\mu_t\}$. The contrivance cost is then written as $\mathsf{KL}(P\|P_0)$, and the boundary conditions appear as marginal constraints $P(X_0 \in \cdot) = \mu_0$ and $P(X_T \in \cdot) = \mu_T$. In that language, the family $\{\mu_t\}$ is not merely an arbitrary interpolation but the set of marginals of the least-contrived path ensemble consistent with the endpoint information. This is one reason the two-ended specification is methodologically attractive: it turns endpoint information into a well-posed selection principle over entire histories.*

Remark 1459. *A simple intuition is to imagine that instead of specifying an initial condition and letting dynamics run, one specifies both an "initial-like" and "final-like" macroscopic condition and asks for the least contrived interpolation. This resembles variational principles in physics and* *control, and in Hyperseed's philosophical register it resonates with the idea that "history" is a selection among possible trajectories subject to constraints, rather than an inert given.*

Remark 1460. *At the level of interpretation, a two-ended formulation also helps separate three notions that are often conflated: (i) microscopic time-reversal symmetry (a property of candidate baseline dynamics), (ii) macroscopic arrow-of-time (a property of typical solutions under special boundary conditions), and (iii) epistemic updating (how an observer infers histories given partial data). In the present subsection, Hyperseed is not committing to a specific microphysical model of the bounce; it is instead emphasizing that, whatever the microphysics, a coupled-boundary representation can make explicit which part of the "arrow" is being attributed to boundary data rather than to asymmetric dynamical laws.*

Definition 434 (Bounce operator and cross-cycle morphic resonance)**.** *A* bounce operator *is a map B sending the terminal boundary to the next-cycle initial boundary:*

$$\mu_0^{\text{next}} = B(\mu_T). \tag{24}$$

A simple way to express "two-sided morphic resonance" across the bounce is to let B depend on pattern content:

$$B(\mu_T) := \arg\min_{\nu} \Big(\mathsf{KL}(\nu \,\|\, \mu_\star) + \lambda\, \mathsf{Res}(\nu, \mu_T) \Big), \tag{25}$$

where $\mu_\star$ is a reference prior for initial conditions and Res *is a (bounded) resonance functional favoring re-instantiation of patterns present in μ_T.*

Remark 1461. *In the displayed formula, $\arg\min_\nu(\cdots)$ selects the distribution ν (candidate next initial condition) that trades off proximity to a baseline prior $\mu_\star$ (via KL divergence) against "resonant" similarity to the previous terminal condition μ_T (via* Res*). The scalar λ tunes the tradeoff. This is intended as a formal placeholder showing that, if one wants to talk about cross-cycle pattern carryover, one can do so in the same optimization and resonance language used elsewhere in Hyperseed. The mention of "morphic resonance" connects to speculative proposals in the broader literature [13] as well as Hyperseed's own resonance formalism [5].*

Remark 1462. *The requirement that* Res *be bounded is not merely cosmetic: it is one simple way to avoid trivializing the optimization by letting resonance dominate all other terms. More generally, one can view* Res *as encoding a* pattern statistic *extracted from μ_T and compared to a candidate ν. For instance, if patterns are represented by a feature map $\phi : \mathcal{X} \to \mathbb{R}^d$ (coarse observables, topological signatures, long-range mode amplitudes, algorithmic motifs, etc.), then a resonance penalty/reward could depend on moment matching such as $\|\mathbb{E}_\nu[\phi] - \mathbb{E}_{\mu_T}[\phi]\|^2$, or on a kernel similarity between distributions. Writing B in this way makes explicit where the hypothesis lives: in the choice of pattern representation and in the form/weight of the coupling.*

Remark 1463. *One should also distinguish the "bounce operator" B from the within-cycle reference dynamics used in the two-ended model. In the present idiom, B is not a time-step of ordinary evolution on $\mathcal{X}$; it is an inter-cycle* boundary map *that may include coarse-graining, information loss, or projection onto a family of admissible next-cycle initial macrostates. Put differently, even if the within-cycle history is selected by least-contrivance relative to a baseline dynamics, the cross-cycle linkage can still be nontrivial because it acts on boundary distributions rather than on instantaneous microstates.*

Remark 1464. *One should notice the methodological point: even when Hyperseed permits speculative anchors, it seeks to express them as operators and functionals that could, in principle,* *be constrained by evidence. This is the Dyson/Sagan virtue in a metaphysical setting: keep the conjecture legible to calculation, so that disagreement can become quantitative rather than merely rhetorical.*

Remark 1465. *In the same methodological spirit, the bounce-operator parametrization suggests at least three distinct kinds of constraints one might imagine (even if only in principle): (i) constraints on the "memory strength" λ (how much cross-cycle similarity is permitted without contradicting observed decoherence or cosmological mixing), (ii) constraints on which observables can plausibly remain informative across a bounce (encoded by the choice of ϕ or of the admissible class of* Res*), and (iii) consistency constraints between within-cycle least-contrivance histories and cross-cycle boundary maps (e.g. fixed-point or cycle-consistency relations such as $\mu_0 \approx B(\mu_T)$ for a stationary cycling regime). These are not claims that such data are currently available; they clarify what, in this formalization, would count as sharpening or refuting the hypothesis.*

Remark 1466 (Status)**.** *This "big bounce" construction is included here as a formal placeholder: it shows how to talk about cross-cycle pattern carryover using the same operators already developed for resonance and least-effort path selection. Hyperseed explicitly notes that quantitative aspects of such a phenomenon are unclear.*

Taken together, these constructions place Hyperseed's cosmological vocabulary inside the same mathematical toolbox as its cognitive vocabulary. The next section (Wu Wei dynamics) uses the variational viewpoint more directly, treating action and history selection as geodesic flow in a weakness-shaped geometry [21].

26 Wu Wei dynamics and optimal control

Hyperseed uses the Taoist term *wu wei* as an ontological-computational slogan: *effective action with minimal forcing.* The informal imagery is "like water" or "like a plant bending in the wind": adaptive, responsive, and skillful, without unnecessary struggle. Earlier sections of this paper formalize (i) representational limits via weakness and (ii) conflicting valuation via paraconsistent evidence and resonance. This section adds a third piece: *control as variational flow in a geometry induced by weakness.*

Remark 1467. *The philosophical gesture behind wu wei in Hyperseed is that* agency need not be identified with strain. *One may act, and act effectively, while remaining close to a "passive" unfolding of events—provided that the passive unfolding already embodies a rich store of learned regularities and habits. In this sense, wu wei is an engineering principle as much as a contemplative one: it says that a good controller should look, mathematically, like a* gentle reweighting *of what would have happened anyway, rather than a continual override of the world and the agent's own default tendencies; compare [21].*

Remark 1468. *Conceptually, this section is primarily about Hyperseed-Concept 206 and Hyperseed-Concept 207, and it also relies on Hyperseed-Concept* **??***, Hyperseed-Concept 100, Hyperseed-Concept 158, and Hyperseed-Concept 202. The formal development below is meant to show how these concepts can be grounded in standard (but remarkably elegant) variational principles, while keeping faith with Hyperseed's emphasis that "minimal forcing" is inseparable from "minimal representational effort" [3, 2].*

The key move is to treat "effort" as having (at least) two components:

- **Effort to move**: changing internal (or external) state has a kinetic/transport cost.
- **Effort to resist**: maintaining a trajectory that diverges from a reference ("natural") dynamics has an informational/forcing cost.

Wu wei then means: among all ways of achieving the intended result, follow the path that minimizes these costs, subject to constraints.

Hyperseed concepts covered here. Wu wei; wu wei dynamics; fluid flow and optimal control; minimum representational effort as the bias shaping the flow.

To make the phrase "geometry induced by weakness" concrete, it is useful to imagine that the agent's state (or belief-state) lives on a manifold (or simply a high-dimensional space) $x \in \mathcal{X}$, and that "weakness" supplies a *local notion of difficulty* for representing, predicting, or enacting changes around x. Mathematically, this can be encoded as a position-dependent metric (or, more generally, a convex local norm) $g_x(\cdot, \cdot)$ that determines which directions are "easy" and which are "hard" given the agent's limited descriptive resources. In such a setting, the effort-to-move term naturally takes the form of a kinetic energy measured in this metric,

$$\mathcal{E}_{\text{move}}[x(\cdot)] \;\equiv\; \int_0^T \frac{1}{2} \langle \dot{x}(t), \dot{x}(t) \rangle_{g_{x(t)}} \, dt,$$

so that a geodesic under g is precisely a path that changes state in the least effortful way *relative to the agent's representational constraints*. This is the sense in which wu wei is not "doing nothing," but rather "moving along directions that are already cheap," i.e., moving in the grain of what the system can express without strain.

The effort-to-resist term can be framed in parallel by introducing a reference dynamics (the "passive unfolding") and measuring how strongly a controlled trajectory must depart from it. For example, one may posit a baseline dynamics $\dot{x} = f(x)$ (or a stochastic baseline, if noise is essential to the model), and represent deliberate intervention via an additive control u,

$$\dot{x}(t) \;=\; f(x(t)) + B(x(t))\, u(t).$$

In this case, "minimal forcing" means not merely that u is small in magnitude, but that it is small *in the right units*: the units are again dictated by weakness, via a cost or norm that penalizes interventions that are informationally expensive for the agent to specify or sustain. A canonical form is

$$\mathcal{E}_{\text{resist}}[u(\cdot), x(\cdot)] \;\equiv\; \int_0^T \frac{1}{2} \langle u(t), u(t) \rangle_{R_{x(t)}} \, dt,$$

where R_x can be interpreted as an inverse "control authority" or, equivalently, as a local resistance tensor (so large R_x means forcing is costly). In probabilistic terms, and especially when one works with stochastic reference dynamics, this same idea can be expressed as an informational divergence between the controlled and uncontrolled *path measures*; then "gentle reweighting" can be taken literally as changing the likelihood of trajectories without inventing fundamentally alien ones, which aligns with the remark above that effective agency can appear as a modest tilt of what would have happened anyway.

Finally, the phrase "subject to constraints" should be read broadly: constraints may encode reaching a target set, matching terminal conditions, satisfying safety bounds, or (in the valuation language of earlier sections) tracking a potential-like objective derived from resonance-weighted evidence. In the variational picture, these constraints enter as boundary conditions or as Lagrange-multiplier terms that shape the Euler–Lagrange equations (or, in control language, the Hamilton–Jacobi–Bellman conditions). The resulting wu wei trajectory is thus the one that (i) respects what the agent *can* represent and execute with low complexity (weakness), (ii) remains close to the reference unfolding unless deviation is genuinely needed (minimal forcing), and (iii) still attains the intended outcome via the least costly reconfiguration of the flow.

26.1 Wu wei as minimal-forcing control relative to a passive dynamics

We start with a discrete-time, finite-state formulation that makes the "minimal forcing" idea explicit. In this setting, "control" does not mean selecting an arbitrary action in a separate action set; instead, the agent's decision is directly a choice of *next-state distribution* $P(\cdot \mid x)$, and the central question becomes how much this chosen distribution departs from a baseline $P_0(\cdot \mid x)$.

Definition 435 (Passive and controlled dynamics)**.** *Let X be a finite state space. A* passive *(or* unforced*) dynamics is a Markov kernel*

$$P_0(\cdot \mid x) \in \Delta(X) \qquad (x \in X),$$

where $\Delta(X)$ is the probability simplex on X. A controlled *dynamics is a kernel $P(\cdot \mid x) \in \Delta(X)$ that the agent may choose. A (stationary)* policy *is a map π that assigns to each state x a controlled kernel $P_\pi(\cdot \mid x)$.*

Remark 1469. *Intuitively, $P_0(\cdot \mid x)$ is "what the world (and agent) tend to do" when currently at x, before we impose any task-specific steering. Saying that $P_0(\cdot \mid x) \in \Delta(X)$ simply means it is a probability distribution over next states: for each fixed x, the numbers $P_0(x' \mid x)$ are nonnegative and sum to 1 as x' ranges over X. A controlled kernel $P(\cdot \mid x)$ is another such distribution, representing the agent's choice of how to bias the next step from x.*

Remark 1470. *It is worth emphasizing what is* not *assumed here: we do not posit an explicit action space A with transition law $P(\cdot \mid x, a)$. One may recover that standard viewpoint by taking $P(\cdot \mid x)$ to be the marginal transition kernel induced by choosing an action (or a randomized action) at x. However, the present formulation is more direct for wu wei because it foregrounds the comparison between an "effortless" flow P_0 and any "steered" flow P.*

Remark 1471. *A simple example is a random walk on a small graph whose nodes are X. The passive kernel $P_0(x' \mid x)$ could put equal probability on each neighbor of x (a "default exploration"). A controlled kernel $P(\cdot \mid x)$ might, at some states, assign higher probability to neighbors leading toward a goal region. The definition is useful because it isolates the central wu wei contrast: instead of choosing arbitrary dynamics from scratch, we measure* how far the controlled choice departs from the passive baseline*.*

Remark 1472. *In graph terms, P_0 encodes the geometry and friction of the environment: which moves are "easy" (high passive probability) and which are "unnatural" (low or zero passive probability). This becomes important later because the KL penalty makes it extremely expensive (indeed impossible at finite cost) to assign positive probability to transitions that are impossible under the passive flow, so the passive dynamics functions as a feasibility scaffold as well as an effort prior.*

Definition 436 (Forcing cost as divergence from the passive flow)**.** *Fix a scale parameter $\lambda > 0$. The* forcing cost *at state x for using a controlled kernel $P(\cdot \mid x)$ is*

$$\mathsf{Force}_\lambda(P \,\|\, P_0)(x) := \lambda\, \mathsf{KL}\big(P(\cdot \mid x) \,\|\, P_0(\cdot \mid x)\big). \tag{26}$$

We interpret this as resistance/effort*: it is zero when we "go with the flow" ($P = P_0$) and grows as we push the dynamics away from its natural tendencies.*

Remark 1473. *Here* $\mathsf{KL}(\cdot\|\cdot)$ *denotes the Kullback–Leibler divergence: for two distributions* $P, Q \in \Delta(X)$ *with* P *absolutely continuous with respect to* Q*,*

$$\mathsf{KL}(P\|Q) = \sum_{x' \in X} P(x') \log \frac{P(x')}{Q(x')}.$$

It is always ≥ 0 *and is* 0 *exactly when* $P = Q$*. The parameter* λ *is a unit/scale parameter that determines how expensive it is to deviate from the passive flow: large* λ *means "forcing is costly," so wu wei strongly prefers near-passive behavior; small* λ *makes deviation cheap. This KL-based penalty is a standard information-geometric way to quantify effort-to-resist [16, 21].*

Remark 1474. *Two additional facts about* $\mathsf{KL}(P\|Q)$ *matter for the wu wei reading. First, it is* asymmetric*: steering away from* P_0 *is penalized according to how surprising the controlled flow would look to an observer who expects* P_0*. Second, the absolute continuity condition (*P *must not put mass outside the support of* P_0*) formalizes a kind of "non-violent" constraint: one cannot, at finite forcing cost, demand transitions that the passive dynamics regards as impossible. In many physical settings this corresponds to respecting hard constraints (walls, forbidden moves), while still allowing soft steering among feasible moves.*

Remark 1475. *As a concrete example, suppose from a state* x *the passive kernel assigns* $P_0(\cdot \mid x) = (1/2, 1/2)$ *on two successors. If the controller changes this to* $(3/4, 1/4)$*, the forcing cost is positive but moderate; if it changes to* $(1, 0)$*, the forcing cost becomes larger (and in fact infinite if* P_0 *assigns zero mass where* P *assigns positive mass). This captures the wu wei intuition that "hard commitment" is a kind of strain when it contradicts what the passive dynamics naturally supports.*

Remark 1476. *The dependence on* λ *can also be read in this example: the same change from* $(1/2, 1/2)$ *to* $(3/4, 1/4)$ *is interpreted as "mild effort" when* λ *is small and as "significant effort" when* λ *is large. Thus* λ *mediates a tradeoff between task achievement and non-interference: it acts like a temperature parameter, where high temperature (small* λ*) permits sharper tilting of probabilities, while low temperature (large* λ*) keeps the controlled kernel close to the passive one.*

Definition 437 (Task cost and total objective)**.** *Let* $q : X \to \mathsf{R}$ *be a bounded* state cost *(negative reward). Given initial state distribution* $\rho_0 \in \Delta(X)$ *and horizon* $T \in \mathbb{N}$*, define*

$$J_T(\pi) := E\Big[\sum_{t=0}^{T-1} \big(q(x_t) + \mathsf{Force}_\lambda(P_\pi \parallel P_0)(x_t)\big) + q_T(x_T)\Big], \tag{27}$$

where $x_0 \sim \rho_0$*,* $x_{t+1} \sim P_\pi(\cdot \mid x_t)$*, and* q_T *is a terminal cost. A* wu wei policy *for this problem is any minimizer*

$$\pi^* \in \arg\min_{\pi} J_T(\pi).$$

Remark 1477. *The assumption that* q *is bounded ensures, in particular, that the task part of the objective does not by itself create divergences in the finite-horizon expectation. Any remaining possibility of infinite cost typically comes from the forcing term (via support mismatch), which is conceptually appropriate: if one tries to "force" transitions not permitted by* P_0*, the penalty becomes prohibitive. The terminal cost* q_T *is included to model goals that are evaluated at the end of the horizon (e.g., "be in a target set at time* T*"), and it also supports dynamic-programming formulations where boundary conditions are naturally expressed at* $t = T$*.*

Remark 1478. *The objective $J_T(\pi)$ combines two desiderata in a single expectation $E[\cdot]$ over trajectories: (i) we want to avoid high-cost states (small q if thinking in rewards, or small negative reward if thinking in costs), and (ii) we want to avoid "fighting" the passive dynamics, quantified by Force_λ. The random variables $x_0, x_1, \ldots, x_T$ are generated by first drawing x_0 from the initial distribution ρ_0 and then propagating forward according to the controlled kernel selected by π at each visited state.*

Remark 1479. *Although the policy is defined as stationary (state-dependent but not time-dependent), the finite-horizon criterion still makes sense: one may either restrict attention to stationary policies for conceptual simplicity, or later allow nonstationary π_t when emphasizing optimality for each remaining time-to-go. In linearly-solvable and KL-regularized control, the stationary restriction is often adopted because the optimal kernels can be expressed as statewise tilts of $P_0(\cdot \mid x)$ by functions of successor-state "desirability," and these tilts have a consistent form across time in the time-homogeneous case.*

Remark 1480. *A simple example is navigation with stochastic drift: $q(x)$ is large in dangerous regions and small near the target; P_0 models wind/current drift; P_π models the effect of steering. A wu wei policy is then one that reaches the target while (in expectation) expending minimal forcing against the drift. This definition is necessary for the later claims about "exponential tilting" and "linear solvability": the KL-regularized form is exactly what makes the optimization admit closed-form local solutions and linear recursions.*

Remark 1481. *It is also useful to notice that the forcing cost is* state-local *while the task cost is* trajectory-coupled *through the state evolution. This is precisely the structure that allows one to write Bellman-style recursions: the immediate cost at x_t is $q(x_t) + \lambda\, \mathsf{KL}(P_\pi(\cdot \mid x_t) \| P_0(\cdot \mid x_t))$, and the future cost depends on the chosen next-state distribution. When one minimizes over $P(\cdot \mid x)$, the KL term acts as a convex regularizer, leading (under standard assumptions) to a unique minimizing controlled kernel at each state given an appropriate value-to-go function.*

Remark 1482 (Where weakness enters)**.** *The forcing term is an information-geometric penalty. To connect it to the paper's weakness theme, interpret P_0 as the dynamics induced by a* weak model *(a maximally general representation that makes few distinctions), while P_π is the refined, task-specific dynamics requiring extra distinctions. Minimizing $\mathsf{KL}(P_\pi \| P_0)$ is then a precise form of* minimum representational effort*: do not add distinctions unless they buy real task value.*

Remark 1483. *This connection can be made even more explicit by reading a controlled kernel $P_\pi(\cdot \mid x)$ as an "annotated" version of the passive kernel: it reallocates probability mass among successor states, thereby encoding which distinctions among successors are behaviorally relevant. If the weak model P_0 already concentrates on a small set of plausible next states, then steering within that set can be cheap, while insisting on a qualitatively different move (outside the passive support) corresponds to introducing a distinction the weak model does not even represent. In this sense, wu wei control implements a disciplined refinement of the weak baseline: it intervenes only to the extent that intervention is justified by the task cost.*

Remark 1484. *This remark is pointing at Hyperseed-Concept 143 and Hyperseed-Concept 202. In the weakness-centered view [3, 2], a "strong" model draws sharper boundaries and therefore supports more specialized, more brittle interventions. The wu wei objective says: sharpen boundaries only where the task truly compels it, and otherwise remain close to the weak/default dynamics. Thus what looks like an external control regularizer can also be read as an internal epistemic ethic: avoid gratuitous distinctions. One can also read this as a warning about* self-induced overfitting of agency*: if the controller commits to distinctions not demanded by the objective, it pays an avoidable "maintenance cost" in the form of higher sensitivity to mismatch between model and world. In that sense, the KL penalty is not merely a numerical convenience but a formal way to encode the preference that intervention should be* locally justified *by task-relevant gradients rather than by the availability of controllable degrees of freedom.*

26.2 A one-step wu wei principle: exponential tilting

The forcing regularizer has a canonical optimization consequence: optimal control is achieved by *tilting* the passive dynamics by an exponential of negative cost. Equivalently, the controller chooses the least-informative (closest-to-passive) distribution that still achieves an improved expected cost, where "least informative" is measured in the KL geometry induced by the passive kernel. This is the same variational template that appears in maximum-entropy inference: an energy term (expected cost) plus an entropic or divergence-based regularizer yields a Gibbs/Boltzmann form.

Proposition 45 (Gibbs form for minimal forcing)**.** *Fix a state $x \in X$, a passive distribution $P_0(\cdot \mid x)$ with full support, and an immediate cost function $c : X \to \mathsf{R}$. Consider the one-step optimization problem*

$$\min_{P(\cdot|x)\in\Delta(X)} \Big\{ E_{x'\sim P(\cdot|x)}[c(x')] + \lambda\,\mathsf{KL}\big(P(\cdot \mid x)\|P_0(\cdot \mid x)\big) \Big\}. \tag{28}$$

Then the unique minimizer is

$$P^*(x' \mid x) = \frac{P_0(x' \mid x)\,\exp\big(-c(x')/\lambda\big)}{Z(x)} \qquad \text{with} \qquad Z(x) = \sum_{y\in X} P_0(y \mid x)\exp\big(-c(y)/\lambda\big). \tag{29}$$

Remark 1485. *In plain terms, the proposition says: if you pay a cost both for "going to expensive next states" and for "departing from the default distribution," then the optimal way to choose your next-state distribution is to take the default $P_0(\cdot \mid x)$ and reweight it by an exponential preference for low cost. The normalization constant $Z(x)$ (often called a* partition function*) is just what makes the reweighted numbers sum to 1 again. It is useful to notice that the exponential weight is* relative*: what matters is not the absolute scale of c but its scale compared to λ. For example, adding a constant to $c(\cdot)$ does not change the minimizer, because it factors out of the numerator and is cancelled by the same factor in $Z(x)$; only cost* differences *across next states affect the tilt.*

Remark 1486. *A further quantitative reading is that $-\lambda \log Z(x)$ is a "soft minimum" of c under the passive distribution. Indeed, $Z(x)$ is a log-sum-exp moment of $-c/\lambda$ under $P_0(\cdot \mid x)$, so $\log Z(x)$ plays the role of a cumulant-generating function and interpolates between averaging and minimizing as λ varies. This is one of the reasons λ is often called a* temperature*: high temperature smooths preferences and low temperature sharpens them. In control terms, this makes explicit how the wu wei regularizer controls the curvature (and therefore brittleness) of the effective objective landscape over actions/policies.*

Remark 1487. *This is important because it is one of the rare places in control theory where a constrained optimization over the whole simplex yields an explicit, closed-form answer. It connects directly to later results in this section: the multi-step "linear desirability recursion" is essentially this one-step tilt applied repeatedly inside dynamic programming. It also connects to the broader Hyperseed theme that "soft" (quantitative, graded) commitments are often the right formalization of non-forcing behavior. A second reason it matters is methodological: having an explicit optimizer* *makes it possible to reason about limits ($\lambda \to 0$ and $\lambda \to \infty$), sensitivity (how P^* changes as c changes), and compositionality (how local tilts combine across time) without appealing to generic existence theorems or black-box numerical solvers.*

Remark 1488. *One can also explicitly write the optimal objective value by substituting P^* back into the functional. A standard calculation yields*

$$\min_{P(\cdot|x)\in\Delta(X)} \Big\{ E_P[c] + \lambda\, \mathsf{KL}(P\|P_0) \Big\} \;=\; -\lambda \log Z(x),$$

so the partition function is not merely a normalization device: it is the quantity that summarizes the best achievable cost–forcing tradeoff at state x. This identity is the one-step version of the "free energy" variational principle, and it is the algebraic reason that log-partition functions recur when one passes from one-step control to multi-step value functions.

Proof. The objective is strictly convex in P because $\mathsf{KL}(\cdot\|P_0)$ is strictly convex on the simplex when P_0 has full support. Introduce a Lagrange multiplier α for the constraint $\sum_{x'} P(x' \mid x) = 1$. Differentiating the Lagrangian with respect to $P(x' \mid x)$ and setting to zero yields

$$c(x') + \lambda\big(\log(P(x' \mid x)/P_0(x' \mid x)) + 1\big) + \alpha = 0.$$

Solving gives $P(x' \mid x) \propto P_0(x' \mid x)\exp(-c(x')/\lambda)$, with the proportionality constant fixed by normalization. Strict convexity implies uniqueness. Because $P_0(\cdot \mid x)$ has full support, the stationarity condition is valid at an interior point of the simplex and the optimizer does not need to place exact zeros in order to be feasible; instead, it can trade off small probabilities continuously against the KL penalty. This interiority is what makes the Euler–Lagrange (first-order) condition sufficient here, rather than merely necessary. □

Remark 1489. *A useful way to read the proof is: KL divergence is the "right" strictly convex barrier on the simplex that makes the calculus work cleanly. The Lagrange multiplier step encodes the single essential constraint (probabilities sum to 1), and the derivative calculation produces a logarithm, which is why the solution comes out exponential. The full-support assumption on P_0 ensures the logarithm is well-defined and enforces uniqueness. Another way to say the same thing is that $\mathsf{KL}(P\|P_0)$ supplies a Legendre-type duality between log-partition functions and moment constraints: exponential families are the natural coordinates in which the tradeoff between expected cost and informational deviation becomes linear. This is why the same mathematical move appears in both "soft" control and in maximum-entropy inference: the optimizer lives in an exponential family anchored at the reference measure $P_0(\cdot \mid x)$.*

Proof sketch. The strategy is to minimize a strictly convex functional on a compact convex set (the simplex), so there is a unique minimizer characterized by first-order optimality. One writes the Lagrangian with a normalization constraint and solves the resulting stationarity condition, which yields an exponential reweighting of the passive distribution. In particular, the stationarity condition forces $\log P$ to differ from $\log P_0$ by an affine function of c, and exponentiating converts that affine relation into multiplicative reweighting. □

Remark 1490. *Geometrically (in information geometry), this minimizer can be viewed as the closest distribution to P_0 (in KL sense) among those that achieve the desired reduction in expected cost. The "tilt" is not an arbitrary trick: it is the canonical way to trade off expectation constraints against divergence penalties, and it recurs throughout variational formulations of inference and control [21]. More precisely, the level sets of expected cost are affine slices of the simplex, while* *the KL divergence supplies a strictly convex "distance-like" function; the optimizer is therefore the unique point where a KL ball around P_0 first becomes tangent to a cost level set. This tangency picture also makes the role of λ intuitive: increasing λ inflates the effective penalty on moving away from P_0, so the tangency occurs closer to P_0.*

Remark 1491 (Interpretation)**.** *The passive kernel supplies a* default motion*. The exponential tilt supplies a* soft bias *toward lower-cost next states. As $\lambda \to \infty$ the policy approaches the passive dynamics (high acceptance / low forcing). As $\lambda \to 0$ the policy concentrates on argmin states (high forcing, potentially brittle). Wu wei is not "do nothing" but rather "bias gently unless strongly necessary." A further operational reading is that λ governs how much evidence (in the form of expected-cost improvement) is required to justify deviating from the default. Large λ demands strong, persistent cost advantages before it will significantly reallocate probability mass, while small λ makes the controller "decisive" in the sense of rapidly collapsing onto whichever next state currently looks best. In applications, this means that wu wei regularization can be used to tune not only average performance but also* mode of failure*: softer tilts tend to fail gracefully (by remaining near baseline behavior under uncertainty), whereas harder tilts can fail catastrophically if the cost model is misspecified.*

26.3 Multi-step wu wei control and linear solvability

The same structure persists over many steps and yields a particularly clean dynamic programming recursion.

Definition 438 (Finite-horizon value function)**.** *Define the optimal cost-to-go*

$$V_t(x) := \inf_{\pi} \; E\Big[\sum_{s=t}^{T-1} \big(q(x_s) + \mathsf{Force}_\lambda(P_\pi \parallel P_0)(x_s)\big) + q_T(x_T) \;\Big|\; x_t = x\Big]. \tag{30}$$

Set $V_T(x) := q_T(x)$.

Remark 1492. *The value function $V_t(x)$ is the standard dynamic programming object: it compresses all future consequences of optimal behavior from time t onward, given that we are currently at state x. The conditioning "$\big|\; x_t = x$" means we evaluate the expected future cost assuming the current state is fixed to x. This definition is useful because it allows the global trajectory optimization problem to be solved recursively (Bellman's principle), and it is precisely this recursion that becomes linear after a change of variables.*

Remark 1493. *As an example, if $T = 1$ then $V_0(x)$ is exactly the one-step objective minimized in Proposition 45 (up to the addition of the immediate $q(x)$ term and terminal cost). For larger horizons, V_t stitches together many such one-step optimizations, with the crucial twist that the "immediate cost" in the tilt becomes the* next-step value V_{t+1}.

Theorem 24 (Linear recursion in desirability variables)**.** *Assume $P_0(\cdot \mid x)$ has full support for all x. Define the* desirability *variables*

$$z_t(x) := \exp\big(-V_t(x)/\lambda\big) \in (0, \infty). \tag{31}$$

Then the Bellman optimality equations are equivalent to the linear *recursion*

$$z_t(x) = \exp\big(-q(x)/\lambda\big) \sum_{x' \in X} P_0(x' \mid x)\, z_{t+1}(x'). \tag{32}$$

Moreover, the optimal controlled kernel at time t is

$$P_t^*(x' \mid x) = \frac{P_0(x' \mid x)\, z_{t+1}(x')}{\sum_{y \in X} P_0(y \mid x)\, z_{t+1}(y)}. \tag{33}$$

Remark 1494. *The theorem says that, for this particular KL-regularized control problem, dynamic programming becomes almost suspiciously simple: if one exponentiates (with scale λ) the negative value function, the nonlinear Bellman minimization turns into a linear update of the transformed quantity z_t. In other words, the "difficulty" of optimal control has been moved into a change of variables, after which the recursion resembles a passive expectation under P_0.*

Remark 1495. *This result matters because linear recursions are algorithmically and conceptually easier than nonlinear ones: they admit superposition, can be estimated by sampling, and connect directly to spectral methods. Within this section, it is the multi-step counterpart of Proposition 45; within the larger Hyperseed development, it supports the claim that "minimal forcing" yields a kind of* computational grace*: one does not merely suffer less, one often computes more cleanly. This "linear solvability" viewpoint is also part of the motivation for connecting wu wei to "geodesics" and "fluid flow" later [21].*

Proof. Start from the Bellman equation

$$V_t(x) = q(x) + \min_{P(\cdot|x)} \Big\{ \lambda\, \mathsf{KL}(P \| P_0)(x) + E_{x' \sim P}[V_{t+1}(x')] \Big\}$$

Apply Proposition 45 with $c(x') := V_{t+1}(x')$. The minimizing kernel satisfies $P_t^*(x' \mid x) \propto P_0(x' \mid x) \exp(-V_{t+1}(x')/\lambda) = P_0(x' \mid x)\, z_{t+1}(x')$. The minimal value of the inner optimization is

$$-\lambda \log\Big(\sum_{x'} P_0(x' \mid x) \exp(-V_{t+1}(x')/\lambda)\Big) = -\lambda \log\Big(\sum_{x'} P_0(x' \mid x)\, z_{t+1}(x')\Big).$$

Thus

$$V_t(x) = q(x) - \lambda \log\Big(\sum_{x'} P_0(x' \mid x)\, z_{t+1}(x')\Big).$$

Exponentiating $-V_t/\lambda$ gives the stated linear recursion. □

Remark 1496. *The proof is essentially "plug Proposition 45 into Bellman recursion." The key move is recognizing that the Bellman minimization over $P(\cdot \mid x)$ has exactly the same KL-regularized form as the one-step problem, with V_{t+1} playing the role of the one-step cost. Once this is seen, everything becomes algebra: the minimizer is an exponential tilt, the minimized value is a log-partition term, and exponentiating cancels the logarithm and produces linearity.*

Proof sketch. One first writes Bellman's equation for V_t and notices that the inner minimization is the one-step KL-regularized optimization from Proposition 45. The minimizer is therefore a Gibbs tilt by $\exp(-V_{t+1}/\lambda)$, and the minimized objective becomes a negative log of a passive expectation. Finally, defining $z_t = \exp(-V_t/\lambda)$ converts the log-sum-exp into a linear sum. □

Remark 1497. *A visual intuition is to imagine a "field" over states whose height is $V_t(x)$; exponentiating turns steep cliffs into near-zero desirabilities. Then the update for z_t says: propagate desirability backward by averaging future desirability under the passive dynamics, while discounting by immediate state cost. This is the sense in which wu wei control can look like "letting passive trajectories vote," rather than issuing a single deterministic command.*

Remark 1498 (Wu wei as "path integral control")**.** *The recursion for z_t expresses desirability as a passive expectation of exponentiated negative cost. This makes explicit a wu wei reading: instead of forcing a single hard plan, we compute a soft "desirability field" and let the passive dynamics flow through it. Algorithmically, this often yields efficient estimation by Monte Carlo sampling.*

26.4 Continuous-time limit: fluid flow, optimal transport, and Schrodinger bridges

Hyperseed also links wu wei to the intuition that *fluid flow behaves like holistic decision*: not as independent particles choosing, but as a coordinated transformation of the entire state. A standard mathematical way to express such "holistic transformation" is to view the state as a probability density (or mass density) $\rho(\cdot, t)$ and the action as a velocity field $v(\cdot, t)$.

Remark 1499. *This subsection is best read as a continuous analogue of the discrete KL-control story. Instead of individual sample paths $x_0, x_1, \dots,$ we work with an evolving distribution of mass $\rho(\cdot, t)$ on a domain $\Omega \subseteq \mathrm{R}^d$. The control variable becomes a velocity field $v(\cdot, t)$, which "pushes" the density around. The continuity equation $\partial_t \rho + \nabla \cdot (\rho v) = 0$ is simply the formal statement that mass is conserved as it flows; it is the PDE counterpart of probability normalization in discrete time. This is a central instance of Hyperseed-Concept* **??** *[21].*

Remark 1500. *At an intuitive level, the pair (ρ, v) is the continuum analogue of a controlled Markov evolution: $\rho(\cdot, t)$ plays the role of the time-marginal distribution, while $v(\cdot, t)$ summarizes the "instantaneous drift" that re-shapes the entire ensemble. This is one precise sense in which the decision is "holistic": rather than selecting separate actions for separate particles, one selects a field that coherently transports mass everywhere in Ω.*

Definition 439 (Transport form of representational effort)**.** *Let $\Omega \subseteq \mathrm{R}^d$ be a domain and let $t \in [t_0, t_1]$. Let $\rho(x, t)$ be a density on Ω and let $v(x, t)$ be a velocity field. Assume the continuity equation*

$$\partial_t \rho + \nabla \cdot (\rho v) = 0 \tag{34}$$

in the weak sense. Let $p(x, t)$ be a reference density (the passive flow). Define the Schrodinger-bridge effort functional

$$\mathsf{WSB}[\rho, v] := \int_{t_0}^{t_1} \int_\Omega \rho(x, t) \Big(\tfrac{1}{2} \|v(x, t)\|^2 + \epsilon \log \frac{\rho(x, t)}{p(x, t)} \Big) \, dx \, dt. \tag{35}$$

Remark 1501. *The weak-sense continuity equation means that for every smooth test function ψ compactly supported in space-time, one has the integral identity*

$$\int_{t_0}^{t_1} \int_\Omega \big(\partial_t \psi(x, t) \, \rho(x, t) + \nabla \psi(x, t) \cdot (\rho(x, t) v(x, t)) \big) \, dx \, dt + \int_\Omega \psi(x, t_0) \rho(x, t_0) \, dx - \int_\Omega \psi(x, t_1) \rho(x, t_1) \, dx \ = \ 0.$$

This formulation is important because, in transport problems, minimizers often exist in classes where ρ is not classically differentiable in t and v is defined only ρ-a.e.; the weak form is the correct notion of "mass conservation" for such low-regularity flows.

Remark 1502. *The notation here is classical in PDE/optimal-transport formalisms. $\|v(x, t)\|$ is the Euclidean norm of the velocity vector at point x and time t. The symbol $\epsilon > 0$ plays a role analogous to λ in the discrete formulation: it sets the scale of the entropic/regularization term. The logarithmic term $\log(\rho/p)$ is the pointwise log-likelihood ratio; integrating $\rho \log(\rho/p)$ over space yields a relative-entropy-type quantity, making this a continuous cousin of a KL penalty.*

Remark 1503. *One can also view $\rho \log(\rho/p)$ as a* local *(in time) mismatch penalty: at each time slice t, it penalizes the divergence between the controlled marginal $\rho(\cdot, t)$ and the passive marginal $p(\cdot, t)$. In many Schrödinger-bridge settings, the passive p itself arises as the time-marginal of an uncontrolled diffusion (e.g. a Fokker–Planck flow); in that case, the entropic term measures how much the controlled evolution "leans away" from what the environment would do without intervention.*

Remark 1504. *A simple example is to take $\Omega = \mathrm{R}$ and imagine $\rho(\cdot, t)$ as a "cloud" of probability mass that begins concentrated near one location at time t_0 and must end concentrated near another at time t_1. The passive reference $p(\cdot, t)$ might represent diffusion or drift (what the cloud would do naturally). The functional* WSB *then measures: how much kinetic energy it takes to transport the cloud (the $\|v\|^2$ term) plus how much informational strain it takes to keep the cloud's distribution from simply behaving like p (the $\log(\rho/p)$ term). This makes the definition useful as a precise continuous formalization of Hyperseed-Concept 100 and Hyperseed-Concept 158.*

Remark 1505 (Two kinds of effort, again)**.** *The kinetic term $\int \rho \, \frac{1}{2}\|v\|^2$ penalizes rapid rearrangement (effort to move). The entropic term $\int \rho \, \log(\rho/p)$ penalizes deviation from the passive reference (effort to resist). Thus* WSB *is a continuous analogue of the discrete forcing-regularized objective.*

Remark 1506. *Two limiting cases are especially informative. If the entropic weight ϵ is set to* 0 *(formally), the functional reduces to the Benamou–Brenier kinetic energy for dynamic optimal transport, and the minimizer becomes a displacement interpolation (a Wasserstein geodesic) between ρ_0 and ρ_1. Conversely, when ϵ is large, the minimization increasingly prefers trajectories whose time-marginals remain close to $p(\cdot, t)$, so the controlled evolution behaves more like a "softly steered" version of the passive flow rather than a purely distance-minimizing rearrangement.*

Definition 440 (Wu wei geodesic)**.** *Fix boundary densities $\rho(\cdot, t_0) = \rho_0$ and $\rho(\cdot, t_1) = \rho_1$. A* wu wei trajectory *between ρ_0 and ρ_1 (relative to passive prior p) is any minimizer (ρ^*, v^*) of* $\mathsf{WSB}[\rho, v]$ *subject to the continuity constraint and boundary conditions.*

Remark 1507. *In practice, the phrase "subject to the continuity constraint" means the admissible set consists of pairs (ρ, v) with $\rho(\cdot, t) \geq 0$, $\int_\Omega \rho(x, t)\, dx = 1$ for each t (when ρ is a probability density), finite kinetic energy $\int \rho \|v\|^2 < \infty$, and with $\partial_t \rho + \nabla \cdot (\rho v) = 0$ holding in the weak sense. These conditions ensure that the velocity field genuinely transports the mass of ρ and that* $\mathsf{WSB}[\rho, v]$ *is well-defined (possibly $+\infty$ if ρ is not absolutely continuous with respect to p at some times).*

Remark 1508. *Calling the minimizer a "geodesic" is not merely metaphor. One is endowing the space of densities with a geometry whose path-length-like functional is* WSB*, and then selecting shortest paths subject to endpoints. The "wu wei" content is that the geometry is not purely kinetic (as in classical least-action transport) but also measures closeness to a passive reference p, so the shortest path is the one that accomplishes the endpoint change with minimal combined motion-and-resistance. This is exactly Hyperseed-Concept 207 [21].*

Remark 1509. *This "geodesic relative to p" viewpoint also clarifies why the reference is called "passive": it is not merely a prior over endpoints, but a preferred* background evolution *that defines what counts as effortless. In the same way that a physical medium can have a prevailing current, the density $p(\cdot, t)$ encodes a baseline flow; wu wei is then the principle that one should exploit that baseline unless there is compensating value in deviating from it.*

Remark 1510. *As a toy case, if $\rho_0 = \rho_1$ and p is stationary, then the trivial path $\rho(x, t) = \rho_0(x)$ and $v \equiv 0$ achieves zero kinetic cost and (typically) minimal entropic cost, embodying the "do nothing because nothing is required" corner of wu wei. At the opposite extreme, if ϵ is tiny and the endpoints are far apart, the minimizer will behave like an almost-deterministic transport map: wu wei does not forbid decisive movement; it penalizes* unnecessary *deviation from the passive flow.*

Remark 1511. *A further subtlety is that "do nothing" depends on what p encodes. If $p(\cdot, t)$ already drifts substantially (for instance, due to a strong ambient drift field), then matching endpoints may still require nontrivial motion in the laboratory frame. In that case, wu wei is naturally interpreted in the co-moving frame defined by the passive dynamics: the minimizer prefers to "ride" the baseline drift and only apply control where the endpoint constraints force a correction.*

Theorem 25 (Euler–Lagrange structure (informal)). *Under standard regularity and positivity assumptions (smooth p, strictly positive ρ_0, ρ_1), there exists a unique minimizer (ρ^*, v^*) of* WSB. *Moreover v^* is a gradient field $v^* = \nabla\phi$ and (ρ^*, ϕ) satisfy a coupled system (the Schrodinger system / entropic optimal transport equations).*

Remark 1512. *The condition that v^* is a gradient field is the continuum analogue of optimal policies being expressible via a value function or potential: it says that, at optimum, the flow is driven by a scalar "pressure" or "cost-to-go" ϕ rather than by an arbitrary solenoidal component. In geometric terms, one is selecting the steepest (most efficient) direction for changing the density subject to the endpoint constraints, which is consistent with the "minimal interference" reading of wu wei.*

Remark 1513. *While the theorem statement above deliberately suppresses formulas, a common way to write the coupled optimality conditions is as a pair consisting of (i) the continuity equation with $v^* = \nabla\phi$, and (ii) a Hamilton–Jacobi-type equation for ϕ with an additional term encoding the entropic preference relative to p. In the classical Schrödinger bridge formulation (with a diffusion-based passive process), the same content is often expressed through two space-time potentials (sometimes called Schrödinger factors) whose product, together with the passive kernel, reconstructs the optimal time-marginals $\rho^*(\cdot, t)$. These equivalent representations make precise the idea that the optimal interpolation is simultaneously a least-effort transport and a least-deviation-from-prior inference problem.*

Remark 1514. *Terminology note: the literature often spells this as "Schrödinger bridge" and "Schrödinger system" (with an umlaut), but the present spelling "Schrodinger" refers to the same object. The essential point is that the minimizer can be characterized either dynamically (via (ρ^*, v^*)) or probabilistically (via an entropy minimization on path space relative to a passive process), and these viewpoints coincide under standard assumptions.*

Remark 1515. *In ordinary language: not only does a best (least-effort) flow exist, but it is essentially unique, and it has a special "potential flow" form. The claim that $v^* = \nabla\phi$ says the optimal velocity field has no rotational component (no "vorticity") in the idealized setting; it is driven by a scalar potential ϕ. This is important because potential flows are mathematically tractable and geometrically interpretable: the system moves "downhill" along a potential landscape rather than stirring itself in complicated loops. In particular, once ϕ is known (or characterized), the dynamics are reduced to solving for a single scalar field coupled to the continuity equation, which is substantially simpler than working with a general vector field. Equivalently, the optimality conditions enforce that any divergence-free "circulation" component would only add kinetic cost without helping satisfy the endpoint constraints, and is therefore ruled out at the minimizer.*

Remark 1516. *This theorem connects to the discrete results above via a shared variational structure: both the Gibbs tilt (Proposition 45) and the linear desirability recursion (Theorem 24) can be seen as discrete shadows of entropic optimal transport/Schrodinger bridge formulations. Within Hyperseed, this provides one route to treat wu wei as a literal "least effort path" principle, consistent with the broader claim that cognition may be organized around minimal representational forcing [21, 3]. A useful way to read this connection is that "tilting" a reference process by exponentiated costs is the discrete analogue of regularizing a transport problem by relative entropy with respect to a reference path measure, so the same object appears either as a reweighted transition law (discrete) or as an entropy-penalized flow (continuous). In this sense, the bridge viewpoint explains why linear recursions and log-transform tricks arise: they are the computational footprint of an underlying convex optimization problem in probability space.*

Proof sketch. The functional WSB is convex in $(\rho, \rho v)$ and strictly convex in appropriate function spaces once boundary conditions are fixed. Existence follows from lower semicontinuity and compactness (via standard calculus of variations arguments). Uniqueness follows from strict convexity. The gradient-field form for v^* arises from introducing a Lagrange multiplier for the continuity constraint and taking first variations; this yields that the optimal momentum ρv is the gradient of a potential. More explicitly, writing the Lagrangian with a multiplier ϕ for $\partial_t \rho + \nabla \cdot (\rho v) = 0$ and differentiating with respect to v yields an optimality condition of the form $v = \nabla \phi$ (up to the precise sign convention), while differentiating with respect to ρ produces a complementary equation that can be recognized as a Hamilton–Jacobi–Bellman-type condition coupled to the continuity/Fokker–Planck side. This pair of first-order conditions is the continuous-time analogue of the "desirability" linearization: the potential ϕ plays the role of a log-transform of a value-like function. □

Remark 1517. *At a high level, the proof follows the classical pattern of the direct method in the calculus of variations: (1) show the functional is bounded below, (2) take a minimizing sequence, (3) use compactness to extract a convergent subsequence, and (4) use lower semicontinuity to pass the limit through the functional. Strict convexity eliminates the possibility of two distinct minimizers. The Euler–Lagrange condition comes from enforcing the continuity equation constraint with a multiplier and computing first variations, which forces the optimal momentum to be a gradient. In addition, the endpoint constraints $\rho(\cdot, 0) = \rho_0$ and $\rho(\cdot, 1) = \rho_1$ remove the usual gauge freedom in ϕ (up to an additive constant in space), which is why the potential is determined essentially uniquely at optimality. From a control perspective, these steps formalize the intuition that any deviation from the gradient structure would represent wasted "sideways" motion that cannot improve the endpoint fit but does increase action.*

Proof sketch. View $(\rho, \rho v)$ as the primary variables so that the constraint becomes linear and the objective becomes convex. Apply existence/uniqueness results for strictly convex constrained variational problems with fixed endpoints, and then compute first variations to obtain the potential-flow condition $v = \nabla \phi$. Concretely, the strict convexity is in the momentum variable ρv (quadratic kinetic term), while the entropic regularizer provides coercivity/regularity that helps rule out oscillatory minimizing sequences; together these properties support the standard compactness arguments needed by the direct method. □

Remark 1518. *A geometric intuition is to picture the density $\rho(\cdot, t)$ as an incompressible-looking "mist" that must morph from shape ρ_0 to shape ρ_1. The potential ϕ acts like a time-dependent height function whose gradient tells the mist how to flow. The entropic term (scaled by ϵ) is like a preference to remain near the reference mist $p(\cdot, t)$, preventing the solution from collapsing into overly sharp, brittle transport when such sharpness is not demanded by the endpoints. Equivalently, ϵ controls how strongly the bridge is allowed to "deviate" from the reference dynamics: small ϵ permits decisive, high-curvature rearrangements, whereas larger ϵ favors smoother, more diffusive, reference-aligned evolution. This also clarifies why the solution can be interpreted as a compromise between matching the boundary marginals and staying statistically typical under the prior flow.*

Remark 1519 (Optimal transport and "fluid optimal control")**.** *When $\epsilon \to 0$ the entropic term vanishes and* WSB *approaches the Benamou–Brenier formulation of Wasserstein-2 optimal transport. Thus wu wei trajectories interpolate between: (i)* pure transport geodesics *(strong commitment, low noise), and (ii)* entropically regularized bridges *(soft, exploratory flow). This is one precise route by which "fluid flow and optimal control" become the same mathematics. In the opposite regime (moderate to large ϵ), the minimizer can be read as the most likely evolution connecting ρ_0 to ρ_1 under a stochastic reference process, with the control v acting as the minimal intervention* *needed to steer the law of the process to the desired endpoint. This makes the "least effort" interpretation literal: the action measures the smallest kinetic forcing (in a quadratic-energy sense) compatible with the imposed marginal constraints, with entropic regularization preventing degenerate, measure-concentrating solutions.*

26.5 Exploration, turbulence, and a cognitive Reynolds number

Hyperseed suggests reading the Reynolds number as a knob for "creative exploration" versus "smooth exploitation." We can capture the same qualitative point with the regularization/noise scale. The classical fluid Reynolds number compares inertial transport to viscous smoothing, and the same structural comparison appears here: a transport scale ("how hard you are trying to move mass/attention through state space") versus a smoothing scale ("how much the dynamics is softened by noise/regularization"). In this sense, the Reynolds analogy is less about literal Navier–Stokes dynamics and more about a dimensionless *ratio of mechanisms* that compete in the objective.

Definition 441 (A simple cognitive Reynolds number)**.** *In the transport setting, define a dimensionless quantity*

$$\mathrm{Re}_c := \frac{\|v\|_{\mathrm{typ}}\, L}{\epsilon}, \tag{36}$$

where L is a characteristic length scale and $\|v\|_{\mathrm{typ}}$ is a characteristic velocity. In discrete-time KL control, an analogous knob is $1/\lambda$. One can think of L as encoding the "task horizon" in state space (how far the distribution must be rearranged), while $\|v\|_{\mathrm{typ}}$ encodes the typical rate of rearrangement demanded by the task (how quickly the rearrangement must occur). The parameter ϵ plays the role of the regularization/noise amplitude, so that increasing ϵ increases smoothing (analogous to increasing viscosity), and decreasing ϵ allows sharper, more "ballistic" rearrangements.

Remark 1520. *This is an analogy, not a claim of literal fluid identity: the point is that ϵ (and similarly λ) behaves like an effective viscosity/regularization. When ϵ is large, the entropic term dominates and the flow prefers to remain close to p, exploring broadly; when ϵ is small, the kinetic term dominates and the flow can "commit" to sharp rearrangements. The definition is useful because it provides a single dimensionless control parameter that summarizes how "strained" the system is allowed to become in pursuit of goals, linking directly to Hyperseed-Concept 100 and Hyperseed-Concept* **??**. *A helpful way to read the ratio is: $\|v\|_{\mathrm{typ}}\, L$ sets a scale for "transport intensity" (distance $\times$ speed), while ϵ sets a scale for "smoothing capacity." Thus Re_c increases either because the task demands faster/farther motion (larger $\|v\|_{\mathrm{typ}}$ or L) or because the system is permitted to regularize less (smaller ϵ). In many entropic transport/Schrödinger-bridge formulations, ϵ is directly tied to diffusion strength, so increasing ϵ literally increases stochastic mixing along paths; here we only need the qualitative implication that larger ϵ widens the effective exploration kernel around passive dynamics. Similarly, in KL control, λ is often interpretable as an inverse-temperature-like parameter in a soft-min/soft-max: larger λ makes control more "cost-aware" and conservative (more weight on staying close to the passive prior), while smaller λ makes the policy more decisive and more willing to pay KL to reshape trajectories.*

Remark 1521. *As a very simple mental picture: take L to be the diameter of the region in state space you must traverse and $\|v\|_{\mathrm{typ}}$ to be the typical speed needed to do so in time. Then Re_c is large when the problem demands fast movement relative to the smoothing scale ϵ. In cognitive terms, this corresponds to contexts where sharp decisions are forced (high "closing") rather than gently sampled (high "opening"). Equivalently, if one fixes a time budget T, a common rough choice is $\|v\|_{\mathrm{typ}} \approx L/T$, yielding $\mathrm{Re}_c \approx L^2/(\epsilon T)$, which makes explicit that shortening the horizon T or* *increasing the spatial span L pushes the system toward higher "cognitive Reynolds" demand. This highlights why deadlines, urgency, or high-stakes constraints tend to shift behavior from exploratory sampling to more committed, lower-entropy action selection: they effectively increase the transport-to-smoothing ratio even if the underlying noise level is unchanged.*

Remark 1522. *Small* Re_c *(large* ϵ *or large* λ*) corresponds to high regularization: the flow stays close to the passive prior and remains smooth (exploration dominates). Large* Re_c *corresponds to low regularization: the system can commit sharply, but may also exhibit brittle forcing and complex transient dynamics. This is a formal handle on the exploration–exploitation tradeoff. In particular, the "turbulence" metaphor can be read as a statement about* sensitivity *and* structure*: at large* Re_c*, small changes in goals or boundary conditions can induce large rearrangements of the optimal transport plan/policy, and intermediate-time behavior can become highly non-uniform (e.g., temporarily concentrating probability mass in narrow channels of state space before spreading again). Conversely, at small* Re_c*, regularization enforces a kind of global coherence: mass moves along many paths with moderate weights rather than a few extreme paths, which in cognitive terms resembles maintaining multiple hypotheses or action options with non-negligible probability. It is also useful to note that* Re_c *is meant as a* scaling guide*, not a precisely measurable constant: different reasonable choices of "typical" speed or length yield different numerical values, but they preserve the core monotonicity that increasing task intensity or decreasing smoothing pushes the system toward sharper, more exploitative behavior.*

26.6 Opening/closing, resistance/acceptance, and resonance-modulated control

Wu wei is not only about external dynamics; it also has a phenomenological signature: low felt resistance, low grasping, and high "openness" to the unfolding situation. Within Hyperseed's formalism, these can be treated as properties of the control objective.

Definition 442 (Resistance and acceptance)**.** *Fix passive dynamics* P_0*. For a policy* π*, define its* instantaneous resistance *at state* x *as*

$$\mathsf{Resist}_\lambda(\pi; x) := \lambda \mathsf{KL}\big(P_\pi(\cdot \mid x) \| P_0(\cdot \mid x)\big).$$

Define its acceptance *at* x *as the complementary score*

$$\mathsf{Accept}_\lambda(\pi; x) := \exp\big(-\mathsf{Resist}_\lambda(\pi; x)/\lambda\big) = \exp\big(-\mathsf{KL}(P_\pi \| P_0)(x)\big).$$

Thus acceptance is high exactly when resistance is low.

Remark 1523. *This definition makes Hyperseed-Concept 158 operational: resistance is not a vague feeling but a measurable divergence from a baseline. The acceptance score is simply a monotone transformation of the same quantity, chosen so that it lies in* $(0, 1]$ *with value* 1 *at perfect non-resistance (*$P_\pi = P_0$*). In this way, "acceptance" becomes mathematically the degree to which action remains compatible with the passive unfolding.*

Remark 1524. *A small example clarifies the scale: if* $\mathsf{KL}(P_\pi \| P_0)(x) = 0.1$ *then acceptance is* $e^{-0.1} \approx 0.905$*; if* $\mathsf{KL} = 2$*, acceptance is* $e^{-2} \approx 0.135$*. Thus acceptance sharply penalizes large divergences. This is useful later when resonance is introduced: resonance can bias action without necessarily producing large KL divergence, so it can yield decisiveness together with high acceptance.*

Definition 443 (Opening and closing as entropy of action)**.** *Suppose the agent chooses an action distribution $\pi(\cdot \mid x)$ over a finite action set A. Define its* opening level *at x by the Shannon entropy*

$$\mathsf{Open}(\pi; x) := -\sum_{a \in A} \pi(a \mid x) \log \pi(a \mid x).$$

High opening means the system keeps many options live; low opening means it commits strongly.

Remark 1525. *This definition links Hyperseed-Concept 125 and Hyperseed-Concept 72 to a standard information measure. If $\pi(\cdot \mid x)$ is uniform on A, opening is maximal; if π concentrates almost all mass on a single action, opening is small. The entropy here is Shannon entropy; one may also compare with alternative measures such as logical entropy (Hyperseed-Concept 105) in contexts where distinctions are the primitive [17].*

Remark 1526. *For example, if $A = \{a_1, a_2\}$ and $\pi(a_1 \mid x) = \pi(a_2 \mid x) = 1/2$, then $\mathsf{Open}(\pi; x) = \log 2$. If instead $\pi(a_1 \mid x) = 0.99$ and $\pi(a_2 \mid x) = 0.01$, then $\mathsf{Open}(\pi; x) \approx 0.056$. The point is not that "high opening is always good," but that wu wei often manifests as avoiding unnecessary premature closing: one stays open until reality (task constraints) demands commitment.*

Remark 1527. *In KL-regularized control, the hyperparameter λ simultaneously: (i) penalizes resistance (forcing), and (ii) prevents premature closing by keeping action distributions soft. Thus "opening" can be viewed as a controlled consequence of maintaining wu wei.*

Adding resonance. Earlier sections derive resonance from paraconsistent evaluation by mapping evidence values to complex amplitudes and measuring constructive vs destructive interference. We can plug a resonance term directly into the minimal-forcing control principle.

Definition 444 (Paraconsistent evaluation amplitudes and resonance reward)**.** *Let a set of internal evaluators (subsystems, value-aspects) be indexed by $k \in \{1, \ldots, K\}$. Given an action $a \in A$ in state x, evaluator k assigns a* p-bit *evidence value $E_k(a \mid x) = (E_k^+(a \mid x), E_k^-(a \mid x)) \in [0,1]^2$. Define a complex amplitude*

$$z_k(a \mid x) := (2E_k^+(a \mid x) - 1) + i\,(2E_k^-(a \mid x) - 1) \in \mathrm{C}. \tag{37}$$

Given nonnegative weights w_k, define the total amplitude

$$z_{\mathrm{tot}}(a \mid x) := \sum_{k=1}^{K} w_k\, z_k(a \mid x) \tag{38}$$

and the (bounded-below) resonance reward

$$r_{\mathrm{res}}(a \mid x) := \left| z_{\mathrm{tot}}(a \mid x) \right|^2. \tag{39}$$

Remark 1528. *The notation is doing something simple but philosophically pointed. Each evaluator supplies* two *evidence channels, E_k^+ and E_k^-, as is natural in paraconsistent settings where positive and negative support need not sum to 1 and need not exclude each other. Mapping (E_k^+, E_k^-) to a complex number z_k treats the two channels as orthogonal components of an "opinion vector". The shift-and-scale $(2E - 1)$ simply recenters $[0,1]$ to $[-1,1]$, so that "neutral" evidence sits near 0 in each component. This connects to Hyperseed-Concept 159 and the paraconsistent-logical machinery motivating it [24, 23].*

Remark 1529. *As a small example, if an evaluator says "strongly positive and weakly negative"* $(E^+, E^-) = (1, 0)$*, then* $z = (1) + i(-1)$*. If it says "strongly positive and strongly negative"* $(1, 1)$*, then* $z = (1) + i(1)$*, which is a different phase: paraconsistency is not erased but encoded. Summing amplitudes* $z_{\text{tot}} = \sum_k w_k z_k$ *causes agreement to add coherently and disagreement to partially cancel, and then* $|z_{\text{tot}}|^2$ *turns that net coherence into a scalar reward. This is useful because it lets "internal harmony" become a control-relevant quantity, without requiring the system to collapse conflicting evidence into a single classical truth value.*

Remark 1530 (What this encodes)**.** *If evaluators agree (phases align), then* $|z_{\text{tot}}|^2$ *is large: constructive interference. If evaluators conflict (phases oppose), then* $|z_{\text{tot}}|^2$ *is smaller: destructive interference. Thus* r_{res} *rewards internal coherence. One can also read this as a "coherence-sensitive gain" term: it is insensitive to which evaluator is "right" in isolation, and instead tracks whether the ensemble forms a mutually reinforcing signal. In particular, if the individual complex votes have comparable magnitudes, then alignment produces a superlinear increase in* $|z_{\text{tot}}|^2$*, whereas cancellation keeps the total near the scale of an individual contribution. This is the sense in which resonance operationalizes the phenomenological idea that an action can feel "easy" when many sub-evaluations point the same way, even if no single evaluation dominates.*

Proposition 46 (Resonant wu wei action selection)**.** *Fix a state* x*, a baseline action distribution* $\pi_0(\cdot \mid x)$ *with full support, a bounded "task cost"* $c(a \mid x)$*, a resonance weight* $\beta \geq 0$*, and a forcing scale* $\lambda > 0$*. Consider*

$$\max_{\pi(\cdot|x)\in\Delta(A)} \Big\{ E_{a\sim\pi}[\beta\, r_{\text{res}}(a \mid x) - c(a \mid x)] - \lambda\, \mathsf{KL}\big(\pi(\cdot \mid x) \| \pi_0(\cdot \mid x)\big) \Big\}. \tag{40}$$

Then the unique maximizer is the tilted distribution

$$\pi^*(a \mid x) = \frac{\pi_0(a \mid x)\, \exp\big((\beta\, r_{\text{res}}(a \mid x) - c(a \mid x))/\lambda\big)}{\sum_{b\in A} \pi_0(b \mid x)\, \exp\big((\beta\, r_{\text{res}}(b \mid x) - c(b \mid x))/\lambda\big)}. \tag{41}$$

Moreover, the denominator is a (finite) partition function for the state x *because* $c(\cdot \mid x)$ *is bounded and* $\beta r_{\text{res}}(\cdot \mid x)$ *is typically bounded by construction of the evaluator ensemble; this guarantees the normalization is well-defined for all* $\lambda > 0$*. In the limiting cases, one recovers familiar behaviors: if* $\beta = 0$ *then* π^* *reduces to the standard cost-tilted baseline (no resonance influence), while for large* λ *the distribution remains close to* π_0 *(strong resistance to change), and for small* λ *the mass concentrates on actions maximizing* $\beta r_{\text{res}} - c$ *(nearly deterministic choice).*

Remark 1531. *This proposition says that adding resonance does not break wu wei's computational simplicity. One still gets a Gibbs/softmax form: start from a baseline* π_0 *(the agent's default habit), and reweight actions by the exponential of (resonance reward minus task cost), scaled by* λ*. Thus resonance enters as a* gentle biasing potential*, not as a hard constraint. In Hyperseed terms, this is a concrete mechanism by which internal coherence can guide action without necessarily increasing resistance (KL divergence) from baseline behavior. It is also worth emphasizing the role of* λ *as a "temperature" or "compliance" parameter: smaller* λ *means the agent is willing to depart more sharply from its default policy in response to the combined score* $\beta r_{\text{res}} - c$*, whereas larger* λ *means it will only adjust mildly even if resonance is high. From the perspective of optimal control with information constraints, the KL term quantifies control effort measured in bits relative to the default controller, so resonance can be interpreted as providing additional internal "reward signal" that justifies spending some of that informational/control budget.*

Remark 1532. *The connection to earlier parts of the document is direct: paraconsistent evaluators can disagree, yet their disagreement does not force the agent into paralysis or into brittle resolution. Instead, the system can behave as if it is "listening" to the interference pattern produced by its own competing value-aspects [24]. This is, mathematically, the same kind of "softness" that makes the minimal-forcing principle compatible with bounded rationality and weakness-based representation [3]. In particular, disagreement need not be eliminated by an explicit tie-breaking rule; it is transduced into a graded modulation of the effective utility via r_{res}, and the KL term ensures that any resulting policy change is smooth and bounded. This makes room for action under unresolved internal tension: the agent can still sample from π^*, with the sampling itself representing a form of non-brittle commitment.*

Proof. This is the standard Gibbs variational principle. Equivalently, minimize the convex functional $\lambda \mathsf{KL}(\pi \| \pi_0) - E_\pi[\beta r_{\text{res}} - c]$ over the simplex. The first-order optimality condition is

$$\lambda \log \frac{\pi(a \mid x)}{\pi_0(a \mid x)} = \beta r_{\text{res}}(a \mid x) - c(a \mid x) + \alpha,$$

where α enforces normalization, yielding the stated tilt. Strict convexity of $\mathsf{KL}(\cdot \| \pi_0)$ implies uniqueness. Concretely, exponentiating the stationarity condition gives $\pi(a \mid x) = \pi_0(a \mid x) \exp((\beta r_{\text{res}}(a \mid x) - c(a \mid x) + \alpha)/\lambda)$, and α is then determined by the requirement $\sum_{a \in A} \pi(a \mid x) = 1$, so $-\alpha/\lambda$ is precisely the log of the partition function in the denominator of the displayed formula. Full support of $\pi_0(\cdot \mid x)$ ensures that the logarithm and the ratio π/π_0 are well-defined at the optimum and that the KL divergence is strictly convex on the feasible set. ☐

Remark 1533. *The proof is structurally identical to Proposition 45, with two substitutions: the state distribution $P(\cdot \mid x)$ is replaced by an action distribution $\pi(\cdot \mid x)$, and the immediate cost c is replaced by the combined score $c - \beta r_{\text{res}}$ (up to sign conventions). The logarithm again produces an exponential form, and full support of π_0 ensures the KL term remains well-defined and strictly convex. One can also view the result as the action-analog of entropic regularization in control: the KL penalty selects, among all policies with similar expected score, the one that stays closest to the baseline in relative-entropy distance. In that reading, resonance does not introduce a new optimization primitive; it only modifies the effective reward shaping term inside the same variational template.*

Proof sketch. Optimize a strictly concave objective (linear utility minus KL penalty) over the simplex. Use a Lagrange multiplier for normalization, solve the stationarity equation for π, and normalize; strict convexity of KL gives uniqueness. Because the objective is strictly concave in π (linear term plus negative KL), any stationary point is automatically the global maximizer, so the softmax form is not merely a convenient solution but the unique optimum compatible with the information-cost geometry induced by $\mathsf{KL}(\cdot \| \pi_0)$. ☐

Remark 1534. *A helpful intuition is that π_0 defines what the agent would do "by habit" (or by weak/default modeling), while the exponential term defines a smooth preference landscape over actions. Resonance affects that landscape by increasing the utility of actions that align internal evaluators. Thus coherence acts like an internal "tailwind": it can make one action stand out without requiring a violent departure from baseline. Equivalently, r_{res} changes the relative odds between actions by a multiplicative factor $\exp(\beta(r_{\text{res}}(a \mid x) - r_{\text{res}}(b \mid x))/\lambda)$, so coherence differences matter primarily through their contrasts, and their influence is softened when λ is large. This clarifies why the mechanism is robust: even if resonance is noisy or imperfectly estimated, the KL-regularized tilt prevents it from producing discontinuous policy jumps.*

Remark 1535 (How this matches the phenomenology)**.** *When internal evaluations are coherent, the resonance reward creates a strong but smooth bias, allowing a decisive choice without large divergence from baseline behavior. When evaluations are incoherent (low resonance), the distribution stays closer to π_0 unless the external task cost strongly forces a choice. Thus "acting without forcing" becomes: let coherence guide action whenever possible; otherwise, minimize resistance while resolving the task. In experiential terms, this predicts a graded transition between "effortless" and "effortful" action: high resonance increases decisiveness at fixed λ, while low resonance shifts behavioral control back toward habit and toward externally imposed costs. It also makes precise how acceptance/allowing can be action-relevant: acceptance corresponds to tolerating evaluator conflict (not artificially collapsing it), while still permitting the induced interference pattern to steer action probabilistically rather than via rigid, overconfident commitment.*

26.7 Closing remarks: wu wei as an implementable principle

The section's message is that wu wei is not merely poetic; it corresponds to a standard and useful mathematical design pattern:

- choose a reference (passive) flow P_0 induced by weak modeling and learned habits,
- express goals as costs on trajectories or endpoints,
- penalize divergence from the reference flow (resistance/forcing), and
- optionally add a resonance term that rewards paraconsistent coherence among value-aspects.

Here "flow" can be read concretely as a path measure (a probability distribution over state–action trajectories) or, in continuous time, as a controlled diffusion law; in either case, P_0 supplies the baseline dynamics that would occur absent deliberate intervention. The second step fixes what is to be achieved, while the third step fixes *how* it is to be achieved: not by arbitrary steering, but by minimal deviation from what is already natural or well-learned. In this language, the "forcing" cost is not an aesthetic add-on but a quantitative proxy for intervention effort, model-mismatch, or cognitive strain, depending on the chosen interpretation of the control channel and state representation. The optional resonance term can be understood as an additional structured preference that is *not* reducible to a single scalar reward without loss, but can still be implemented by coupling multiple value-aspects into a single optimization objective.

The resulting dynamics can be viewed equivalently as: (i) KL-regularized optimal control, (ii) entropic optimal transport / Schrodinger bridge interpolation between boundary conditions, or (iii) "fluid decision" in which the whole probability mass distribution moves along minimal representational effort geodesics. A compact way to phrase the shared structure is that one selects a path measure P by trading off task cost against relative entropy to the baseline,

$$P^\star \in \arg\min_P \Big(\mathbb{E}_P[\,\text{task-cost}\,] + \lambda\,\mathrm{KL}(P\|P_0) - \eta\,(\text{resonance})\Big),$$

with weights λ, η chosen to set the strength of "non-forcing" and the strength of coherence-seeking, respectively. In discrete-time Markov settings this objective specializes to the familiar "soft" control laws in which optimal policies are reweighted versions of passive dynamics, and in continuous-time diffusion settings it yields drift adjustments that are small in the sense of relative entropy rate. The equivalence to Schrödinger bridges emphasizes that, when one constrains initial and terminal marginals (or more general boundary conditions), the KL penalty produces the most likely interpolation under P_0, i.e., the least-informative change consistent with the constraints; this is a precise sense in which wu wei implements "getting there without forcing."

Remark 1536. *From the Hyperseed point of view, these equivalences are not merely technical: they suggest a unifying way to speak about behavior, inference, and phenomenology. What looks like "control" in one vocabulary appears as "inference under a passive prior" in another, and as "least-effort geometry" in a third. The wu wei slogan, then, is not an appeal to mystification; it is a reminder that the same formal object can be read as action, as belief update, or as the unfolding of a field. In particular, wu wei becomes implementable precisely because the KL/entropy regularizers yield tractable Gibbs forms and (in special cases) linear recursions [21]. Concretely, the Gibbs form implies that optimal choices reweight baseline tendencies by exponentiated (negative) cost, so that "trying" corresponds to* tilting P_0 *rather than replacing it by an unrelated plan. This is also the technical reason that many such models admit efficient dynamic programming variants: after an exponential transform, the Bellman optimality conditions become linear in the transformed value, so the computation aligns with standard inference machinery (message passing, path integrals, or linear solvers), depending on the domain. On the phenomenological reading, the same mathematics says that deliberate action can feel like "allowing" a trajectory when the objective is achieved by small informational departures from an already coherent baseline.*

Remark 1537. *Finally, the weakness connection is not optional ornamentation. If P_0 is learned from a weak representational stance (few distinctions, broad generalization), then staying close to P_0 is simultaneously (a) low forcing in the environment and (b) low forcing in the agent's own representational apparatus. This recovers a single mathematical mechanism underlying Hyperseed-Concept 206 and Hyperseed-Concept 202: act effectively, but let effectiveness arise from well-chosen priors and coherent internal structure rather than continual override [3, 2]. More explicitly, a weak stance implies that the hypothesis class used to learn P_0 prefers simple, stable regularities; the KL penalty then discourages policies that demand fine-grained distinctions the agent does not robustly maintain. In that sense, the "cost of forcing" doubles as a cost of representational overreach: if one must continually inject detailed corrections to compensate for brittle modeling, then* $\mathrm{KL}(P\|P_0)$ *grows, signaling a departure from both environmental and cognitive economy. Conversely, when the baseline already captures broad invariances, the same KL-regularized update yields behavior that is both low-intervention and resilient under uncertainty, because the solution inherits the generalization properties of P_0 while still permitting targeted deviations where the task-cost strongly demands them.*

27 Discussion, limitations, and next steps

This section is intentionally reflective rather than deductive: it does not add new primitives, but asks what has (and has not) been achieved by the formalization so far. In Russell's spirit, one may say that the gain of formal work is a certain disciplined clarity about *what follows from what*; but the price is that every formal system must declare (sometimes tacitly) which distinctions it is willing to draw, and which it will treat as blurred, incomplete, or even contradictory. Hyperseed leans into this price by treating inconsistency and vagueness as first-class citizens, via paraconsistent evidence and weakness-based compositional structure (cf. Hyperseed-Concept 198, 143, 202 and [3, 2]).

Remark 1538 (How to read this section)**.** *This section is a map of plausible continuations, not a list of settled conclusions. The formal core (paraconsistent evidence, quantale weakness, compositional structure) was built to be extended; the items below indicate* where *extensions may be required for particular applications (cognitive architectures, philosophy of science, or speculative cosmology). When the text mentions a Hyperseed notion (e.g. morphic resonance), it should be read as an interface point: a place where one might connect the ontology to either mathematical or empirical constraints.*

Outline

- Discuss alternative formalizations (topos semantics, other paraconsistent logics, other quantales).
- Discuss what parts of Hyperseed remain underspecified and how to tighten them.
- Discuss computational realizations (knowledge graphs, proof assistants, agent architectures).
- List open problems and potential empirical tests (especially around morphic resonance).

Remark 1539 (Why these four bullets are the natural "pressure points")**.** *The four bullets correspond to four distinct questions one can ask of any formal ontology: (i)* Semantics: *what mathematical universes can interpret the axioms (toposes, Kripke models, algebraic semantics)? (ii)* Completeness of specification: *which parts of the intended meaning are still carried by informal prose rather than axioms, and which extra axioms would capture them without overcommitting? (iii)* Implementability: *what data structures and algorithms support reasoning with the primitives at scale? (iv)* Falsifiability or at least empirical constraint: *which claims are intended to be empirically tethered (even weakly), and what would it mean for the tether to fail? In Hyperseed, these questions are especially salient because the theory explicitly treats* context, evidence*, and* weakness *as observer-relative (Hyperseed-Concept 86,* **??** *is not in the core-concept list, but paraconsistent evidence relates directly to 198 and 104).*

Summary and Hyperseed concepts covered

This section is explicitly meta: it reviews the extent to which the formal core captures the original ontology, where additional axioms are needed, and how to implement the ontology in software.

Hyperseed concepts covered.

- Cross-cutting: all concepts, with emphasis on morphic resonance, paraconsistent valuation, and weakness-based pattern theory.

Remark 1540 (Pointers to the concept index for the emphasized notions)**.** *For quick navigation, the three emphasized themes correspond most directly to: morphic resonance (Hyperseed-Concept 115), paraconsistent valuation (Hyperseed-Concept 198 and also the broader idea of logical vs. empirical truth, Hyperseed-Concept 104), and weakness-based pattern theory (Hyperseed-Concept 202, 143, 130,* **??***). Background sources that motivated these emphases include [5, 3, 2, 24].*

Alternative formalizations: semantics and logical choices

Remark 1541 (Topos semantics as a principled way to internalize "context")**.** *A recurring implicit structure in Hyperseed is that what counts as a "fact" depends on a context of observation, inference, and action. One classical mathematical way to express context-dependence without collapsing into mere relativism is to work in a topos: truth values live in an internal logic whose semantics varies with the chosen topos, often realized as sheaves over a space of contexts. In such a setting, the move from absolute propositions to observer-indexed propositions can be rendered as the move from Set-based semantics to sheaf semantics. This resonates with the paper's general stance that "reality" is (at least partly) stabilized predictive structure relative to observers (cf. Hyperseed-Concept* **??** *and the philosophy-of-science perspective in [20]).*

Remark 1542 (Other paraconsistent logics: keeping inconsistency local)**.** *Hyperseed uses paraconsistent evidence to prevent contradiction from entailing triviality. The specific choice of paraconsistent machinery can vary. For example, 4-valued paraconsistent logics (including constructive variants) provide a truth-functional account of "both true and false" and "neither true nor false"; these align naturally with the idea of maintaining positive and negative evidence channels. In such settings, the bookkeeping distinction is not merely semantic but operational: one can treat "positive support" and "negative support" as independently accruing resources, and then interpret the four truth-values as different coarse summaries of that resource state (supported, refuted, both, or neither). Constructible Duality Logic [23] is one relevant anchor when one wants a typed, constructive discipline around such multi-valued reasoning. The appeal of a typed, constructive discipline is that it supports a more explicit separation between (1) judgments that are computationally witnessed (proof-relevant) and (2) judgments that are merely consistent with current information, which matters when Hyperseed is instantiated as an actual system that must decide when it is permitted to act versus when it must suspend judgment. In other directions, one could emphasize dynamic or modal paraconsistent logics, to better encode temporal updating of evidence (connecting to the later helper-theorem sections on time and becoming). Here the modal/dynamic operators can be read as tracking how the evidence state evolves under actions, observations, or interventions, so that "inconsistency local" means not only "non-explosive" but also "confined to the regions of the state space that the update rules actually touch." The key desideratum is preserved: contradictions should be* registered *and* reasoned with*, not suppressed, and not allowed to explode. One practical consequence is that the logic should permit selective inferences that remain stable under the addition of further evidence, so that local inconsistencies do not globally invalidate downstream planning or learning. This is consonant with the use of resonance-like mechanisms linking inconsistency with dynamical effects [24].*

Remark 1543 (Other quantales: what changes when the "evidence algebra" changes)**.** *Quantales serve as a flexible algebraic substrate for combining graded evidence and measuring weakness/effort (Hyperseed-Concept 143, 202). The canonical choice $V = [0,1]^2$ with componentwise order and product tensor is mathematically convenient, but not obligatory. One can view this choice as fixing a particular notion of "how independent pieces of support compose" and a particular notion of "how costs/weaknesses accumulate," and different applications may require different compositional semantics. If one changes the tensor (e.g. from multiplication to* min *or to a Lukasiewicz t-norm), one changes the interpretation of "independent accumulation" versus "bottleneck conjunction." Concretely:*

- *Using multiplication makes repeated moderate evidence decay (or amplify) multiplicatively, matching an "independent likelihood" intuition. This is especially natural when one expects approximate conditional independence between evidence sources, or when one wants long chains of weak support to gradually attenuate rather than saturate.*
- *Using* min *makes conjunction governed by the weakest link, matching a "necessary condition" intuition. This is appropriate when a claim is only as credible as its most fragile prerequisite (e.g. safety constraints, brittle sensor requirements, or proof obligations where any missing lemma blocks the result).*

The philosophical point is that such a choice is not just technical: it declares what sort of composition the ontology is willing to treat as basic. In particular, it fixes whether "more evidence" behaves like accumulating mass, like satisfying a set of constraints, or like consuming a limited budget of slack. The paper's emphasis on weakness suggests that these choices should be evaluated by *how they support minimum-distinction representation and compositional control [3, 2]. From an engineering perspective, a useful additional test is whether the chosen quantale admits well-behaved residuals/implications (when present), since these determine how one can pose and solve inverse questions of the form "how much additional evidence/effort is needed to reach a target threshold?"*

What remains underspecified, and how to tighten it

This subsection is best read as a set of explicit "degrees of freedom" that separate the core ontology from any particular instantiation. The goal is not to postpone precision indefinitely, but to make clear which precisifications are domain commitments (and therefore revisable) versus which are constitutive of the framework.

Remark 1544 (Underspecification is not a defect, but it creates obligations)**.** *Any broad ontology that aims to serve both metaphysical and computational ends must initially leave some degrees of freedom. However, leaving degrees of freedom creates obligations of two kinds: (i) to state clearly* what is fixed *(axioms) and* what is variable *(model class), and (ii) to articulate criteria by which a variable choice becomes justified in a given application. A useful way to think about (ii) is that justification can be empirical (predictive performance), computational (tractability and robustness), or interpretive (faithfulness to the intended metaphysical reading), and in practice a system design will trade these against one another rather than optimize a single axis. Hyperseed's core is deliberately permissive about representational granularity and about which distinctions are "worth making"; this permissiveness is exactly what weakness is meant to formalize (Hyperseed-Concept 202 and [3, 2]). In particular, weakness is meant to make it possible to say not merely that two models differ, but that the* cost of maintaining the difference *(in attention, memory, proof burden, or control complexity) may dominate its benefits, thereby providing a principled reason to coarsen a representation.*

Remark 1545 (Examples of places one may want extra axioms)**.** *The following are typical points where a research program must decide whether to add structure:*

- ***Threshold choices and stability.*** *Many definitions use thresholds (for distinctions, focus/fringe, etc.). To "tighten" the theory one may specify how thresholds vary across contexts, or impose robustness constraints: e.g. require that small perturbations of thresholds do not flip key classifications too often. One may also require monotonicity constraints (e.g. as resources increase, thresholds do not become harder to satisfy) or hysteresis-like constraints (to prevent oscillation when evidence hovers near a boundary), depending on whether the intended system is more like a classifier or more like a controller.*
- ***Coherence constraints on evidence updating.*** *Paraconsistency permits inconsistency, but does not determine how evidence should be updated in time or merged across agents. One may impose additional coherence axioms (probabilistic, order-theoretic, or dynamical) when building concrete systems, at the cost of narrowing the model class. For instance, one might demand commutativity/associativity of certain merge operations (to model order-insensitive aggregation) or explicitly reject them (to model path-dependence and learning trajectories), and either choice should be treated as a substantive modeling commitment rather than an implementation detail.*
- ***Pattern/evidence interfaces.*** *The ontology of patterns, emergence, and pattern webs is deliberately broad (Hyperseed-Concept 130,* **??***, 132; see also [5]). A tighter theory might specify a privileged family of pattern formalisms (graphical models, programs, logical theories, dynamical systems) together with translations between them. Such translations may themselves carry*

weakness/effort costs (e.g. compilation blowups, loss of fine structure, or the introduction of approximation error), and spelling out these costs is one way to connect the abstract ontology of patterns to concrete computational budgets.

These tightenings do not change the spirit of Hyperseed; they determine how the spirit becomes an engineering discipline. In other words, the point is not to eliminate pluralism, but to ensure that pluralism is controlled by explicit principles so that different instantiations remain comparable.

Remark 1546 (Dependency structure as a recurring hidden variable)**.** *A subtle but pervasive underspecification concerns* dependency*: which assertions depend on which representational commitments, resources, or background regularities (Hyperseed-Concept 93, 94). Formal work on dependency towers and tradeoff theorems provides one route to make this explicit [8, 9]. In practice, making dependency explicit can mean recording not only* that *a claim holds but* under which supports it was derived *(data sources, inference rules, time windows, or modeling assumptions), so that revisions can be localized when some supports are withdrawn or contradicted. The philosophical benefit is a more candid separation between what is claimed "in the abstract" and what is claimed "given the scaffold" (Hyperseed-Concept 51, 83). This also clarifies how paraconsistency interacts with engineering: if contradiction is confined to a particular scaffold component, then one can degrade gracefully by revising or isolating that component rather than treating the entire knowledge state as unusable.*

Computational realizations

Remark 1547 (Knowledge graphs with paraconsistent annotations)**.** *A straightforward implementation path is to treat entities/patterns as nodes in a knowledge graph, and attach to each edge or assertion a p-bit-like evidence annotation capturing positive and negative support. Concretely, one can view each annotation as a small record (e.g.* $(\mathrm{e}^+, \mathrm{e}^-)$*) whose components are updated independently as new sources arrive, so that contradictory sources need not collapse the representation into triviality. This aligns with the intent of paraconsistent valuation (Hyperseed-Concept 198) and makes explicit the difference between "absence of evidence" and "evidence of absence." In practice, the former corresponds to leaving* e^+ *and/or* e^- *near a designated neutral element, while the latter corresponds to actively increasing the negative channel; the distinction is especially important in sparse graphs where missing edges are common. One then implements inference as propagation and aggregation of these annotations, respecting the chosen quantale operations (Hyperseed-Concept 143). Operationally, propagation specifies how evidence moves along paths (e.g. composing along relations), while aggregation specifies how multiple paths, witnesses, or sources combine at a node, and quantale structure provides a principled way to make these combinations associative and order-respecting. Such an approach is compatible with the broader engineering perspective in [19]. It also suggests a natural interface to existing KG toolchains: the paraconsistent layer can often be implemented as an annotation algebra on top of otherwise standard storage, indexing, and query machinery, with the main novelty living in the update rules and the inference semiring/quantale.*

Remark 1548 (Proof assistants and typed internalization)**.** *A different realization strategy is to internalize fragments of Hyperseed in a proof assistant. Here the goal is not merely to compute, but to ensure that complex chains of reasoning about contexts, translations, and compositional structure remain checkable. This shifts the emphasis from runtime performance to auditability: proofs become artifacts that record which context-shifts were permitted and which coherence conditions were used. Dependently typed settings are particularly apt for expressing context-indexed notions without losing rigor. For example, one can index claims by explicit context parameters and require that any "change of context" be witnessed by a term that states the translation/transport* *map, preventing accidental equivocation between similar-looking but non-identical situations. Work on program structure and type-theoretic constructions (e.g. McBride-style derivations in type theory) offers inspiration for making "change of context" and "differentiation of structure" first-class [22]. A practical deliverable along these lines would be a small library of primitives (contexts, morphisms/translation witnesses, and composition laws) together with a collection of derived rules encoding common Hyperseed patterns, so that later mechanized arguments can reuse them rather than re-proving basic bookkeeping lemmas.*

Remark 1549 (Agent architectures, cognitive synergy, and transfer)**.** *For agent architectures, the central design question is how to allocate attention and computation among many partial models and heuristics. In concrete systems, this becomes a scheduling and resource-allocation problem: which models get run, at what fidelity, for how long, and with what sharing of intermediate results. Hyperseed's emphasis on weakness suggests policies that prefer coarse, low-effort representations until task pressure forces refinement. One can interpret "task pressure" as any signal of mismatch (loss, surprise, failure rate, or utility gradient) that justifies paying the cost of a more discriminating model, and interpret "refinement" as moving along a ladder of increasingly structured representations rather than committing to maximal structure from the start. This rhymes with the cognitive-synergy engineering stance in [19] and with transfer-learning frameworks aiming to reuse structure across tasks (Hyperseed-Concept 192, 193; see [7]). From an implementation viewpoint, transfer then becomes the disciplined reapplication of previously validated partial morphisms: components that were weak-but-useful in one context are tested as candidate scaffolding in a new one, with explicit bookkeeping of where the fit succeeds and fails. In multi-agent settings, one also needs a theory of when cooperation improves group-level effectiveness; the pro-social efficiency argument in [6] provides one candidate mathematical lens (touching Hyperseed-Concept 170, 81). Here, "improves" should be read operationally: cooperation must pay for its coordination costs, and thus the relevant predictions concern regimes where communication bandwidth, trust calibration, and division of labor create net gains in collective inference or exploration.*

Remark 1550 (Complexity and information measures as operational proxies for weakness)**.** *When implementing weakness, one often needs computable proxies. In particular, many theoretical notions of "minimal structure" or "least commitment" are defined abstractly, whereas engineering requires scalars or efficiently estimated quantities that can guide search, compression, or model selection. Algorithmic information theory (Kolmogorov complexity) provides one principled family of proxies (Hyperseed-Concept* **??***; [16]). Even when true Kolmogorov complexity is uncomputable, practical approximations (compression-based scores, MDL-style criteria, or restricted model classes) can still serve as consistent heuristics for preferring weaker descriptions that nonetheless fit the data. Logical entropy offers an alternative, partition-centric lens that can be more natural when the primitive notion is "distinction" rather than "code length" (Hyperseed-Concept 105; [17]). This viewpoint is often convenient in settings where the agent's first act is to carve the world into equivalence classes (what is treated as the "same") and only later to assign probabilistic weights or codes within each class. These measures do not replace the ontology; they offer handles by which the ontology can be made computationally testable. They also provide a bridge to empirical evaluation: by tying weakness to measurable surrogates, one can compare alternative implementations by checking whether the proxies track improved generalization, transfer, or robustness under perturbations of context.*

Open problems and potential empirical tests

Remark 1551 (Morphic resonance: what it would mean to test a speculative coupling)**.** *Morphic resonance (Hyperseed-Concept 115) is the most empirically charged and controversial notion named in the outline. Sheldrake's proposal [13] is not used here as a settled fact, but as an invitation to state clearly what sort of empirical signature Hyperseed would treat as evidence for a nonlocal, pattern-mediated coupling. That is, the role of the concept is methodological: it forces the framework to spell out what would count as a residual effect after ordinary causal pathways have been accounted for, rather than leaving the notion vague or purely rhetorical. In Hyperseed terms, a "morphic" effect would look like a reproducible improvement in prediction, learning speed, or pattern stabilization that cannot be accounted for by the explicit causal and informational channels included in the modeled context. A useful sharpening is to demand not merely statistical significance, but robustness across modest changes of experimental realization: if the effect depends delicately on uncontrolled details, it is more plausibly an unmodeled ordinary channel than a genuine context-transcending coupling. The practical challenge is to design experiments where such a residual cannot be too easily explained away by hidden ordinary channels, while also not demanding an unrealistic level of isolation. In other words, the experiments must balance two failure modes: being so open that mundane leakage dominates, and being so closed that the study becomes infeasible or so artificial that external validity is lost.*

Remark 1552 (Paraconsistent experimental methodology)**.** *If one expects borderline effects (small, context-sensitive, partially inconsistent), a classical binary hypothesis-testing posture may be epistemically mismatched. In such regimes, it is common for replications to produce mixed outcomes, and the key scientific question often becomes whether the pattern of success/failure aligns with specific contextual moderators rather than whether a single global null can be rejected. A paraconsistent stance instead records both supporting and disconfirming evidence channels and asks how stable the* net *pattern is under changes of context and analysis pipeline. Operationally, this means tracking which preprocessing choices, inclusion criteria, modeling assumptions, and instrumentation changes strengthen or weaken the effect, and representing the result as an evidence profile rather than a single scalar verdict. This is a natural extension of the social-computational-probabilistic philosophy of science view in [20], where science is treated as a dynamical process of community-level belief revision rather than a one-shot adjudication. The methodological implication is that publishing "negative" and "positive" channels together is not a concession but a requirement, because downstream reasoning needs access to the full inconsistency structure in order to update responsibly.*

Remark 1553 (Stability of self-modifying goals as an additional testbed)**.** *Another empirical-leaning direction is to test formal predictions about stability of goal systems in self-modifying agents (Hyperseed-Concept 110). Here "stability" can be understood in several related senses (e.g. invariance of a goal under allowed self-modifications, bounded drift under noise, or convergence to an attractor set of policies), and different formalisms may target different senses. Fixed-point methods applied to goal dynamics provide one route to generate concrete mathematical criteria for stability/instability that can be simulated and, in limited domains, experimentally checked [10]. One advantage of this testbed is that it permits closed-loop experiments: the agent's own updates change the object being studied, so one can measure not only performance but also the geometry of goal evolution under explicit intervention. This connects back to the theme that "realness" and "reality-systems" are stabilized predictive structures, now applied to the internal economy of goals rather than external perception. In this light, a goal system counts as "real" for the agent insofar as it persists as a coherent predictive constraint through the agent's own attempts to optimize, compress, or re-express it.*

Remark 1554 (Resource-rich minds and shifts in cognitive regime)**.** *Some open questions become visible only when the agent's resources become large. For example: if a mind can afford extensive simulation, model search, or self-replication, then its "natural" weakness profile and attention-allocation strategies may qualitatively change (Hyperseed-Concept 162; [11]). One way to read this is as a warning against extrapolating human-default priors: scarcity shapes which approximations feel "natural," and abundance may make previously unaffordable forms of meta-reasoning (e.g. maintaining many candidate contexts in parallel) the dominant strategy. This matters because the ontology aims to be scale-robust: it should describe not only humans and current machines, but also potential successors. Accordingly, a next step is to identify which claims are invariant under resource scaling (true structural constraints) versus which are artifacts of a particular computational regime, so that future empirical work can separate principled predictions from contingent ones.*

Remark 1555 (Philosophical anchoring: Peirce and Whitehead as interpretive constraints)**.** *Finally, it is worth noting that Hyperseed's stance is not only technical but metaphysical: it treats process, mediation, and relational structure as primary. Peirce's categories of Firstness, Secondness, and Thirdness [14] offer an interpretive schema for understanding why the formalism insists on both raw qualitative givenness (First), brute interaction and resistance (Second), and lawful mediation/pattern (Third) (Hyperseed-Concept* **??***, 163, 190). In this reading, the point is not to "reduce" the mathematical objects to Peircean terms, but to treat the triad as a constraint on what a satisfactory account must be able to represent without smuggling in extra assumptions: a place for immediacy as such, a place for constraint as such, and a place for the mediating structures that render sequences of constraints intelligible as patterns. This is also a way of articulating why purely extensional descriptions (e.g., sets of outcomes) are often inadequate on their own: they may list what happened, yet fail to encode the modalities of how it was encountered (First), what resisted (Second), and what stabilized as a rule-like linkage (Third). Whitehead's process ontology [15] likewise provides a philosophical context in which "entities" are stabilized occasions and relations rather than timeless substances (Hyperseed-Concept 124, 140). On that view, persistence is something achieved—a repeated compatibility of successive occasions—and the formalism's emphasis on relational consistency conditions can be read as a technical analogue of that achievement, rather than as an a priori commitment to fixed, globally valid objecthood. It also clarifies a limitation: if one imports substance-style intuitions (fixed identity across all contexts), one may misread observer-relative or paraconsistent constructions as defects rather than as deliberate representations of partial stabilization in the presence of incompatible constraints. These references do not prove the mathematics; they help one see what the mathematics is trying to be faithful to. They also function as a guardrail against overinterpreting convenience: when a representation is chosen for tractability, the philosophical anchoring prompts the question of which aspects of process and mediation have been idealized away, and whether that idealization is appropriate for the intended domain of application.*

Remark 1556 (A note on euryphysics and cosmological ambition)**.** *The earlier sections that extend toward cosmos/multiverse/eurycosm aim at a general formal vocabulary for talking about "the wider world" beyond any one stabilized observer-bound reality (Hyperseed-Concept* **??***, 89; see [18]). One motivation for introducing such vocabulary is pragmatic: without a disciplined way to talk about "external" structure, it is easy to oscillate between naive realism (treating one observer's stabilized world as the world simpliciter) and instrumentalism (treating all structure as mere bookkeeping with no cross-context constraint). The caution is that cosmological reach can outrun empirical grip. In particular, once the formalism is used to compare or relate multiple observer-relative stabilizations, it becomes tempting to read purely formal degrees of freedom as ontological commitments; resisting that temptation requires an explicit account of what would count as evidence for, or constraint on,* *those degrees of freedom. The opportunity is that a paraconsistent, observer-relative formalism can at least let us state the limits of our grip precisely, rather than masking them as false certainty. This "precision about limits" is itself a methodological next step: to classify which claims are invariant across observer-stabilizations, which are only locally stable, and which are artifacts of representational choices, thereby turning philosophical caution into concrete criteria for model comparison. A further limitation, closely related, is communicability: the more general the euryphysical language becomes, the more work is required to show how it reduces to familiar empirical practices in special cases (e.g., when observers agree, when inconsistencies are negligible, or when a classical limit is appropriate). Conversely, a near-term opportunity is to develop explicit translation principles that connect eurycosmic statements to testable predictions in restricted regimes, making cosmological ambition continuous with ordinary scientific inference rather than a separate, unconstrained layer of speculation.*

Part II

Helper theorems for reasoning about Hyperseed concepts

28 Helper theorems for phenomenological primitives (Section 6)

Standing assumptions and notation. Fix a context $c = (X_c, \Pi_c, \delta_c, \iota_c)$ and a (commutative) p-bit quantale V with componentwise order $\leq$ and monotone commutative product $\otimes$. Write $v = (v^+, v^-) \in V$ for positive/negative evidence channels. Fix thresholds $\tau_\delta, \tau_\iota, \tau_I \in (0, 1)$. Recall:

$$\mathrm{Diff}_c(x \to y) := \delta_c(x, y), \qquad \mathrm{Dist}_c(x, y) := \mathrm{Diff}_c(x \to y) \otimes \mathrm{Diff}_c(y \to x),$$

and the crisp distinction $x \#_c y$ means $\mathrm{Dist}_c(x, y)^+ \geq \tau_\delta$. Repetition/variety/non-duality/non-dual-variety are the threshold predicates of Defs. 42–43. Intensity is $I_c : X_c \to [0, 1]$, with $\mathrm{Focus}_c(\tau_I)$ and $\mathrm{Fringe}_c(\tau_I)$ as in Def. 49. An abstraction is a surjection $q : X_c \twoheadrightarrow A$ with preorder $q_1 \preceq q_2$ iff $\exists r : A_1 \to A_2$ such that $q_2 = r \circ q_1$ (Def. 51). A context translation is a function $T : X_c \to X_d$, and T is non-dually compatible if it does not erase strong δ-distinctions (Def. 53).

It is useful to keep in mind the qualitative role of the three thresholds. The parameter τ_δ governs when directed evidential differences "count" as a stable, symmetric separation at the level of Dist_c; it is the place where the evidence-valued notion is intentionally collapsed to a crisp predicate $x \#_c y$ only for the purpose of stating combinatorial claims. Similarly, τ_ι controls when the ι_c-based predicates (Defs. 42–43) transition from graded evidence to crisp repetition/variety conditions, while τ_I is the intensity cutoff that turns the scalar field I_c into the two regions $\mathrm{Focus}_c(\tau_I)$ and $\mathrm{Fringe}_c(\tau_I)$. In later lemmas, monotonicity properties typically show that if a statement holds at some threshold, then it continues to hold at weaker thresholds (e.g. lowering τ_δ makes $x \#_c y$ easier to satisfy), whereas strengthening a threshold expresses a more demanding notion of "strong evidence".

Also note that Dist_c is built to enforce a "two-way" requirement: even when δ_c is highly directed, $\mathrm{Dist}_c(x, y)$ aggregates the evidence for x differing from y together with the evidence for y differing from x. Thus Dist_c should be read as a symmetry-enforcing composite, while Diff_c is the primitive directed quantity. The helper results in this section repeatedly exploit exactly this separation: asymmetry is allowed at the Diff level, but many of the later predicates are deliberately phrased using Dist in order to avoid baking in any a priori directionality.

Remark 1557. *This subsection of helper theorems is a kind of "elementary geometry" for the phenomenological primitives: it records the algebraic consequences of how* Difference *(Hyperseed-Concept 96),* Distinction *(Hyperseed-Concept 98),* Repetition *(Hyperseed-Concept 155),* Variety *(Hyperseed-Concept 199),* Non-Duality *(Hyperseed-Concept 121), and* Non-Dual Variety *(Hyperseed-Concept 120) were defined earlier. The guiding idea is that these are not treated as crisp, classical predicates from the outset; rather, they are built from evidence-bearing quantities taking values in a p-bit quantale, i.e. a two-channel structure that can simultaneously support evidence* for *and evidence* against *the same claim. This is one clean way to keep faith with paraconsistent intuitions without abandoning formal discipline (see, e.g., constructive/paraconsistent semantics as discussed in [23] and the resonance-motivated uses in [24]; for the broader Hyperseed framing see [1]).*

A practical consequence of this "two-channel" setup is that later statements can be formulated so that they only depend on the +-channel (as with $x \#_c y$), or depend on both channels when non-duality is at stake. In particular, one should not read the presence of a large v^- component as a contradiction in the classical sense; rather, it represents structured counterevidence that is retained rather than forced into a binary truth value. This is why many helper lemmas are phrased as monotonicity or preservation results: they guarantee that the constructions used to define phenomenological predicates do not behave erratically when evidence is strengthened in either channel.

Remark 1558. *A few notational conventions are worth making explicit the first time they are used in this helper section.*

- *The arrow in* $\mathrm{Diff}_c(x \to y)$ *is* not *a function type; it is a suggestive way of marking that δ_c is generally* directed*: $\delta_c(x, y)$ need not equal $\delta_c(y, x)$.*
- *An element $v \in V$ is written as $v = (v^+, v^-)$, where v^+ and v^- are the positive and negative evidence coordinates. When we write inequalities like $\mathrm{Dist}_c(x, y)^+ \geq \tau_\delta$, we mean: take the +-component of the p-bit value and compare it to the scalar threshold.*
- *"Componentwise order" means: $(a^+, a^-) \leq (b^+, b^-)$ iff $a^+ \leq b^+$ and $a^- \leq b^-$ (in the underlying order on each component). This matters because it guarantees that threshold comparisons behave monotonically under $\leq$.*
- *"Monotone commutative product" means: $u \leq u'$ and $v \leq v'$ implies $u \otimes v \leq u' \otimes v'$, and also $u \otimes v = v \otimes u$. The commutativity will be the only property used in Lemma 6; monotonicity will be the key engine in Lemma 18.*

For a concrete mental model, one may keep in mind the canonical example $V = [0, 1]^2$ with componentwise order and a componentwise multiplicative $\otimes$, though the lemmas below intentionally avoid committing to that special case.

Two further interpretive points will help when reading the proofs that follow. First, in the canonical picture $V = [0, 1]^2$, the multiplication-like behavior of $\otimes$ makes $\mathrm{Dist}_c(x, y)$ act like an "AND"-style aggregator: both directions $x \to y$ and $y \to x$ must carry substantial positive evidence in order for $\mathrm{Dist}_c(x, y)^+$ to be large. This is why the crisp predicate $x \#_c y$ is naturally phrased in terms of Dist_c rather than Diff_c: it encodes the idea that a distinction is not merely a one-way detectability but a mutual separation.

Second, the preorder on abstractions (Def. 51) is best read as "q_2 is at least as coarse as q_1". Indeed, if $q_2 = r \circ q_1$, then any two points identified by q_1 are necessarily identified by q_2 after applying r, so q_2 forgets at least as much as q_1. Several helper lemmas later on implicitly use this coarsening intuition when relating repetition/variety properties across different quotients of the same underlying X_c.

Finally, the notion of non-dual compatibility for translations (Def. 53) can be viewed as a minimal invariance requirement: a translation T is allowed to change intensities, reorder elements, or even merge weakly distinguished items, but it should not collapse pairs that were already separated by strong positive evidence at the δ-level. In that sense, Lemma 18 will function as a "functoriality" statement for the geometry induced by δ_c, ensuring that the basic combinatorics of strong distinctions survive passage between contexts whenever T is intended to respect phenomenological structure.

28.1 Difference, distinction, repetition, variety, and non-duality

Remark 1559. *These first lemmas are "sanity checks" in the best sense: they verify that the formal primitives behave as their names suggest. The theme is that while δ_c is directed (so difference can be asymmetric), the derived quantity Dist_c is engineered to be symmetric by combining both directions. This separation mirrors a philosophical caution: one may experience x as differing-from y in a way that is not reciprocated, yet the* mutual *relation of distinction ought to reflect a bilateral comparison. In the background, the thresholds (e.g. τ_δ and τ_ι) serve as explicit "decision levels" that turn graded, possibly multi-channel evidence into crisp assertions; the lemmas below confirm that these decision levels interact with the primitives in the intended minimal ways.*

Lemma 6 (Symmetry of mutual distinction)**.** *For all $x, y \in X_c$, $\mathrm{Dist}_c(x, y) = \mathrm{Dist}_c(y, x)$. Hence the induced crisp relation $\#_c$ is symmetric.*

Remark 1560. *Intuitively, the lemma says: even if "x points away from y" differs in strength from "y points away from x," once we define* mutual *distinction by multiplying the two directed evidences, the order of the two factors no longer matters. This is important because $\#_c$ is used as a crisp proxy for "the context actually makes a distinction here": crisp distinctions should not depend on which element is named first. A related point is that this symmetry is achieved without requiring δ_c itself to be symmetric; instead, it is the* construction *of Dist_c that enforces reciprocity at the level where later relational predicates will operate.*

Sketch. By definition, $\mathrm{Dist}_c(x, y) = \delta_c(x, y) \otimes \delta_c(y, x)$. Since $\otimes$ is commutative, this equals $\delta_c(y, x) \otimes \delta_c(x, y) = \mathrm{Dist}_c(y, x)$. For crisp symmetry: $\mathrm{Dist}_c(x, y)^+ = \mathrm{Dist}_c(y, x)^+$, so $\mathrm{Dist}_c(x, y)^+ \geq \tau_\delta$ iff $\mathrm{Dist}_c(y, x)^+ \geq \tau_\delta$. ☐

Remark 1561. Proof sketch and intuition. *The strategy is to unfold the definition of Dist_c and use only one algebraic axiom: commutativity of $\otimes$. Geometrically (in the heuristic $[0, 1]^2$ picture), one can imagine $\delta_c(x, y)$ and $\delta_c(y, x)$ as two "directed arrows" with lengths in each evidence channel; taking $\otimes$ is a way of insisting that mutual distinction is strong only when both arrows support it. Swapping the endpoints swaps the arrows, but the combined strength stays the same. From the standpoint of later constructions, this is also what makes $\#_c$ a well-behaved undirected edge relation on X_c: it can be used to define graphs, neighborhoods, and partitions without having to keep track of an orientation that would otherwise be arbitrary at the level of crisp distinguishability.*

Lemma 7 (Repetition/variety imply a made distinction)**.** *For all $x \neq y$:*

$$\mathrm{Rep}_c(x, y) \;\to\; x \#_c y, \qquad \mathrm{Var}_c(x, y) \;\to\; x \#_c y.$$

Remark 1562. *This lemma expresses a design constraint baked into the definitions:* repetition *and* variety *are only meaningful when there is at least some robust distinction being made between*

x and y in the first place. Said differently: the ontology does not allow "repetition" to collapse into mere identity, nor "variety" into unstructured difference; both are modes of relation under distinction*. This will matter later when non-duality is allowed to create simultaneous support for seemingly opposing relational predicates. One can also read the condition $x \neq y$ as a guardrail against trivial self-comparisons: even if a formal system could assign nonzero directed difference to (x, x) in degenerate cases, the intended phenomenological reading treats repetition/variety as relations between two items presented as distinct positions in experience.*

Sketch. Both $\mathrm{Rep}_c(x, y)$ and $\mathrm{Var}_c(x, y)$ include the conjunct $\mathrm{Dist}_c(x, y)^+ \geq \tau_\delta$ by definition; that conjunct is exactly $x \#_c y$. □

Remark 1563. Proof sketch and intuition. *The proof is purely definitional: it observes that $\#_c$ is literally a named subcondition of* Rep_c *and* Var_c*. The conceptual picture is that repetition/variety are "decorations" on top of a basal fact of distinguishability: without the basal fact, the decoration is not even syntactically permitted. This definitional dependence is intentional: it ensures that later arguments can freely use $x \#_c y$ whenever either* $\mathrm{Rep}_c(x, y)$ *or* $\mathrm{Var}_c(x, y)$ *is assumed, without separately re-checking a distinction threshold.*

Lemma 8 (Non-dual variety yields simultaneous repetition and variety under distinction)**.** *If $x \neq y$ and* $\mathrm{NDVar}_c(x, y)$ *and* $\mathrm{Dist}_c(x, y)^+ \geq \tau_\delta$*, then* $\mathrm{Rep}_c(x, y)$ *and* $\mathrm{Var}_c(x, y)$ *both hold.*

Remark 1564. *This lemma makes precise a subtle but central phenomenological possibility: a pair (x, y) can be unmistakably distinguished and yet also carry strong evidence for both "repetition" and "variety." In ordinary classical logic, one is tempted to treat these as mutually exclusive labels; the present framework refuses that temptation by allowing a controlled, thresholded form of co-presence. One may read* $\mathrm{NDVar}_c(x, y)$ *as asserting that the indistinction signal $\iota_c(x, y)$ is* bi-valent*: it is simultaneously high in the positive and negative evidence channels, and therefore can support both readings when combined with a baseline distinction. In particular, the lemma emphasizes that non-dual variety does not erase distinction: the hypothesis explicitly retains* $\mathrm{Dist}_c(x, y)^+ \geq \tau_\delta$*, so the "both at once" reading is not a collapse into undifferentiated identity, but rather an instance of jointly sustained, potentially tension-bearing relational structure.*

Sketch. $\mathrm{NDVar}_c(x, y)$ means $\iota_c(x, y)^+ \geq \tau_\iota$ and $\iota_c(x, y)^- \geq \tau_\iota$. Together with $\mathrm{Dist}_c(x, y)^+ \geq \tau_\delta$, these are exactly the defining conjuncts of both $\mathrm{Rep}_c(x, y)$ (uses ι^+) and $\mathrm{Var}_c(x, y)$ (uses ι^-). □

Remark 1565. Proof sketch and intuition. *Again the proof proceeds by unpacking conjunctive definitions. The key step is noticing that* Rep_c *and* Var_c *differ only in which channel of ι_c they consult. Thus, when* NDVar_c *asserts that* both *channels are above threshold, it automatically supplies the missing half needed for each predicate. A useful mental image is a two-axis meter for ι: the point lies in the "upper-right quadrant," so both one-sided tests pass. One may also view this as a formal version of a familiar experiential report: two moments can be clearly told apart (high* Dist_c^+*) while still being "the same again" in one respect (captured by ι^+ crossing threshold) and "genuinely different" in another respect (captured by ι^- crossing threshold), with the framework explicitly allowing these to be simultaneously licensed rather than forcing a premature choice.*

Lemma 9 (Consistency condition makes repetition and variety disjoint)**.** *Assume $x \neq y$ and* $\neg\mathrm{NDVar}_c(x, y)$*. Then* $\neg(\mathrm{Rep}_c(x, y) \wedge \mathrm{Var}_c(x, y))$*.*

Remark 1566. *This lemma articulates the complementary regime to Lemma 8: if non-dual variety is* not *present, then the framework behaves more like a classical either/or with respect to the pair of predicates* Rep_c *and* Var_c*. Formally,* $\neg\mathrm{NDVar}_c(x, y)$ *means that it is* not *the case that both* *evidence channels of $\iota_c(x, y)$ simultaneously clear the threshold τ_ι. Consequently, one cannot meet the definitional requirements for repetition (which needs $\iota_c(x, y)^+ \geq \tau_\iota$) and for variety (which needs $\iota_c(x, y)^- \geq \tau_\iota$) at the same time. The role of $x \neq y$ is again to keep the statement aligned with the intended domain of application of these predicates.*

Sketch. Assume for contradiction that $\mathrm{Rep}_c(x, y) \wedge \mathrm{Var}_c(x, y)$ holds. Unpacking definitions, $\mathrm{Rep}_c(x, y)$ supplies $\iota_c(x, y)^+ \geq \tau_\iota$ (and the shared distinction conjunct), while $\mathrm{Var}_c(x, y)$ supplies $\iota_c(x, y)^- \geq \tau_\iota$ (and the shared distinction conjunct). Therefore both $\iota_c(x, y)^+ \geq \tau_\iota$ and $\iota_c(x, y)^- \geq \tau_\iota$ hold, i.e. $\mathrm{NDVar}_c(x, y)$ holds, contradicting the assumption $\neg\mathrm{NDVar}_c(x, y)$. Hence $\neg(\mathrm{Rep}_c(x, y) \wedge \mathrm{Var}_c(x, y))$. □

Remark 1567. Proof sketch and intuition. *The argument is a straightforward contrapositive-style use of the definitions: if both repetition and variety were simultaneously true, then the positive and negative channels of ι_c would both have to be above threshold, which is precisely what* NDVar_c *asserts. Thus* $\neg\mathrm{NDVar}_c$ *functions as a* consistency constraint *preventing the co-presence of the two predicates. Conceptually, the lemma clarifies that non-duality is not an automatic background feature of the system; rather, it is an explicit, checkable condition. When it fails, the framework reverts to a more exclusive reading in which the same pair cannot be certified as both "repetition" and "variety" at once.*

Remark 1568. *Where Lemma 8 shows how coexistence is possible, the present lemma shows how coexistence is* controlled. *If* $\mathrm{NDVar}_c(x, y)$ *fails, then at least one of the two evidence channels of* $\iota_c(x, y)$ *is not strong enough, and therefore the theory prevents both* Rep_c *and* Var_c *from holding simultaneously. In this way, the system distinguishes (i) genuine non-dual superposition (both channels strong) from (ii) ordinary situations where one channel dominates. In particular, the control mechanism is not a separate axiom but is enforced by the same thresholding convention used throughout: "coexistence" is permitted only when* each *requisite inequality clears the stipulated bar (here τ_ι), so a single weak channel is sufficient to block the simultaneous attribution. This provides an operational reading of "dominance": it is precisely the regime in which only one of $\iota_c(x, y)^+$ and $\iota_c(x, y)^-$ is above threshold, so the model records an asymmetric evidential profile rather than a balanced one.*

Sketch. If $\mathrm{Rep}_c(x, y) \wedge \mathrm{Var}_c(x, y)$ held, then by definitions we would have $\iota_c(x, y)^+ \geq \tau_\iota$ and $\iota_c(x, y)^- \geq \tau_\iota$, which is exactly $\mathrm{NDVar}_c(x, y)$, contradicting the assumption. Equivalently, one can view the argument as unpacking the conjunctive structure of the predicates: the conjunction $\mathrm{Rep}_c(x, y) \wedge \mathrm{Var}_c(x, y)$ forces *both* of the requisite lower bounds on the two coordinates of $\iota_c(x, y)$, and that joint lower-boundedness is precisely the definitional content of $\mathrm{NDVar}_c(x, y)$. □

Remark 1569. Proof sketch and intuition. *This is a standard contrapositive pattern: assume both predicates hold and derive the defining condition for* NDVar_c. *Conceptually, it says that the only route to "both repetition and variety" is the explicitly named non-dual-variety regime. Thus paraconsistency is not an ambient fog; it is localized and testable via thresholds. A further conceptual payoff is that the lemma makes the interaction between predicates diagnostically reversible: if an application ever yields credible evidence for both* Rep_c *and* Var_c*, then the framework commits you to the stronger claim that both evidence channels of ι_c are simultaneously high, rather than allowing an unprincipled mixture of partial conditions. This is exactly the sense in which the coexistence is "controlled": the model does not merely tolerate tension, it specifies the unique evidential pattern under which tension is licensed.*

Lemma 10 (Non-duality entails paraconsistent distinctness, but does not force equality). *If* $\mathrm{NonDual}_c(x, y)$ *then* $\mathrm{Dist}_c(x, y)^+ \geq \tau_\delta$ *and* $\mathrm{Dist}_c(x, y)^- \geq \tau_\delta$ *simultaneously (hence* $x \#_c y$*), i.e. the system carries strong evidence for and against the distinction. Moreover, the conclusion is explicitly two-sided: it asserts the co-presence of high positive and high negative evidence about the same distinction claim, not an averaged or reconciled value. In particular, the lemma is compatible with* x *and* y *remaining syntactically separate items in the language and, semantically, with later updates that may lower one channel without forcing any retroactive identification.*

Remark 1570. *This lemma states, in a deliberately careful way, what non-duality is* not. *It is not the collapse of two items into literal identity; it is the simultaneous presence of strong evidence on both sides of a distinction. In paraconsistent terms, the distinction is both supported and opposed at the evidence level; classical explosion is avoided because we do not equate "evidence for* $x = y$*" with the syntactic rewrite rule "replace* x *by* y*" (compare the motivations for paraconsistent semantics in [23] and the resonance-oriented perspective in [24]). Stated differently, the framework treats "distinctness" as a graded, two-channel report rather than as a classical bivalent predicate:* $\mathrm{Dist}_c(x, y)^+$ *and* $\mathrm{Dist}_c(x, y)^-$ *are tracked independently, and non-duality corresponds to both being large enough to pass* τ_δ*. The notation* $x \#_c y$ *is therefore best read as "paraconsistently distinguished in context* c*" rather than as a commitment to either* $x \neq y$ *or* $x = y$ *in the classical sense, and the lemma highlights that this is a stable middle position rather than a temporary inconsistency to be immediately resolved.*

Sketch. Immediate from the defining conjuncts of $\mathrm{NonDual}_c(x, y)$. The extra point for implementation is that this is evidence-level paraconsistency, not syntactic equality: one should not rewrite $x = y$ from $\mathrm{NonDual}_c(x, y)$. Concretely, if $\mathrm{NonDual}_c(x, y)$ is defined by the conjunction of the two threshold conditions on $\mathrm{Dist}_c(x, y)^+$ and $\mathrm{Dist}_c(x, y)^-$ (possibly together with auxiliary side conditions such as $x \neq y$), then the conclusion follows by direct projection onto those conjuncts, without any additional inference principles. □

Remark 1571. Proof sketch and intuition. *Formally, nothing more is happening than reading off the conjuncts in the definition of* $\mathrm{NonDual}_c$*. The interpretive force lies in the last sentence: the algebra remembers two channels of evidence, so it can represent the felt "both/and" without collapsing the computational universe by identification. A helpful visual is to imagine two dials, one for* Dist^+ *and one for* Dist^-*; non-duality means both dials are high, not that the two entities have been merged. One can also read the lemma as a guardrail on downstream reasoning: any subsequent rule that requires a* univocal *distinction should check for a one-sided condition (e.g. only* Dist^+ *being high, or only* Dist^- *being low), whereas rules that are explicitly designed for non-dual regimes may safely assume the simultaneous high-high configuration. In this way the lemma clarifies which inferences are legitimate in a non-dual context and why the framework refrains from identifying items even when the phenomenology suggests a strong "togetherness".*

Lemma 11 (Threshold monotonicity of the primitive predicates). *Let* $\tau'_\delta \leq \tau_\delta$ *and* $\tau'_\iota \leq \tau_\iota$*. Then for all* $x \neq y$*,*

$$\mathrm{Rep}_c^{(\tau_\delta, \tau_\iota)}(x, y) \to \mathrm{Rep}_c^{(\tau'_\delta, \tau'_\iota)}(x, y),$$

and similarly for Var_c*,* $\mathrm{NonDual}_c$*,* NDVar_c*. In other words, the parameterization by thresholds is monotone in the expected direction: weakening the acceptance criteria (by lowering thresholds) can only expand, never shrink, the extension of each predicate. The restriction* $x \neq y$ *ensures that the claim is about the intended "two-item" use of these predicates, and prevents any degenerate boundary case for which the predicates might have special conventions when* $x = y$*.*

Remark 1572. *This lemma confirms that thresholds behave the way one expects: lowering the bar cannot invalidate a previously valid claim. It is not deep, but it is structurally important because it lets one compare contexts or agents that choose different strictness levels. In particular, any later theorem that is proved at stringent thresholds automatically holds (in the same direction) for more permissive thresholds, which is often the right notion of robustness for phenomenological predicates. A common use is "calibration transfer": if one analyst uses conservative settings* $(\tau_\delta, \tau_\iota)$ *and another uses more permissive settings* $(\tau'_\delta, \tau'_\iota)$*, then any instance certified by the conservative analyst is automatically certified by the permissive one. The lemma thus supports principled comparisons across experimental regimes, interpretive stances, or modeling choices without requiring any further assumptions about the underlying evidence values beyond their order structure.*

Sketch. All four predicates are conjunctions of lower bounds of the form $u \geq \tau$. If a value exceeds a larger threshold, it exceeds any smaller threshold. More explicitly, suppose $\mathrm{Rep}_c^{(\tau_\delta,\tau_\iota)}(x, y)$ holds. Unpacking its definition yields a finite list of inequalities, each of which compares some evidence coordinate (e.g. a component of Dist_c or ι_c) to either τ_δ or τ_ι. Replacing τ_δ by the smaller τ'_δ and τ_ι by the smaller τ'_ι preserves truth of each inequality, hence of their conjunction, giving $\mathrm{Rep}_c^{(\tau'_\delta,\tau'_\iota)}(x, y)$. The other predicates follow identically. ☐

Remark 1573. Proof sketch and intuition. *The argument uses only the transitivity of* $\geq$ *on* $[0, 1]$ *(or whatever ordered set the components live in). The key step is recognizing that each predicate is assembled from statements of the form "some evidence coordinate is at least a threshold," so monotonicity in thresholds is inherited componentwise. It is worth noting that no continuity, additivity, or probabilistic interpretation is required: the lemma is purely order-theoretic. Consequently, it remains valid under many possible implementations of evidence coordinates (e.g. scores, normalized measures, or bounded utilities), provided only that the comparison relation is a partial or total order with the usual transitivity property.*

28.2 Presentational immediacy: focus and fringe

Remark 1574. *We now move from relational predicates to an internal scalar field* $I_c : X_c \to [0, 1]$ *encoding* intensity *in a context. The induced sets* $\mathrm{Focus}_c(\tau_I)$ *and* $\mathrm{Fringe}_c(\tau_I)$ *formalize a simple attentional phenomenology: some items are in the bright center of awareness, others are faintly present at the periphery. This connects directly to* Presentational Immediacy *(Hyperseed-Concept 138) and* Attention / Attentional Focus *(Hyperseed-Concept 60).*

Remark 1575. *The only structure assumed here is that each context c comes with a carrier set* X_c *and a numerical intensity assignment* I_c*. In particular, no topology, metric, similarity relation, or ordering on* X_c *is required in order to state (and later reuse) the basic focus/fringe facts. All comparisons are pushed into the codomain* $[0, 1]$*, so the subsequent lemmas are essentially consequences of elementary order properties of real numbers.*

Remark 1576. *The threshold parameter* τ_I *should be read as a* convention for discretizing *a graded phenomenon. Different choices of* τ_I *correspond to different attentional "grain sizes": low thresholds treat many items as focused, while high thresholds reserve focus for only the most intense items. This explicit dependence on* τ_I *is useful later when one wants to model shifts of attention without changing the underlying intensity field* I_c *itself.*

Lemma 12 (Focus/fringe are disjoint)**.** $\mathrm{Focus}_c(\tau_I) \cap \mathrm{Fringe}_c(\tau_I) = \emptyset$.

Remark 1577. *The lemma says there is no ambiguous "half-in, half-out" element: at a fixed threshold τ_I, an item cannot be both above threshold (focus) and strictly below it while still positive (fringe). This is important because later constructions may treat focus and fringe as distinct computational roles (e.g. a focus-like set receiving expensive processing while the fringe is handled heuristically).*

Remark 1578. *Note also that the disjointness hinges on the* asymmetric boundary convention*: focus is defined using $\geq \tau_I$ while fringe uses $< \tau_I$ (together with > 0). Thus an item with $I_c(x) = \tau_I$ is classified as focused rather than fringed, which matches the idea that "meeting the criterion" counts as being in the attended set. Other conventions (e.g. making both sets closed or both open at τ_I) would require separate handling of the boundary case and can introduce unwanted ambiguity.*

Sketch. If x were in both, we would have $I_c(x) \geq \tau_I$ and $0 < I_c(x) < \tau_I$, contradiction. ☐

Remark 1579. Proof sketch and intuition. *The proof is a direct contradiction: it combines the defining inequalities for membership in each set. Visually, if one plots $I_c(x)$ on the unit interval,* Focus *is the right-closed ray $[\tau_I, 1]$ while* Fringe *is the open interval $(0, \tau_I)$; these do not overlap.*

Remark 1580. *An additional way to see the same point is to observe that, for each fixed τ_I, the predicates*

$$x \in \mathrm{Focus}_c(\tau_I) \iff I_c(x) \in [\tau_I, 1], \qquad x \in \mathrm{Fringe}_c(\tau_I) \iff I_c(x) \in (0, \tau_I)$$

pull back two disjoint subsets of $[0,1]$ along the function I_c. No properties of I_c beyond being single-valued are needed for this pullback-disjointness argument.

Lemma 13 (Focus/fringe partition the positive-intensity region)**.** *Let $P_c := \{x \in X_c : I_c(x) > 0\}$. Then $P_c = \mathrm{Focus}_c(\tau_I) \,\dot\cup\, \mathrm{Fringe}_c(\tau_I)$ (disjoint union).*

Remark 1581. *This lemma states that, among whatever is present at all (positive intensity), the threshold τ_I induces an exhaustive dichotomy: everything present is either salient enough to be in focus or weakly present enough to be in fringe. The restriction to P_c matters: elements with $I_c(x) = 0$ are treated as absent rather than as "infinitely fringe."*

Remark 1582. *Operationally, one can read P_c as the set of "currently activated" or "presented" items, with focus and fringe giving a two-tier stratification of that active set. This avoids forcing a trichotomy in which $I_c(x) = 0$ would have to be assigned to one of the two attentional tiers; instead, $I_c(x) = 0$ is reserved for non-presentation. In many applications, this makes later aggregation steps cleaner: sums, averages, or normalizations over "present" items can be taken over P_c without inadvertently counting absences.*

Sketch. If $I_c(x) > 0$ then either $I_c(x) \geq \tau_I$ (so $x \in$ Focus) or $I_c(x) < \tau_I$ (so $x \in$ Fringe). Disjointness is Lemma 12. ☐

Remark 1583. Proof sketch and intuition. *The proof is a case split on whether a real number is at least τ_I or below it. One can think of τ_I as a moving "attentional horizon": everything above the horizon is foreground, everything below (but not zero) is background.*

Remark 1584. *At the extremes, the statement behaves as expected (when the definitions are instantiated): if $\tau_I = 0$, then* $\mathrm{Focus}_c(\tau_I)$ *coincides with P_c and* $\mathrm{Fringe}_c(\tau_I)$ *is empty, corresponding to an "everything present is focused" idealization. If $\tau_I = 1$, then* $\mathrm{Focus}_c(\tau_I)$ *consists precisely of items at maximal intensity (those with $I_c(x) = 1$), and all other present items lie in the fringe. These boundary cases can be useful as sanity checks when calibrating τ_I in examples.*

Lemma 14 (Monotonicity in the focus threshold). *If $\tau_1 \leq \tau_2$ then*

$$\mathrm{Focus}_c(\tau_2) \subseteq \mathrm{Focus}_c(\tau_1), \qquad \mathrm{Fringe}_c(\tau_1) \subseteq \mathrm{Fringe}_c(\tau_2).$$

Remark 1585. *Raising the focus threshold makes focus smaller (harder to qualify) and fringe larger (easier to qualify), exactly as one would expect. This monotonicity is useful when comparing different "modes" of the same agent or different agents: an agent with a stricter focus criterion is literally focusing on fewer items, in the precise sense of set inclusion.*

Remark 1586. *Formally, Lemma 14 says that the assignment $\tau \mapsto \mathrm{Focus}_c(\tau)$ is* antitone *(order-reversing) in τ, while $\tau \mapsto \mathrm{Fringe}_c(\tau)$ is* monotone *(order-preserving). Thus, as τ varies, the focus sets form a nested family (a decreasing "filtration" by thresholds), and the fringe sets form a nested family in the opposite direction. This nestedness is often what one needs when proving stability statements under changes of attentional resolution.*

Sketch. If $I_c(x) \geq \tau_2$ and $\tau_1 \leq \tau_2$ then $I_c(x) \geq \tau_1$. If $0 < I_c(x) < \tau_1$ and $\tau_1 \leq \tau_2$ then $0 < I_c(x) < \tau_2$. □

Remark 1587. Proof sketch and intuition. *The argument is again order-theoretic on* $[0, 1]$. *On a number line, moving the threshold right shrinks the $\geq$-region and expands the $<$-region; the inclusions are just that picture translated into set language.*

Remark 1588. *In applications, one sometimes varies τ_I dynamically (e.g. to model fatigue, time pressure, or deliberate concentration). Lemma 14 then provides immediate "directional" guarantees: any item that remains focused under a stricter threshold must also have been focused before the shift, and any item that was in the fringe under a looser threshold will remain in the fringe when the criterion is tightened. These implications can be used to justify reusing previously computed information for items that are guaranteed not to have changed attentional tier.*

28.3 Abstraction and concreteness

Remark 1589. *Abstraction here is treated as a controlled* forgetting*: a surjection $q : X_c \twoheadrightarrow A$ partitions X_c into fibers, and elements in the same fiber are "identified" at the abstract level. The preorder $q_1 \preceq q_2$ says: q_2 is at least as abstract as q_1 (it can be obtained by further collapsing the outputs of q_1). This is a standard idea in mathematics (factorization through quotients), but in Hyperseed it is also a disciplined way of discussing* Abstract *vs.* Concrete *(Hyperseed-Concepts 51 and 83) within a fixed context (Hyperseed-Concept 86).*

Remark 1590. *It is sometimes helpful to keep in mind the quotient-set picture: a surjection $q : X_c \twoheadrightarrow A$ is (up to bijection of codomains) the same data as an equivalence relation $\sim$ on X_c, where $x \sim y$ iff $q(x) = q(y)$, together with a choice of* names *for the equivalence classes. From this viewpoint, "controlled forgetting" means replacing X_c by the set of its $\sim$-classes, and the order relation $\preceq$ compares how much information is retained by comparing the induced partitions.*

Lemma 15 (The abstraction preorder is a preorder). *The relation $\preceq$ on abstractions $q : X_c \twoheadrightarrow A$ is reflexive and transitive.*

Remark 1591. *The point is modest but foundational: we can reason about "more abstract than" in the usual order-theoretic way, without worrying that the relation fails basic coherence conditions. Once this is established, one may meaningfully talk about chains of abstractions, maximal elements under admissibility constraints, and so on.*

Remark 1592. *Note that a preorder need not be antisymmetric: it can happen that $q_1 \preceq q_2$ and $q_2 \preceq q_1$ without $q_1 = q_2$ as functions, for example when q_1 and q_2 induce the same partition of X_c but use different codomains or different labels for the same fibers. Thus, the correct "equality notion" implicit in $\preceq$ is often equality of induced equivalence relations (or isomorphism of quotients) rather than literal equality of maps.*

Sketch. Reflexive: $q = \mathrm{id}_A \circ q$. Transitive: if $q_2 = r_{12} \circ q_1$ and $q_3 = r_{23} \circ q_2$, then $q_3 = (r_{23} \circ r_{12}) \circ q_1$. □

Remark 1593. Proof sketch and intuition. *Reflexivity uses the trivial observation that composing with an identity changes nothing. Transitivity uses associativity of function composition: if q_1 factors to q_2 and q_2 factors to q_3, then q_1 factors directly to q_3. In terms of partitions, refining (collapsing) and then refining again is the same as refining once by the composite collapse.*

Lemma 16 (Factorization iff inclusion of induced equivalence relations)**.** *Let $q_i : X_c \twoheadrightarrow A_i$ and define $x \sim_{q_i} y \iff q_i(x) = q_i(y)$. Then*

$$q_1 \preceq q_2 \quad \iff \quad (\sim_{q_1} \subseteq \sim_{q_2}).$$

Equivalently: $q_1 \preceq q_2$ iff for all x, y, $q_1(x) = q_1(y) \to q_2(x) = q_2(y)$.

Remark 1594. *This lemma gives an extremely useful reformulation: instead of explicitly producing a map r with $q_2 = r \circ q_1$, we can check an inclusion between the equivalence relations (partitions) induced by q_1 and q_2. Intuitively, "q_2 is coarser" means: whenever q_1 fails to distinguish two points (puts them in the same fiber), q_2 must also fail to distinguish them. Thus, the lemma translates a statement about existence of a factor map into a purely relational statement about fibers.*

Remark 1595. *Two small technical clarifications are often useful when applying Lemma 16. First, surjectivity of q_1 is exactly what guarantees that the definition of $r : A_1 \to A_2$ by "pick an x with $q_1(x) = a$" is total. Second, the factor map r is then forced (and hence unique) by the requirement $q_2 = r \circ q_1$: for each $a \in A_1$, $r(a)$ must be the common value of q_2 on the fiber $q_1^{-1}(a)$ (well-definedness is the only real issue).*

Sketch. ($\to$) If $q_2 = r \circ q_1$ and $q_1(x) = q_1(y)$ then $q_2(x) = r(q_1(x)) = r(q_1(y)) = q_2(y)$. ($\Leftarrow$) Assume q_2 is constant on fibers of q_1. Define $r : A_1 \to A_2$ by choosing any x with $q_1(x) = a$ (exists since q_1 is surjective) and setting $r(a) := q_2(x)$. Well-definedness follows from the fiber-constancy assumption. Then $q_2 = r \circ q_1$. □

Remark 1596. Proof sketch and intuition. *The forward direction is immediate: composing with r cannot split a fiber that q_1 has already collapsed. The reverse direction is the more instructive step: if q_2 does not distinguish within any fiber of q_1, then each fiber-label $a \in A_1$ can be sent to the common value of q_2 on that fiber, producing the required r. The only delicate point is well-definedness, and it is secured precisely by the assumption that q_2 is constant on fibers.*

Corollary 4 (Fiber inclusion along $\preceq$)**.** *If $q_1 \preceq q_2$, then for all $x \in X_c$,*

$$q_1^{-1}(q_1(x)) \ \subseteq \ q_2^{-1}(q_2(x)).$$

Remark 1597. *This corollary states the same "coarsening" idea at the level of individual fibers: the equivalence class of x under the finer abstraction is contained in the equivalence class of x under the coarser abstraction. This is often the most directly used form in arguments about concreteness constraints, because many such constraints are phrased in terms of fiber sizes.*

Remark 1598. *In particular, whenever a size notion is monotone under inclusion (e.g. cardinality, measure, diameter bounds stated as "at most", or any predicate* Small *that is downward closed as in Lemma 17), Corollary 4 immediately transports such statements from a coarser fiber to a finer one, and contrapositively transports "not small" statements from a finer fiber to a coarser one. This is the basic mechanism behind many "abstractness persists under further abstraction" arguments.*

Sketch. If $y \in q_1^{-1}(q_1(x))$, then $q_1(y) = q_1(x)$. By Lemma 16, this implies $q_2(y) = q_2(x)$, hence $y \in q_2^{-1}(q_2(x))$. $\square$

Remark 1599. Proof sketch and intuition. *Pick any point y identified with x by q_1. Since q_2 is coarser, it must also identify y with x. In partition language: every block of the fine partition sits inside a block of the coarse partition.*

Lemma 17 (Abstractness propagates to coarser admissible abstractions (mild assumption))**.** *Fix a concreteness constraint K_c and a predicate* $\mathrm{Small}(\cdot)$ *on subsets of X_c. Assume* Small *is downward closed: $A \subseteq B$ and* $\mathrm{Small}(B)$ *implies* $\mathrm{Small}(A)$*. Let $x \in X_c$ be abstract in the sense of Def. 52, witnessed by some K_c-admissible q_1 such that $\neg\mathrm{Small}(q_1^{-1}(q_1(x)))$. If $q_1 \preceq q_2$ and q_2 is also K_c-admissible, then x is also witnessed abstract by q_2.*

Remark 1600. *The "mild assumption" is the downward-closure of* Small*, which is exactly the property needed to ensure that "not small" is upward closed with respect to inclusion: if $A \subseteq B$ and A is not small, then B cannot be small. This matches the intended reading in typical cases: for instance, if* $\mathrm{Small}(S)$ *means "S has at most N elements" or "S has diameter at most ε", then any superset of a non-small set remains non-small.*

Sketch. By Corollary 4, from $q_1 \preceq q_2$ we have

$$q_1^{-1}(q_1(x)) \subseteq q_2^{-1}(q_2(x)).$$

Suppose for contradiction that $\mathrm{Small}(q_2^{-1}(q_2(x)))$ holds. Since Small is downward closed, the inclusion would imply $\mathrm{Small}(q_1^{-1}(q_1(x)))$, contradicting the witnessing condition $\neg\mathrm{Small}(q_1^{-1}(q_1(x)))$. Hence $\neg\mathrm{Small}(q_2^{-1}(q_2(x)))$. Together with the assumed K_c-admissibility of q_2, this makes q_2 a valid witness (in the sense of Def. 52) that x is abstract. $\square$

Remark 1601. Proof sketch and intuition. *Coarsening an abstraction can only make fibers larger (never smaller), so any "largeness" phenomenon exhibited by the q_1-fiber of x persists for the corresponding q_2-fiber. The admissibility hypotheses are logically separate: they ensure that both q_1 and q_2 are permitted abstractions under the same concreteness constraint K_c, so that the witness can legitimately be replaced by the coarser abstraction without leaving the intended model class.*

Remark 1602. *The content is: if an element is already "too coarse" (its fiber is not small) under some admissible abstraction, then making the abstraction even coarser cannot restore concreteness. This matches an intuitive irreversibility: once you have thrown away distinctions, you cannot recover them by throwing away even more. The only extra hypothesis is a weak regularity condition on what counts as "small": downward closure says that if a big set is small (which is unusual), then all its subsets are small; contrapositively, if a subset is not small then no superset can be small. This is exactly what the proof uses. Equivalently, the statement can be read as a monotonicity principle: "being abstract" is upward closed along coarsenings of the abstraction, because coarsening only ever enlarges the equivalence class of x (its fiber), and enlarging a set cannot turn a non-small set into a small one when smallness is downward closed. In this sense, the remark isolates the precise point where regularity of the size predicate enters: nothing about cardinality is needed, only the order-theoretic behavior of the predicate* $\mathrm{Small}(\cdot)$ *with respect to $\subseteq$.*

Sketch. By Corollary 4, $q_1^{-1}(q_1(x)) \subseteq q_2^{-1}(q_2(x))$. If $\mathrm{Small}(q_2^{-1}(q_2(x)))$ held, downward closure would imply $\mathrm{Small}(q_1^{-1}(q_1(x)))$, contradicting the witness. So $\neg\mathrm{Small}(q_2^{-1}(q_2(x)))$; hence q_2 also witnesses abstractness of x. In slightly more explicit contrapositive form: since $q_1^{-1}(q_1(x))$ is *not* small and is contained in $q_2^{-1}(q_2(x))$, the closure condition forces $q_2^{-1}(q_2(x))$ to be not small as well, because otherwise the smaller set would inherit smallness. The admissibility condition is used only to ensure that q_2 is among the abstractions one is allowed to consider as potential witnesses. □

Remark 1603. Proof sketch and intuition. *The proof is a simple order argument on sets. Step (1) uses the previously proved fiber inclusion: coarsening enlarges fibers. Step (2) uses downward closure in contrapositive form: "not small" propagates upward to supersets. Thus, the witness of abstractness persists along $\preceq$ so long as admissibility (K_c) is preserved. One can also view this as a stability property of counterexamples: once x has a fiber that is "too large to be concrete" under some q_1, any q_2 that forgets at least as much as q_1 must produce a fiber that contains that same counterexample, hence cannot pass the smallness test. This makes precise the informal slogan that loss of distinctions is one-way: refinement may restore concreteness, but coarsening cannot.*

28.4 Non-duality as a bridge between perspectives (context translations)

Remark 1604. *A context translation $T : X_c \to X_d$ formalizes the act of viewing the "same" situation through a different lens. The compatibility condition is deliberately phrased negatively: it forbids erasing strong distinctions. In cognitive terms, this is a minimal requirement for* transfer*: if a salient distinction in one context becomes invisible in the translated context, then predicates like repetition/variety/non-duality will not be stably comparable across perspectives. This resonates with the general transfer-learning motivation of Hyperseed (Hyperseed-Concepts 192 and 193) and the associated mathematical program (see [7] for broader context). At the level of interpretation, this means T is not required to preserve* all *structure (it may merge some states, rename features, or otherwise reinterpret them), but it is required to preserve whatever the theory treats as evidence of distinction. The point of stating the condition in terms of δ-inequalities is that it directly controls the quantities that feed into later definitions (e.g. mutual distinction, crisp thresholds, and the paraconsistent pairing that underlies non-duality), rather than imposing an external notion of similarity.*

Lemma 18 (Non-dually compatible translations preserve distinction evidence)**.** *Let $T : X_c \to X_d$ be non-dually compatible (Def. 53). Then for all $x, y \in X_c$,*

$$\mathrm{Dist}_c(x, y) \;\leq\; \mathrm{Dist}_d(Tx, Ty).$$

In particular, if $x \#_c y$ then $Tx \#_d Ty$ (using the same τ_δ). Moreover, $\mathrm{NonDual}_c(x, y)$ *implies* $\mathrm{NonDual}_d(Tx, Ty)$*. In other words, T is monotone with respect to the derived evidence ordering on mutual distinction: it cannot reduce the "two-way" support for distinguishing x from y. The threshold clause emphasizes that the result is not merely qualitative: it preserves whatever fixed operational cutoff τ_δ is used to declare a distinction to be crisp in the source context.*

Remark 1605. *In plain language: a non-dually compatible translation cannot make two things* less *mutually distinct (in the evidence order), so any crisp distinction is preserved. The second clause says that even the more delicate paraconsistent situation of non-duality is preserved: strong evidence both for and against distinction survives translation. This is a rigorous expression of a phenomenological aspiration: shifting perspective may reinterpret an experience, but it should not arbitrarily delete its salient tensions. Put differently, a translation may add nuance (e.g. by increasing evidence for distinction in one or both directions), but it may not "flatten" a distinction* *that was already present at or above the salient level. The non-duality preservation is especially important because it says the translation respects not only clean separations but also ambiguous or tension-laden pairings where both poles of evidence are simultaneously significant.*

Sketch. Non-dual compatibility gives (for all x, y) inequalities of the form $\delta_c(x, y) \leq \delta_d(Tx, Ty)$ and, by swapping x, y, also $\delta_c(y, x) \leq \delta_d(Ty, Tx)$. Monotonicity of $\otimes$ yields $\delta_c(x, y) \otimes \delta_c(y, x) \leq \delta_d(Tx, Ty) \otimes \delta_d(Ty, Tx)$, i.e. $\mathrm{Dist}_c(x, y) \leq \mathrm{Dist}_d(Tx, Ty)$. Componentwise order then preserves threshold exceedance in both channels, giving the crisp and non-dual consequences. Concretely, for the crisp clause: if $\mathrm{Dist}_c(x, y) \geq \tau_\delta$ (in the relevant ordering), then the inequality forces $\mathrm{Dist}_d(Tx, Ty) \geq \tau_\delta$ as well, because increasing a p-bit value cannot make it fall below a fixed threshold. For the non-dual clause, the same componentwise monotonicity applies simultaneously to the "distinguish" and "do-not-distinguish" components that define NonDual, so having both components above their respective thresholds in context c implies the same in context d. □

Remark 1606. Proof sketch and intuition. *The proof composes three monotonicities: (1) compatibility gives two directed inequalities for δ (one for each direction); (2) monotonicity of $\otimes$ lifts directed inequalities to an inequality about mutual distinction* Dist*; (3) componentwise order ensures that if a p-bit value increases, then any threshold condition that held before still holds after. One may picture T as an embedding that may stretch distances but is not allowed to collapse them below salient levels. A useful mental model is that $\delta(\cdot, \cdot)$ supplies directed "pushes apart" evidence; $\otimes$ aggregates the two directed pushes into a single mutual signal. Non-dual compatibility says each directed push is not weakened by translation; therefore the aggregate mutual signal is not weakened either. The preservation of non-duality then follows because non-duality is formulated as a conjunction of threshold conditions on the same underlying evidence channels, and conjunction of monotone properties remains monotone under such translations.*

Lemma 19 (Closure under composition; identity translation)**.** *If $T : X_c \to X_d$ and $U : X_d \to X_e$ are non-dually compatible, then $U \circ T : X_c \to X_e$ is non-dually compatible. The identity map id_{X_c} is non-dually compatible. This shows that "non-dually compatible translation" behaves like a structural constraint rather than an ad hoc property of a single map: it is stable under chaining of perspective shifts, and it is satisfied by the trivial shift that changes no perspective at all.*

Remark 1607. *This lemma says that non-dually compatible translations form a small but robust algebra: they compose and include identities. As a result, contexts and their admissible translations can be treated categorically (at least informally): one can build multi-step perspective shifts without losing the guarantee that distinctions are not erased. In particular, once a downstream analysis is stated in a target context X_e, one may safely precompose it with any sequence of such translations from a source context without worrying that crisp distinctions (or non-dual tensions) were artifacts of a particular viewpoint and disappear under the change of lens. The lemma is thus a technical enabler for discussing families of contexts connected by permissible reinterpretations.*

Sketch. For all x, y, $\delta_c(x, y) \leq \delta_d(Tx, Ty) \leq \delta_e(U(Tx), U(Ty))$ by transitivity of $\leq$, and similarly for the swapped-argument inequality. This is exactly Def. 53 for $U \circ T$. For the identity, both inequalities reduce to $\delta_c(x, y) \leq \delta_c(x, y)$. No further properties of δ are needed beyond the order structure already assumed, which is why the argument is purely diagrammatic: it is just the fact that an order-preserving lower bound remains a lower bound after applying another order-preserving lower bound. □

Remark 1608. Proof sketch and intuition. *Composition uses nothing mysterious: it is simply the transitivity of the underlying order $\leq$. If T does not reduce distinction evidence and U does not* *reduce distinction evidence, then doing T and then U does not reduce it either. The identity case is the degenerate translation that changes nothing, so it trivially preserves every distinction. From the perspective-bridging viewpoint, this means that "respecting salient distinctions" is a property that can be required locally at each step of a translation pipeline, while still guaranteeing the global property for the entire pipeline. This aligns with modularity: one can design or learn translations in stages, checking the same simple inequality condition at each stage, and then compose them without re-verifying everything from scratch.*

29 Helper theorems for order, time, and becoming (Section 7)

Standing assumptions and notation. A *proto-time* is a pair $(T, <)$ with $<$ a strict partial order (Defs. 54–55). Where needed, fix the canonical p-bit quantale $V = [0, 1]^2$ with componentwise order $\leq$, join $\oplus$ as componentwise max, and tensor $\otimes$ as componentwise multiplication. A p-bit temporal evidence relation is $B : T \times T \to V$ (Def. 56). Optional coherence constraints are those in Def. 57. For linearization/quotients, Past/Future sets and $\sim$ are as in Def. 59. For becoming, $Dist : T \times E \times E \to V$ and NDVar/Becoming are as in Defs. 60–62. For event calculus, predicates and operators are as in Defs. 63–66. TimeCtx/similarity/TemporalSimilarity are as in Defs. 67–69. Regularity predicates are as in Defs. 70–72. The functorial process view is Def. 73.

Remark 1609. *The organizing thought here is that "time" is treated in two layers. First there is a thin, structural layer: a set T of "time-like" indices equipped with a strict partial order $<$, yielding what the core calls a proto-time (Hyperseed-Concept 142). This is intentionally weaker than a linear timeline: it permits branching and incomparability, which is often what one has before imposing a narrative or a measurement protocol.*

Second there is a graded, paraconsistent evidential layer, in which comparisons $t_1 < t_2$ may be supported or disputed by data. Concretely, the canonical p-bit quantale $V = [0, 1]^2$ encodes a pair $v = (v^+, v^-)$ of positive *and* negative *evidence channels (in the sense of paraconsistent valuation; see also [23, 24]). Componentwise order means $(a^+, a^-) \leq (b^+, b^-)$ iff $a^+ \leq b^+$ and $a^- \leq b^-$. The join $v \oplus w$ is componentwise* max*, representing "take the stronger of two arguments"; the tensor $v \otimes w$ is componentwise multiplication, representing "compose pieces of support" along a chain. A temporal evidence map $B : T \times T \to V$ thus assigns to each ordered pair (t_1, t_2) a degree of support $B^+(t_1, t_2)$ and a degree of counter-support $B^-(t_1, t_2)$ for the claim "t_1 is before t_2" (Hyperseed-Concepts 63 and 52). This style of quantale-based graded reasoning connects to the broader weakness/quantale program [3] and to the original Hyperseed presentation [1].*

How the two layers interact. Although $(T, <)$ and B are introduced separately, the intended use is that the structural order provides a baseline constraint (e.g. what is allowed in a model), while the evidential map provides a flexible mechanism for learning, aggregating, and revising order-claims from heterogeneous sources. In particular, one should read $B(t_1, t_2)$ as *evidence about* the ordering claim, not as the ordering claim itself: the strict partial order $<$ can be taken as a conservative "skeleton" that may later be refined, quotiented, or linearized (Def. 59) using the evidential layer. This separation is what allows the later helper results to state clean monotonicity and closure properties for the constructions built from B without requiring that the underlying proto-time be total, well-founded, or otherwise timeline-like.

Interpreting p-bits and inconsistency. The p-bit value $v = (v^+, v^-) \in [0, 1]^2$ can be read as allowing independent degrees of affirmation and denial. Thus, values near $(1, 0)$ represent strong support with little objection, values near $(0, 1)$ represent strong counter-evidence, and values with both components large represent a state of *inconsistent* information (in the paraconsistent sense) rather than a collapse of the framework. The componentwise operations are chosen so that common evidential patterns have direct algebraic expressions: $\oplus$ merges alternative arguments by retaining the strongest available pro and con components, while $\otimes$ models the idea that support (and counter-support) can be propagated along compositional patterns such as chains of "before" comparisons. Optional coherence constraints (Def. 57) can then be seen as enforcing minimal compatibility conditions between direct and composed evidence (for example, requiring that direct evidence for $t_1 < t_3$ not be weaker than what is obtained by composing evidence for $t_1 < t_2$ and $t_2 < t_3$), while still permitting the presence of both support and objection in the same comparison.

Why the remaining definitions are grouped here. The later notions referenced above (Past/Future sets and $\sim$, becoming via *Dist* and NDVar/Becoming, the event-calculus operators, TimeCtx and TemporalSimilarity, regularity predicates, and the functorial process view) are all ways of turning proto-time plus graded evidence into derived structures that behave like temporal semantics. The point of this section is not to reintroduce those constructions, but to collect helper theorems that show they respect the underlying order/evidence architecture: closure properties under $\oplus$ and $\otimes$, invariance under quotienting by $\sim$, and the stability of becoming- and event-level predicates under the similarity/regularity constraints. Establishing these routine facts once lets later sections focus on modeling choices rather than re-proving basic algebraic and order-theoretic properties.

29.1 Strict proto-time order: basic derived rules

Lemma 20 (Asymmetry from strictness)**.** *If $(T, <)$ is a strict partial order, then for all $t_1, t_2 \in T$,*

$$t_1 < t_2 \;\to\; \neg(t_2 < t_1).$$

Remark 1610. *Intuitively, this lemma says that if "t_1 is strictly before t_2," then t_2 cannot be strictly before t_1. In ordinary temporal language this is almost tautological, but it is worth isolating because it is exactly where the* strict *nature of $<$ matters: asymmetry is derived from irreflexivity plus transitivity.*

More explicitly, recall that a strict partial order *is, by definition, a relation that is (i)* irreflexive *($\neg(t < t)$ for all t) and (ii)* transitive *(if $t_1 < t_2$ and $t_2 < t_3$ then $t_1 < t_3$). The point of the lemma is that one does not need to add asymmetry as an independent axiom: it is already forced by (i)–(ii). This matters later because we will treat $<$ as the base "proto" structure and layer additional semantic/evidential notions on top; keeping the base assumptions minimal prevents accidental circularity when richer principles are introduced.*

This result functions as the minimal sanity check on proto-time (Hyperseed-Concept 142): it rules out the simplest temporal contradiction inside the underlying order, even before we add graded/paraconsistent evidence. Later results on cycles and linear extensions reuse the same idea in increasingly global forms.

A useful reformulation is that the binary relation $<$ defines an orientation on pairs: once $t_1 < t_2$ holds, the opposite orientation is ruled out. In particular, even if $<$ is not total (so that some pairs are incomparable), whenever comparability does occur it is one-way only; this is the precise sense in which strictness provides a minimal directional constraint.

Sketch. Assume $t_1 < t_2$ and $t_2 < t_1$. By transitivity, $t_1 < t_1$, contradicting irreflexivity. $\square$

Remark 1611. Proof sketch (strategy). *Suppose both directions hold; then compose them to obtain a self-loop, which strictness forbids.*

Key step. *The only real move is applying transitivity to the pair of inequalities; irreflexivity then closes the door. One may picture $t_1 < t_2$ as an arrow $t_1 \to t_2$ in a directed graph: having also $t_2 \to t_1$ forces a 2-cycle, hence a loop.*

Geometric intuition. *In a strict order, time cannot "bend back" onto itself at a point; if it did, the point would be both before and after itself, collapsing the meaning of "before" (Hyperseed-Concept 63).*

It is also worth noting what the lemma does not *assert: it does not say that either $t_1 < t_2$ or $t_2 < t_1$ must hold. Thus, the absence of symmetry is compatible with branching or partially ordered temporal structures, where two moments may be incomparable (neither earlier nor later in the proto-time sense), even though any asserted ordering must be coherent.*

Lemma 21 (No directed cycles)**.** *If $(T, <)$ is a strict partial order, there is no finite cycle $t_0 < t_1 < \cdots < t_{n-1} < t_0$ for any $n \geq 1$.*

Remark 1612. *This lemma globalizes Lemma 20: not only are 2-cycles forbidden, but* any *finite directed cycle is. In graph terms, the directed graph of the relation $<$ is a DAG.*

*Two boundary cases are worth keeping in view. When $n = 1$, the "cycle" would read $t_0 < t_0$, which is excluded exactly by irreflexivity; so Lemma 21 may be seen as extending irreflexivity from length-*1 *loops to all finite loops. When $n = 2$, the cycle is precisely the configuration ruled out by Lemma 20. For $n \geq 3$, the lemma says that one cannot return to a starting point by stepping strictly forward finitely many times.*

The importance is practical as well as conceptual. Many constructions—linear extensions, topological sorts, inductive proofs over time—silently presuppose acyclicity. Here we see that acyclicity is not an extra axiom but a theorem of strictness, which will be exploited immediately in Lemma 22 and Theorem 27.

From the standpoint of later "becoming"-style talk, acyclicity is the minimal condition under which iterative "advance" operations are guaranteed not to revisit a prior state in finitely many steps. This provides a clean separation: any apparent temporal looping must come from additional structure (e.g. evidential layers) rather than from the underlying proto-time relation itself.

Sketch. By repeated transitivity, the cycle implies $t_0 < t_0$, contradicting irreflexivity. □

Remark 1613. Proof sketch (strategy). *Collapse the whole cycle into a single inequality $t_0 < t_0$ by composing along the chain.*

Key step. *"Repeated transitivity" is simply iterated application of transitivity to the successive links $t_0 < t_1$, $t_1 < t_2$, …, $t_{n-1} < t_0$.*

Visual intuition. *Any directed cycle is a closed directed path; transitivity lets us treat a path as a single arrow. But a closed path becomes a self-arrow, which strictness excludes.*

For readers who prefer a fully explicit symbolic form: apply transitivity to $t_0 < t_1$ and $t_1 < t_2$ to get $t_0 < t_2$; then combine this with $t_2 < t_3$ to get $t_0 < t_3$; continue until reaching $t_0 < t_{n-1}$, and finally combine with $t_{n-1} < t_0$ to conclude $t_0 < t_0$. The proof uses no finiteness of T, only the finiteness of the alleged cycle.

Lemma 22 (Minimal and maximal elements exist in the finite case)**.** *If T is finite and $(T, <)$ is a strict partial order, then T has at least one minimal element (no predecessor) and at least one maximal element (no successor).*

Remark 1614. *In a finite proto-time, there must be at least one "earliest" point (a minimal element) and at least one "latest" point (a maximal element), though there may be many of each.*

This does not *mean time is linear; it means only that in any finite acyclic directed graph there is a source and a sink.*

Concretely, "minimal" here means: $t \in T$ such that there is no $s \in T$ with $s < t$; "maximal" means: there is no $u \in T$ with $t < u$. In the directed-graph picture (with an arrow $s \to t$ whenever $s < t$), a minimal element is a vertex of indegree 0 *and a maximal element is a vertex of outdegree* 0*. The lemma therefore states a familiar graph-theoretic fact about finite DAGs, restated in order-theoretic language suited to proto-time.*

This lemma is the engine behind linearization (Theorem 27): the standard topological sorting argument repeatedly removes a minimal element and continues. Philosophically, it exhibits a mild form of "temporal directionality" without imposing a single global present: direction emerges from the impossibility of cycles.

It is also useful to compare this finite result with the stronger (and non-equivalent) notion of well-foundedness *in the infinite case. Finiteness guarantees that one cannot keep moving to predecessors forever; in infinite structures, the existence of minimal elements can fail unless one assumes additional well-foundedness conditions. The present lemma thus isolates exactly what finiteness buys us, without building in stronger assumptions than needed.*

Sketch. If there were no minimal element, start at any t_0 and choose $t_1 < t_0$, then $t_2 < t_1$, etc. Finiteness forces a repeated element, yielding a cycle, contradicting Lemma 21. The maximal case is dual. □

Remark 1615. Proof sketch (strategy). *Assume the opposite and build an infinite descending (or ascending) chain by always stepping to a predecessor (or successor); finiteness forces repetition, hence a cycle.*

Key step. *The pigeonhole principle turns an infinite walk in a finite set into a repeated vertex; strictness turns the repeat into a contradiction via Lemma 21.*

Geometric intuition. *Think of repeatedly walking "backward in time." If you can always take one more step, then in a finite universe you eventually revisit a moment, implying time has looped.*

The "dual" maximal-element argument can be read either by reversing all inequalities or, equivalently, by applying the same reasoning to the opposite relation $>$ (which is also a strict partial order whenever $<$ is). This symmetry clarifies why the finite DAG picture yields both a source and a sink rather than only one of them.

29.2 Graded/paraconsistent temporal evidence: useful inequalities

Lemma 23 (Path lower bound under transitive support)**.** *Assume the optional* transitive support *constraint (Def. 57.2): $B(t_0, t_2) \geq B(t_0, t_1) \otimes B(t_1, t_2)$. Then for any chain $t_0, t_1, \ldots, t_n \in T$,*

$$B(t_0, t_n) \;\geq\; \bigotimes_{i=1}^{n} B(t_{i-1}, t_i).$$

In particular, on the positive channel, $B^+(t_0, t_n) \geq \prod_{i=1}^{n} B^+(t_{i-1}, t_i)$ in the canonical $[0,1]^2$ quantale.

Remark 1616. *This lemma states a very general principle: if evidence for "before" composes transitively, then the evidence for a long-range ordering is at least as strong as the cumulative composition of the short-range evidences along any chosen chain. In the canonical quantale, "composition" on the positive channel is multiplication, so support decays (unless values are* 1*).*

The usefulness is algorithmic and epistemic. Algorithmically, it provides a guaranteed lower bound when one infers distant temporal relations from local ones. Epistemically, it mirrors a sober

Russellian caution: chained inferences should not become more certain merely because they are longer. In paraconsistent settings [23, 24], one may carry positive and negative channels in parallel; this lemma is about the monotone accumulation of support (not the resolution of conflict).

Sketch. Induct on n. The case $n = 2$ is Def. 57.2. The inductive step composes $B(t_0, t_n) \geq B(t_0, t_{n-1}) \otimes B(t_{n-1}, t_n)$ and applies the hypothesis to $B(t_0, t_{n-1})$. $\square$

Remark 1617. Proof sketch (strategy). *Reduce an n-step chain to an $(n-1)$-step chain plus one final step, then apply induction.*

Key step. *The transitive-support axiom (Def. 57.2) is exactly the $n = 2$ case; everything else is bookkeeping of repeated composition via associativity of $\otimes$ (implicit in the quantale structure).*

Visual intuition. *Picture a path $t_0 \to t_1 \to \cdots \to t_n$ with each arrow labeled by a strength. Transitive support says the direct arrow $t_0 \to t_n$ must be at least as strong as the composed label of the path.*

Lemma 24 (Two-step threshold propagation)**.** *Assume transitive support (Def. 57.2) and the canonical $[0,1]^2$ tensor. If $B^+(t_1, t_2) \geq \alpha$ and $B^+(t_2, t_3) \geq \beta$, then*

$$B^+(t_1, t_3) \geq \alpha\beta.$$

Equivalently, if $B^+(t_1, t_2) \geq \tau$ and $B^+(t_2, t_3) \geq \tau$, then $B^+(t_1, t_3) \geq \tau^2$.

Remark 1618. *This is the concrete numerical form of Lemma 23 for a chain of length 2. The statement is almost pedagogical: if each of two links has at least some reliability, the inferred two-step relation has at least the product reliability.*

Its conceptual role is to make explicit how thresholds behave under inference. If one chooses a single threshold τ for "strong evidence," then chaining two strong evidences yields a weaker lower bound τ^2. This warns us that thresholding is not invariant under composition: in long chains, one may need renormalization, alternative t-norms, or different proof policies.

Sketch. Take the positive component of Lemma 23 for $n = 2$. $\square$

Remark 1619. Proof sketch (strategy). *Specialize the general chain bound to $n = 2$ and read off the positive coordinate.*

Key step. *In the canonical $[0,1]^2$ quantale, $\otimes$ is componentwise multiplication, so the composed positive evidence is $\alpha\beta$.*

Intuition. *Each step is a filter on certainty; two filters in series multiply their pass-through.*

Lemma 25 (No positive-evidence 2-cycles under transitive+irreflexive support)**.** *Assume transitive support (Def. 57.2),* irreflexive support $B^+(t,t) = 0$ *(Def. 57.3), and the canonical $[0,1]^2$ tensor. Then for all $t_1, t_2 \in T$,*

$$B^+(t_1, t_2) \cdot B^+(t_2, t_1) = 0.$$

So it is impossible to have strictly positive evidence for both directions simultaneously.

Remark 1620. *This lemma translates the strict-order intuition "no two-way arrows" into the evidence layer. Under transitive support, a 2-cycle would yield evidence for a self-loop; irreflexive support forbids any positive self-loop, so at least one direction of the 2-cycle must have zero positive evidence.*

The significance is methodological: it separates two notions of inconsistency. One may have paraconsistent *evidence (positive and negative simultaneously) without having* positive *evidence for both temporal directions. The latter would be a particularly strong kind of incoherence, and this lemma shows how to preclude it with simple constraints.*

Sketch. Apply transitive support to the length-2 loop $t_1 \to t_2 \to t_1$: $B^+(t_1, t_1) \geq B^+(t_1, t_2) \cdot B^+(t_2, t_1)$. But $B^+(t_1, t_1) = 0$, hence the product must be 0. $\square$

Remark 1621. Proof sketch (strategy). *Turn the two-way evidence into evidence for a self-loop via transitivity, then use irreflexivity to force the product to vanish.*

Key step. *The inequality $B^+(t_1, t_1) \geq B^+(t_1, t_2) \cdot B^+(t_2, t_1)$ is the transitive-support axiom applied to $t_0 = t_1$, $t_1 = t_2$, $t_2 = t_1$.*

Graph intuition. *If both arrows $t_1 \to t_2$ and $t_2 \to t_1$ had positive weight, then the round trip $t_1 \to t_1$ would inherit positive weight; irreflexive support declares that no round trip is allowed to count as "forward in time."*

Lemma 26 (Conflict detection from anti-symmetry-as-evidence)**.** *Assume the optional constraint (Def. 57.1): $B^+(t_1, t_2) \leq B^-(t_2, t_1)$. Then any strong positive evidence for $t_1 < t_2$ forces at least as-strong negative evidence for $t_2 < t_1$. If additionally $B^+(t_2, t_1)$ is also strong, then (t_1, t_2) is* paraconsistently ordered*: both directions have strong positive and strong negative evidence.*

Remark 1622. *The axiom $B^+(t_1, t_2) \leq B^-(t_2, t_1)$ can be read as a disciplined bookkeeping rule: support for one direction counts as (counter-)evidence against the reverse direction. Under this discipline, strong belief that t_1 is before t_2 automatically implies strong disbelief that t_2 is before t_1.*

The second sentence isolates a characteristic paraconsistent phenomenon (Hyperseed-Concept 198 in the general style, and paraconsistent valuation as in [23, 24]): one may still end up with strong $B^+(t_1, t_2)$ and strong $B^+(t_2, t_1)$ simultaneously, in which case the bookkeeping forces strong negative evidence in both directions too. This is not "resolved" here; rather, it is detected and made explicit, so later mechanisms can decide how to act on it.

Sketch. Immediate from Def. 57.1 and symmetry of the statement under swapping indices. $\square$

Remark 1623. Proof sketch (strategy). *Unpack the constraint and apply it directly.*

Key step. *The condition is already pointwise: for each ordered pair it gives an inequality relating $+$ in one direction to $-$ in the reverse.*

Intuition. *The lemma is less a "derivation" than a clarifying rephrasing: it tells you what Def. 57.1 means operationally.*

Remark 1624. *To make the phrase "strong" fully concrete, one may read it relative to any chosen strength threshold θ (often with θ near the top of the scale in use). In that case the first conclusion can be restated as the monotonic implication*

$$B^+(t_1, t_2) \geq \theta \implies B^-(t_2, t_1) \geq \theta,$$

which is exactly what the inequality $B^+(t_1, t_2) \leq B^-(t_2, t_1)$ guarantees. No additional algebra is needed: the inequality transfers lower bounds on $B^+(t_1, t_2)$ into the same lower bounds on $B^-(t_2, t_1)$.

In the same thresholded reading, the "paraconsistently ordered" situation described in the lemma can be written as the joint satisfaction of four strong-evidence conditions,

$$B^+(t_1, t_2) \geq \theta, \qquad B^-(t_1, t_2) \geq \theta, \qquad B^+(t_2, t_1) \geq \theta, \qquad B^-(t_2, t_1) \geq \theta,$$

where the two negative terms arise from the two positive terms by applying Def. 57.1 once to (t_1, t_2) and once to (t_2, t_1). Thus the bookkeeping constraint functions as a conflict amplifier *in the following precise sense: if the data source or aggregation procedure supplies strong support in both directions, then the constraint necessarily yields strong opposition in both directions as well, making the inconsistency explicit rather than latent.*

Remark 1625. *The name "anti-symmetry-as-evidence" is intended to highlight the distinction between (i) enforcing classical antisymmetry of an order, which would prohibit $t_1 < t_2$ and $t_2 < t_1$ from both holding, and (ii) enforcing a relation between* evidence values *for opposite directions. Def. 57.1 is of type (ii): it does not directly forbid having strong $B^+(t_1, t_2)$ and strong $B^+(t_2, t_1)$ at the same time, but it ensures that such a situation cannot occur without simultaneously producing correspondingly strong B^- values. In other words, the constraint does not remove paraconsistency; it makes its presence measurable in the $B^\pm$ fields, which is the relevant output for later decision policies.*

Further detail (optional). Fix t_1, t_2 and assume Def. 57.1, i.e. $B^+(t_1, t_2) \leq B^-(t_2, t_1)$. If $B^+(t_1, t_2)$ is strong (e.g. $\geq \theta$ for a chosen θ), then by transitivity of $\leq$ we have $\theta \leq B^+(t_1, t_2) \leq B^-(t_2, t_1)$, hence $B^-(t_2, t_1)$ is strong. If, in addition, $B^+(t_2, t_1)$ is strong, then applying the same constraint with indices swapped gives $B^+(t_2, t_1) \leq B^-(t_1, t_2)$, so $B^-(t_1, t_2)$ is also strong. This yields the four strong-evidence statements described in the lemma's final sentence. □

29.3 Linearization and quotient-by-indistinguishability

Lemma 27 ($\sim$ is an equivalence relation)**.** *Let $\sim$ be defined by equality of Past/Future sets (Def. 59). Then $\sim$ is reflexive, symmetric, and transitive.*

Remark 1626. *The relation $\sim$ collapses time points that are observationally indistinguishable with respect to the order structure: two points are equivalent if they have the same Past-set and the same Future-set. This is a structural instance of an equivalence relation (Hyperseed-Concept* **??***) arising from an invariance principle: if nothing in the order-theoretic neighborhood distinguishes t from s, we treat them as the same "abstract time."*

This quotienting move is philosophically suggestive: it echoes the idea that time is partially constituted by relations (Whitehead's process-relational stance [15]), and technically it prepares the ground for a clean strict order on the quotient (Theorem 26).

Sketch. Reflexive/symmetric are immediate from set equality. For transitivity, if Past(t)=Past(s) and Past(s)=Past(r), then Past(t)=Past(r), and similarly for Future. □

Remark 1627. Proof sketch (strategy). *Use the standard fact that equality is an equivalence relation, applied separately to Past and Future.*

Key step. *Transitivity is inherited from transitivity of equality: if two sets are equal to a third, they are equal to each other.*

Intuition. *This is the formal stamp that "indistinguishable" behaves the way one expects: it partitions T into classes.*

Lemma 28 (Indistinguishable points are incomparable)**.** *If $t \sim s$ and $t \neq s$, then neither $t < s$ nor $s < t$.*

Remark 1628. *This lemma asserts that if two distinct points have identical Past/Future profiles, then the order cannot place one before the other. If it did, that very fact would change the Past/Future profile and hence destroy indistinguishability.*

The result matters because it ensures the quotient $T/\sim$ is not hiding genuine order information: when we collapse t and s, we are not collapsing a real before/after distinction (Hyperseed-Concept 98); rather, we are collapsing redundancy in the representation of proto-time (Hyperseed-Concept 142).

Sketch. If $t < s$, then $t \in \mathit{Past}(s)$ but $t \notin \mathit{Past}(t)$ (irreflexivity), contradicting Past(t)=Past(s). The case $s < t$ is symmetric. □

Remark 1629. Proof sketch (strategy). *Show that comparability forces an asymmetry in the Past sets.*

Key step. *Irreflexivity is crucial:* $t \notin \mathit{Past}(t)$, *but if* $t < s$ *then* $t \in \mathit{Past}(s)$. *Thus* $\mathit{Past}(t) \neq \mathit{Past}(s)$.

Visual intuition. *If t were before s, then t would cast a "shadow into the past" of s that is absent from the past of itself.*

Lemma 29 (Quotient map is order-preserving and order-reflecting)**.** *Let* $q : T \to T/\sim$ *be* $q(t) = [t]$ *and let the quotient order be as in Def. 59. Then for all* $t_1, t_2 \in T$,

$$t_1 < t_2 \iff [t_1] < [t_2].$$

Remark 1630. *This lemma says the quotient is faithful to the original strict order: it neither invents new strict order relations nor loses old ones. Order-preserving* ($t_1 < t_2 \Rightarrow [t_1] < [t_2]$) *is expected; order-reflecting is the deeper assurance that if two equivalence classes are ordered, then their representatives really were ordered.*

This is the technical heart of treating $T/\sim$ *as an "abstracted" proto-time. In Hyperseed language, it is a disciplined abstraction (Hyperseed-Concept 51) that respects temporal structure (Hyperseed-Concept 142), a theme that also appears elsewhere in the system as abstraction-by-quotient.*

Sketch. ($\rightarrow$) If $t_1 < t_2$, then by definition $[t_1] < [t_2]$. ($\Leftarrow$) If $[t_1] < [t_2]$, there exist representatives $s_1 \sim t_1$ and $s_2 \sim t_2$ with $s_1 < s_2$. If t_1 were not $< t_2$, Past/Future equalities plus the existence of a comparable representative force a contradiction (same kind of reasoning used to show well-definedness in Lemma 1). □

Remark 1631. Proof sketch (strategy). *The forward direction is definitional. The reverse direction argues that comparability is a class property: if some representatives are comparable, then all representatives must align, because* $\sim$ *fixes Past/Future structure.*

Key step. *The Past/Future invariants prevent a situation in which* $s_1 < s_2$ *but* t_1 *and* t_2 *are not ordered: if* s_1 *is in the Past of* s_2*, then (via equality of Past/Future sets within each class) the corresponding membership relations must transfer to* t_1 *and* t_2.

Intuition. *Equivalence classes are meant to be "structural positions" in the order. If one representative sits before another, the whole class sits before the other class; otherwise, the classes would not be positions but merely bags of points.*

Theorem 26 (Quotient order is strict (helper restatement of Lemma 1))**.** *The relation* $<$ *on* $T/\sim$ *defined in Def. 59 is well-defined and makes* $(T/\sim, <)$ *a strict partial order.*

Remark 1632. *This theorem assures that the quotient construction yields a genuine proto-time again: it is not merely a set of classes, but a set of classes equipped with a strict partial order. "Well-defined" is the subtle point: we must not let the ordering depend on which representative of a class one picks. It connects directly to Lemmas 27–29: the equivalence relation gives the partition, incomparability protects against collapsing real order, and order-reflection preserves the semantics of before/after. Taken together, they justify the quotient as an abstraction step in the sense of Hyperseed (Hyperseed-Concept 51). In particular, the quotient does not "invent" new temporal distinctions: it merely re-expresses the original proto-time in a coarser vocabulary where indistinguishable points are treated as a single abstract point, while all genuine* $<$*-constraints remain detectable at the level of equivalence classes.*

Sketch. Well-definedness: comparability of one representative is incompatible with incomparability of another when Past/Future sets are equal; strictness descends because any cycle in the quotient would lift to a cycle in T. (This is the proof idea of Lemma 1.) More explicitly, if the quotient order is defined by $[t_1] < [t_2]$ iff there exist representatives $t_1' \in [t_1]$, $t_2' \in [t_2]$ with $t_1' < t_2'$, then Past/Future equality is used to show that whenever one such witnessing pair exists, every choice of representatives remains compatible with $<$ in the sense that the opposite inequality cannot be witnessed without contradicting incomparability preservation. For strictness, if $[t_0] < [t_1] < \cdots < [t_k] = [t_0]$ were a directed cycle among classes, choosing witnesses for each step produces a directed cycle in T, contradicting Lemma 21. □

Remark 1633. Proof sketch (strategy). *For well-definedness, show that if* $[t_1] < [t_2]$ *holds via some representatives, it cannot fail via others. For strictness, transfer irreflexivity/transitivity (or equivalently, acyclicity) from* T *to the quotient.*

Key steps. *(i) Past/Future equality makes "being before" a class invariant. (ii) Any directed cycle among classes would choose representatives to yield a directed cycle in* T*, contradicting Lemma 21. Concretely, (i) is used in the contrapositive form: if two elements have identical Past/Future sets, then there is no third point that can distinguish them by being before one but not the other; this blocks the possibility that swapping representatives could flip a strict inequality into a non-inequality. Step (ii) is the familiar "lift a cycle" maneuver: since each edge in the quotient is witnessed by at least one edge in* T*, a cyclic chain of class-edges forces a cyclic chain of element-edges.*

Intuition. *Quotienting is safe here because the equivalence relation was designed from the order itself; it forgets only redundancy, not structure. Put differently: proto-time is the primary structure, and the quotient is a controlled compression of that structure, justified exactly because the defining indistinguishability criterion is stated in terms of observable order-theoretic behavior (Past/Future), rather than in terms of an external labeling.*

Theorem 27 (Finite proto-times admit linear extensions (helper restatement of Theorem 5))**.** *If* $(T, <)$ *is a finite proto-time, there exists a strict total order* $\prec$ *on* T *such that* $t_1 < t_2 \to t_1 \prec t_2$*.*

Remark 1634. *A linear extension is a way of telling a complete story from a partial order: it imposes a total order* $\prec$ *that respects all the constraints of* $<$*. When proto-time represents a web of "must-be-before" constraints, a linear extension is a choice of one consistent timeline compatible with them.*

This is important because many algorithms (simulation, scheduling, event calculus iteration) are most naturally run over a linear order. The theorem says that for finite proto-times this is always possible: one may add arbitrary tie-breaks among incomparable points without creating contradictions. The proof relies on Lemma 22 and is the standard topological sorting argument. Equivalently, one may view $(T, <)$ *as a finite acyclic directed graph and produce* $\prec$ *by repeatedly selecting a node with no incoming edges; the finiteness assumption ensures the process terminates, while acyclicity ensures one can always continue. Note that the construction generally produces many possible* $\prec$*, reflecting the underdetermination present in the original proto-time.*

Sketch. Induct on $|T|$ using existence of a minimal element (Lemma 22), place it first, and extend the remainder inductively (standard topological sort proof). More explicitly, choose a $<$-minimal $m \in T$, define $\prec$ to start with m, restrict $<$ to $T \setminus \{m\}$ (which remains a finite proto-time), apply the induction hypothesis to obtain a linear extension $\prec'$ on the remainder, and then concatenate m with $\prec'$. Minimality of m ensures no constraint $t < m$ is violated, and the induction hypothesis ensures all constraints internal to $T \setminus \{m\}$ are respected. □

Remark 1635. Proof sketch (strategy). *Repeatedly peel off a minimal element and put it next in the total order.*

Key step. *Lemma 22 guarantees there is always at least one minimal element to peel off until the set is empty. Induction then assembles these choices into a strict total order. The strictness of $\prec$ is automatic because the construction never places two distinct elements in the same position, and transitivity follows from the fact that each stage appends a well-ordered remainder.*

Intuition. *In a finite acyclic dependency graph, there is always something you can do first; do it, remove it, and repeat. When there are several minimal choices at some stage, each choice corresponds to a different but equally valid "completion" of the partial temporal information encoded by $<$.*

Lemma 30 (Soundness of linearization; incomparability is not preserved)**.** *Let $\prec$ be a linear extension of $(T, <)$. Then:*

$$t_1 < t_2 \to t_1 \prec t_2 \quad \textit{(soundness)},$$

but in general,

$$t_1 \prec t_2 \not\to t_1 < t_2 \quad \textit{(not complete)}.$$

In particular, if t_1 and t_2 are incomparable in $<$, $\prec$ still forces exactly one of $t_1 \prec t_2$ or $t_2 \prec t_1$.

Remark 1636. *This lemma is a cautionary counterpart to Theorem 27. A linear extension is* sound *with respect to $<$: it never violates the original constraints. But it is not* complete*: it introduces additional comparabilities that were not present in the proto-time. Incomparable events become artificially ordered.*

The point is conceptual as much as technical. Linearization is an interpretive act: it selects a narrative from a partial structure. Hyperseeds stance is to keep proto-time primary and treat any $\prec$ as a derived convenience, not as ontology itself (Hyperseed-Concept 142). This distinction prevents one from mistaking a bookkeeping choice for a metaphysical fact. A simple example is a proto-time with two events a, b such that neither $a < b$ nor $b < a$; any linear extension must pick either $a \prec b$ or $b \prec a$, but that choice encodes no additional constraint in the underlying model. Accordingly, any subsequent reasoning that depends on the newly introduced order (e.g., treating $a \prec b$ as evidence that a "really" precedes b in proto-time) is methodologically unsound unless it is explicitly stated as a convention or an extra assumption.

Sketch. Soundness is the definition of linear extension. Non-completeness holds because a total order must compare incomparable pairs, introducing an arbitrary choice that does not imply $<$. Formally, if t_1 and t_2 are incomparable under $<$, then $t_1 < t_2$ is false and $t_2 < t_1$ is false, but totality of $\prec$ forces exactly one of $t_1 \prec t_2$ or $t_2 \prec t_1$; hence either way one obtains an instance of $t_1 \prec t_2$ (or its reverse) that does not correspond to a $<$-fact. This shows that $\prec$ may strictly extend $<$ by adding relations not entailed by the proto-time. $\square$

Remark 1637. Proof sketch (strategy). *The first implication is immediate from the definition; the second is forced by the nature of total orders.*

Key step. *Totality means every pair is comparable under $\prec$, so $\prec$ contains at least one of (t_1, t_2) or (t_2, t_1) even when $<$ contains neither. Thus, while $<$ embeds into $\prec$ (soundness), the embedding is typically proper: $\prec$ contains additional ordering information not justified by proto-time alone.*

Intuition. *Linearization is like choosing an ordering of chapters in a book built from partially ordered notes: it respects the dependency constraints but still chooses an order where none was mandated. The extra order is best understood as a convenient serialization for execution or exposition, not as a discovery of hidden temporal structure.*

29.4 Becoming as boundary non-duality: operational lemmas

Lemma 31 (Necessary paraconsistent boundary condition)**.** *If x becomes y along $(T,<)$ (Def. 62), then there exists a neighborhood $U \subseteq T$ near the transition such that for all $u \in U$,*

$$Dist(u;x,y) \geq (\theta,\theta)$$

for the chosen NDVar threshold θ (Def. 61).

Remark 1638. *The core idea of* becoming *(Hyperseed-Concept 62) here is neither simple replacement nor mere succession. Rather, it is characterized by a boundary region in which x and y are held together in a kind of structured ambiguity: strong evidence both for and against their distinction, formalized via NDVar (Hyperseed-Concept 120) and ultimately via a paraconsistent Dist valuation.*

This lemma extracts the operational test that any implementation must satisfy: if the theory declares "x becomes y," then there must exist some time neighborhood where Dist is simultaneously high in both channels. This is the minimal trace of Whiteheadian transition (process and becoming [15]) rendered in quantale-valued evidence.

Sketch. Immediate: boundary non-duality (Def. 62.2) is NDVar at each u near the transition, and NDVar is $Dist(u;x,y) \geq (\theta,\theta)$ by Def. 61. □

Remark 1639. Proof sketch (strategy). *Unpack the definitions: Def. 62 reduces becoming to boundary NDVar; Def. 61 reduces NDVar to a threshold on Dist.*

Key step. *The inequality $Dist(u;x,y) \geq (\theta,\theta)$ is simply the bundled form of "both positive and negative components are at least θ."*

Intuition. *Becoming must leave a signature: a zone where the system is compelled to treat x and y as both distinct and not-distinct (Hyperseed-Concept 121), rather than switching instantaneously.*

Remark 1640. Further operational reading. *The neighborhood U in Lemma 31 should be understood as an* interval of indeterminacy *around the transition locus, not necessarily symmetric and not necessarily unique. In applications where T carries additional structure (e.g. a topology or a metric), "near the transition" can be instantiated as a small open interval, a finite window in discrete time, or any other admissible neighborhood notion used by Def. 62. The lemma itself only needs the minimal neighborhood concept already assumed in the definition of becoming.*

Why the inequality is two-channel. *Since $Dist(t;x,y)$ is paraconsistent, the condition $Dist(u;x,y) \geq (\theta,\theta)$ does not mean "maximal confusion"; it means that* both *(i) evidence for distinction and (ii) evidence against distinction cross the same operational floor. This is exactly the boundary-style signal: the system is pulled in incompatible directions strongly enough that a classical crisp predicate (distinct vs. identical) cannot be consistently applied in that region.*

Threshold dependence. *For fixed Dist, the choice of θ tunes how demanding the test is. Increasing θ makes becoming harder to certify, shrinking the set of times counted as boundary; decreasing θ enlarges it. Thus the lemma is best read as a* relative *statement: given the θ that defines NDVar (Def. 61), becoming forces a θ-robust paraconsistent band to exist around the transition.*

Remark 1641. Implementation note (minimal check). *In a computational or empirical setting, Lemma 31 can be used as a necessary diagnostic: sample or estimate $Dist(t;x,y)$ on a candidate transition window and verify that there exists a contiguous set of times on which both components exceed θ. Failure of this diagnostic rules out becoming* regardless *of any higher-level narrative about x and y.*

Lemma 32 (Non-becoming tests)**.** *Fix $(T,<)$ and Dist.*

1. *If there is no $t \in T$ with $Dist(t;x,y) \geq (\theta,\theta)$, then x does* not *become y.*
2. *If $Dist(t;x,y) \geq (\theta,\theta)$ for* all *$t \in T$, then x does* not *become y (because Def. 62.3 cannot be satisfied).*

Remark 1642. *This lemma gives two complementary failure modes for becoming. The first is the obvious one: if x and y are never in the required non-dual-variety relation, then there is no boundary region and hence no becoming. The second is subtler: if x and y are in NDVar* everywhere*, then the boundary ceases to be a boundary—there is no "outside" where the system recovers ordinary distinguishability.*

Operationally, these tests matter because they prevent over-ascription. Without them, one might call everything a becoming, either by never checking for the boundary signature or by allowing a perpetual blur to count as transition. The formalism insists that becoming is a localized phenomenon: neither absent everywhere nor present everywhere.

Sketch. (1) Contrapositive of Lemma 31. (2) Def. 62 requires a boundary region U where NDVar holds, but also that away from U the pair is more distinguishable (not strongly paraconsistent). If NDVar holds everywhere, the "outside" clause fails. ☐

Remark 1643. Proof sketch (strategy). *Part (1) is direct contrapositive reasoning; part (2) checks the "boundary vs. outside" clause in the definition of becoming.*

Key step. *The distinction between "there exists a neighborhood U" and "outside U something different happens" is what blocks the degenerate case where NDVar is ubiquitous.*

Intuition. *A boundary is meaningful only if it separates regions with different character; otherwise it is just uniform fog.*

Remark 1644. Clarifying the two failure modes. *Items (1) and (2) exclude opposite extremes:*

- *In (1), Dist never reaches the paraconsistent threshold in both channels simultaneously, so there is no candidate region in which x and y can be held in the structured ambiguity required by boundary non-duality. Even if Dist occasionally makes x and y look* similar *(e.g. one channel high), the defining feature of NDVar is the joint lower bound.*
- *In (2), the condition holds everywhere, so NDVar becomes the background state rather than a transition signature. The intended reading of Def. 62.3 is that becoming is witnessed not only by a boundary band but also by a recovery of "ordinary" discriminability away from that band. If there is no such recovery, then the situation is better described as persistent non-duality (a standing ambiguity) rather than becoming (a bounded passage).*

These tests therefore delineate a middle regime*: becoming is compatible with NDVar holding for* some *times (enough to form a neighborhood) but not for* all *times.*

Remark 1645. Discrete vs. continuous time. *When T is discrete (e.g. $T = \mathbb{Z}$ or a finite sequence of frames), a "neighborhood" U can be instantiated as a finite block of indices around a transition index. Lemma 32(1) then becomes a simple scan for any index with $Dist(t;x,y) \geq (\theta,\theta)$, while Lemma 32(2) becomes a check for the degenerate case where* every *index satisfies the NDVar inequality. When T is continuous, the same logic applies, but the existence of U is naturally read as the presence of an interval (possibly small) on which the inequality persists.*

Remark 1646. Robustness under strengthening the outside clause. *The exclusion in Lemma 32(2) is intentionally weak: it does not require specifying* how much *more distinguishable x and y must become outside U, only that Def. 62.3 fails if NDVar holds everywhere. In settings where one strengthens Def. 62.3 (for example, by requiring $Dist(t; x, y) \ngeq (\theta, \theta)$ on a nontrivial set outside U, or by requiring a quantitative drop in at least one component), the same failure mode remains: ubiquitous NDVar leaves no room for any strengthened "outside" behavior either.*

29.5 Quantale-valued event calculus: monotonicity and inertia rules

Lemma 33 (Rule contributions are lower bounds; multiple proofs join)**.** *For a quantale-valued Horn rule (Def. 64),*

$$P(\bar{x}) \Leftarrow Q_1(\bar{x}_1) \wedge \cdots \wedge Q_n(\bar{x}_n),$$

the semantics enforces the pointwise lower bound

$$[\![P(\bar{x})]\!] \;\geq\; [\![Q_1(\bar{x}_1)]\!] \otimes \cdots \otimes [\![Q_n(\bar{x}_n)]\!].$$

If multiple rules/instantiations derive the same head, the resulting head value is at least the $\oplus$-join (componentwise max in $[0,1]^2$) of all contributions.

Remark 1647. *This lemma clarifies how quantale-valued inference behaves: each rule instance contributes a* lower bound *on the heads truth-value. Conjunction in the body corresponds to $\otimes$ (so evidence composes), and multiple independent derivations aggregate via $\oplus$ (so the strongest derivation in each channel dominates, in the canonical model).*

The importance is that it makes explicit the proof-theoretic meaning of the quantale connectives. One can read $\oplus$ as "alternative reasons" and $\otimes$ as "joint reasons," which aligns with the broader goal of implementing a graded, potentially paraconsistent event calculus (Hyperseed-Concept **??***) using algebraic semantics [23, 24].*

Sketch. This is exactly Def. 64: conjunction maps to $\otimes$ and alternative derivations aggregate by $\oplus$. □

Remark 1648. Proof sketch (strategy). *This is definitional: interpret the rule under the chosen semantics.*

Key step. *The only "work" is remembering which connective maps to which quantale operation.*

Intuition. *A rule is not a claim that the head equals the bodys value; rather, it guarantees at least that much support. Additional rules can only add more support (via $\oplus$), never subtract it.*

Remark 1649. *A useful way to read the displayed inequality is as a semantic analogue of modus ponens for graded proofs: whenever the body holds to some degree (in the quantale order), the head must hold to at least the corresponding combined degree. In particular, if $V = [0,1]^2$ with the pointwise order, the inequality means that* each coordinate *of $[\![P(\bar{x})]\!]$ is bounded below by the corresponding coordinate of the $\otimes$-product of the body coordinates. This coordinatewise reading is what makes the "componentwise max" description of $\oplus$ operationally transparent: independent derivations can improve one channel without harming the other.*

Note also that the lemma is phrased as a lower bound rather than an equality because the canonical model is designed to be proof-accumulative: the semantics must admit additional support for $P(\bar{x})$ coming from other rules, from facts, or from later iterations in a fixpoint construction. Thus the inequality is the correct algebraic statement of "sound rule application" in a setting where multiple sources of evidence may coexist.

Lemma 34 (Monotonicity of proof accumulation)**.** *Assume all rules are built using only $\oplus$, $\otimes$, and monotone operations on V (as in Theorem 6). Then increasing any premise value (in the pointwise order on assignments) cannot decrease any derived head value.*

Remark 1650. *Monotonicity is the quiet structural condition that makes fixpoint semantics possible. It says: if you strengthen the premises (in either evidence channel), you cannot end up with weaker conclusions. This is the algebraic analogue of the ordinary Horn-clause property that adding facts does not invalidate derivations.*

This lemma is the hinge connecting local rule evaluation to global least-fixpoint constructions (Theorem 28). Without monotonicity, iterative semantics may oscillate or depend on evaluation order. With it, one may safely "accumulate proofs" as a growing approximation.

Sketch. $\oplus$ and $\otimes$ are monotone in each argument; joins over index sets preserve monotonicity. Thus each rule contribution is monotone, and the aggregate is monotone. □

Remark 1651. Proof sketch (strategy). *Reduce the claim to the monotonicity of the constructors used to build rule bodies and aggregation.*

Key step. *The pointwise order on $V^{(\cdot)}$ means monotonicity is checked coordinatewise at each ground atom/time; $\oplus$ and $\otimes$ preserve inequalities coordinatewise.*

Intuition. *If inference is built only from operations that never reverse inequalities, then inference itself never reverses them.*

Remark 1652. *Concretely, if $\nu \leq \nu'$ are two assignments of values in V to ground atoms (so $\nu(A) \leq \nu'(A)$ for every atom A), then for any fixed rule instance, the body evaluation under ν is $\leq$ the body evaluation under ν' because it is computed by composing monotone operations (iterated $\otimes$ and any other admissible monotone connectives). Applying the lemma repeatedly over all rule instances shows that a single "round" of consequence generation defines a monotone operator on the complete lattice of assignments, which is the exact hypothesis needed to justify least fixpoints (and hence canonical minimal models) by standard order-theoretic arguments.*

This also explains why non-monotone connectives (for example, a classical negation interpreted as order-reversing) are excluded from the rule building blocks in this fragment: they would break the monotone-operator property and thereby undermine the intended "accumulate and join" reading of proofs.

Lemma 35 (Clipped lower bound and monotonicity)**.** *Define Clipped as in Def. 65:*

$$Clipped(f;t_1,t_2) := \bigoplus_{a\in A,\ u\in T:\ t_1<u<t_2} Happens(a,u) \otimes Terminates(a,f,u).$$

Then for any particular witness (a,u) with $t_1 < u < t_2$,

$$Clipped(f;t_1,t_2) \ \geq\ Happens(a,u) \otimes Terminates(a,f,u).$$

Moreover, Clipped is monotone in each of $Happens$ and $Terminates$.

Remark 1653. *The operator Clipped expresses the idea that a fluent f might fail to persist from t_1 to t_2 because some terminating action happened in between. Quantale-valuedly, we aggregate* all *such potential terminating witnesses by a big $\oplus$. The lemma says two things: any particular terminating witness contributes a guaranteed lower bound, and strengthening either the evidence for actions happening or for their terminating effects can only increase the clippedness.*

This is a typical pattern in the algebraic event calculus (Hyperseed-Concept **??***): existential search over possible witnesses becomes a join over an index set, and the order-theoretic properties (lower bounds, monotonicity) become immediate consequences of the quantale operations.*

Sketch. The witness inequality holds because *Clipped* is a $\oplus$-join over a set that includes that term. Monotonicity follows from monotonicity of $\otimes$ and $\oplus$. $\square$

Remark 1654. Proof sketch (strategy). *Use the universal property of joins: a join is above each joined element.*

Key step. *The specific pair (a, u) is among the indices being joined, so its term is bounded above by the join.*

Intuition. *"Clipped" means "there exists evidence of a terminator"; $\oplus$ is the algebraic stand-in for that existential.*

Remark 1655. *It is often helpful to separate two layers in the definition of Clipped: (i) for each candidate witness (a, u), the conjunction "$Happens(a, u)$ and $Terminates(a, f, u)$" is evaluated by $\otimes$, producing a single combined piece of evidence that f is terminated in the open interval (t_1, t_2); and (ii) these candidate pieces of evidence are pooled by $\oplus$ across all intermediate times and actions. The first layer corresponds to requiring both an occurrence and an appropriate effect; the second corresponds to allowing any intervening terminator to suffice.*

*In particular, in the $[0, 1]^2$ setting, if one coordinate tracks positive support and the other tracks negative support (or, more generally, two independent evidential channels), then Clipped can increase in either coordinate as soon as there is a single witness whose combined $\otimes$-value increases in that coordinate. This coordinatewise behavior is precisely what is needed later when inertia is formulated as a rule with a condition like "*not clipped*": the clippedness score provides a graded obstruction to persistence that can be compared and combined monotonically in the subsequent fixpoint computation.*

Lemma 36 (One-step inertia propagation bound)**.** *Let Φ be the inertia update operator (Def. 66):*

$$(\Phi HoldsAt)(f, t_2) := HoldsAt_0(f, t_2) \;\oplus\; \bigoplus_{t_1 < t_2} HoldsAt(f, t_1) \otimes \neg Clipped(f; t_1, t_2).$$

Then for any $t_1 < t_2$,

$$(\Phi HoldsAt)(f, t_2) \;\geq\; HoldsAt(f, t_1) \otimes \neg Clipped(f; t_1, t_2).$$

Remark 1656. *This lemma isolates a single contribution to inertia: if f held at some earlier time t_1, and there is strong evidence that it was* not *clipped between t_1 and t_2, then the update Φ ensures that f holds at t_2 with at least the composed strength. It is the quantale-valued analogue of the familiar persistence axiom.*

The reason to spell this out is practical: in implementations, one often wants interpretable justifications for why a fluent holds. This inequality tells you exactly which term in the big join witnesses that justification.

Remark 1657. *Two order-theoretic facts are being used implicitly here and will reappear throughout: (i) in any join-semilattice, a join dominates each of its summands, i.e. $\bigoplus_i x_i \geq x_j$ for every j; and (ii) $\oplus$ itself is a join-like operation, so for any a, b one has $a \oplus b \geq b$ (and also $a \oplus b \geq a$). In particular, even if $HoldsAt_0(f, t_2)$ is weak (or $\perp$), the joined inertia support still lower-bounds the total update.*

Note also that the term $HoldsAt(f, t_1) \otimes \neg Clipped(f; t_1, t_2)$ is a single causal path *from past to present: it composes (i) the degree to which f held at t_1 with (ii) the degree to which the interval $[t_1, t_2]$ is free of terminating events for f. The lemma says that Φ never discards such a candidate path; it can only keep it or be strengthened by other paths via $\oplus$.*

Sketch. Immediate: the right-hand term is one of the joined summands in Def. 66. □

Remark 1658. Proof sketch (strategy). *Again use the fact that a join dominates each summand.*

Key step. *The index t_1 is included in the join over all $t_1 < t_2$, so its corresponding term provides a lower bound.*

Intuition. *Inertia is modeled as "take the best surviving support from the past"; any particular past-support path is a candidate, and the operator keeps at least the best one via $\oplus$.*

Remark 1659. *For readers who want the inequality written as an explicit chain, one may unpack Def. 66 as follows. Let*

$$S := \bigoplus_{t<t_2} HoldsAt(f,t) \otimes \neg Clipped(f;t,t_2).$$

Then $(\Phi HoldsAt)(f,t_2) = HoldsAt_0(f,t_2) \oplus S \geq S$ by join-domination, and $S \geq HoldsAt(f,t_1) \otimes \neg Clipped(f;t_1,t_2)$ because t_1 is one of the indices in the join defining S. Chaining these inequalities yields the claimed bound.

Operationally, the lemma can be read as a local certificate*: to justify a lower bound on $(\Phi HoldsAt)(f,t_2)$, it suffices to exhibit one earlier witness time t_1 together with the corresponding unclipped evidence, without needing to inspect the other summands.*

Theorem 28 (Least fixpoint semantics for monotone temporal inference (helper restatement of Theorem 6))**.** *Assume T is finite and all event-calculus rules use only $\oplus$, $\otimes$, and monotone operations on V. Then the induced immediate-consequence operator (e.g. Φ) is monotone on the complete lattice $(V^{F\times T}, \leq)$ and hence has a least fixpoint.*

Remark 1660. *This theorem provides the semantic foundation for the quantale-valued event calculus: the meaning of the theory is given by the* least *stable assignment of truth-values to all fluent-time pairs that satisfies the rules. That least fixpoint corresponds to "nothing is believed unless forced by the rules," generalized to graded/paraconsistent belief.*

The result is important because it replaces ad hoc procedural evaluation with an order-theoretic guarantee: iterating the immediate-consequence operator from the bottom converges (in finitely many steps when T is finite) to a canonical model. This style of reasoning via fixed points is a recurring tool in analyzing self-referential or self-updating systems (see also [10] for related fixed-point analyses in agent goal dynamics), and it sits naturally within the process view (Hyperseed-Concept 140) where "what holds" is stabilized by iterated update.

Remark 1661. *A useful way to read the statement is to separate (a) the* domain *and (b) the* operator*. The domain $V^{F\times T}$ is the space of all functions assigning each fluent-time pair (f,t) a value in V; the order is pointwise: $X \leq Y$ iff $X(f,t) \leq Y(f,t)$ for all (f,t). Completeness then follows from the fact that arbitrary joins and meets can be taken pointwise, e.g.*

$$\Big(\bigoplus_{i\in I} X_i\Big)(f,t) = \bigoplus_{i\in I} X_i(f,t), \qquad \Big(\bigwedge_{i\in I} X_i\Big)(f,t) = \bigwedge_{i\in I} X_i(f,t),$$

so the Knaster–Tarski theorem applies as soon as monotonicity of the immediate-consequence map is established.

The finiteness of T is used for the computational reading (finite convergence of iteration). Existence of lfp *itself does not require T finite; it is guaranteed by Knaster–Tarski on any complete lattice. What finiteness buys is that the ascending chain produced by Kleene iteration from $\perp$ cannot increase indefinitely through distinct time-slices without eventually stabilizing in the finite product.*

Sketch. $V^{F\times T}$ is a complete lattice under pointwise order. Each rule contribution is monotone (Lemma 34), hence the overall operator is monotone. Apply Knaster–Tarski to obtain a least fixpoint. $\square$

Remark 1662. Proof sketch (strategy). *Prove the operator is monotone; then invoke the Knaster–Tarski theorem, which guarantees least and greatest fixpoints for monotone maps on complete lattices.*

Key steps. *(i) Completeness of $V^{F\times T}$ comes from taking joins/meets pointwise. (ii) Monotonicity is inherited from the rule constructors by Lemma 34. (iii) Knaster–Tarski supplies existence of* lfp.

Intuition. *The lattice is the space of all possible temporal valuations; the operator is "one round of reasoning." A least fixpoint is the smallest valuation that survives another round unchanged: the minimal stable story consistent with the rules.*

Remark 1663. *For later use, it is often convenient to recall the equivalent characterization of the least fixpoint:*

$$\mathrm{lfp}(\Phi) = \bigwedge\{X \in V^{F\times T} \mid \Phi(X) \le X\},$$

i.e. the meet of all pre-fixpoints*. This emphasizes why the semantics is conservative: any valuation that is stable (or over-approximates stability) must lie above* $\mathrm{lfp}(\Phi)$*. Dually,* $\mathrm{gfp}(\Phi) = \bigoplus\{X \mid X \le \Phi(X)\}$ *exists as well, but the event-calculus reading typically privileges* lfp *as the "minimal commitment" model.*

When implementing the iteration from bottom, one typically starts from the pointwise least element $\bot \in V^{F\times T}$ (assigning $\bot$ everywhere) and forms the chain $\bot \le \Phi(\bot) \le \Phi^2(\bot) \le \cdots$. Monotonicity ensures this is ascending, and any stage in the sequence provides an under-approximation to $\mathrm{lfp}(\Phi)$*, which is useful when one wants progressively refined bounds on $HoldsAt(f,t)$.*

29.6 Time contexts, similarity, and regularity predicates

Lemma 37 (Basic properties of similarity and TemporalSimilarity)**.** *Let $\pi : V \to [0,1]$ be monotone and define $sim_V(v,w) = 1 - |\pi(v) - \pi(w)|$ (Def. 68). Let sim_T be the average over fluents (Def. 68) and TemporalSimilarity be the threshold predicate (Def. 69). Then:*

1. *$sim_V(v,w) = sim_V(w,v)$ and $0 \le sim_V(v,w) \le 1$, with $sim_V(v,v) = 1$.*
2. *$sim_T(t_1,t_2) = sim_T(t_2,t_1)$ and $0 \le sim_T(t_1,t_2) \le 1$, with $sim_T(t,t) = 1$.*
3. *TemporalSimilarity is symmetric, and is reflexive whenever the threshold $\tau \le 1$.*
4. *If $\tau_1 \le \tau_2$ then $\mathit{TemporalSimilarity}_{\tau_2}(t_1,t_2) \to \mathit{TemporalSimilarity}_{\tau_1}(t_1,t_2)$.*

Remark 1664. *The map $\pi : V \to [0,1]$ is a chosen* projection *from p-bit values to a single scalar—for instance, one might take $\pi(v) = v^+$ to measure "support" alone, or something more nuanced. Similarity $sim_V(v,w)$ is then the simplest possible metric-like notion: values are similar when their projected scalars are close. The time similarity sim_T averages this across all fluents, producing a single number in* $[0,1]$ *that summarizes how alike two timepoints look in the given time context (Def. 67).*

The lemma collects basic sanity properties: symmetry, boundedness, reflexivity, and monotonicity in the threshold. These are not deep, but they are the kinds of properties one needs later when building higher-level reasoning about regularity (Hyperseed-Concept **??***) and when interpreting temporal clustering or compression as abstraction.*

Sketch. (1) Absolute value is symmetric and bounded; (2) averages preserve symmetry and bounds; (3) follows from (1–2); (4) is threshold monotonicity. □

Remark 1665. Proof sketch (strategy). *Reduce everything to elementary properties of* $|\cdot|$ *and of averaging.*

Key steps. *(i)* $|\pi(v) - \pi(w)| = |\pi(w) - \pi(v)|$ *gives symmetry. (ii) Since* $\pi(v) \in [0, 1]$*, the difference lies in* $[-1, 1]$*, so* $1 - |\cdot|$ *lies in* $[0, 1]$*. (iii) Averaging preserves inequalities and range. (iv) Threshold predicates are monotone by definition.*

Intuition. *Similarity is engineered to behave like a sane resemblance score; the lemma verifies it does so.*

Lemma 38 (Continuity gives a projection-difference bound)**.** *If a fluent* f *is continuous (Def. 70) with parameter* $\eta \in (0, 1]$*, then for any* t_1, t_2*,*

$$TemporalSimilarity(t_1, t_2) \to |\pi(HoldsAt(f, t_1)) - \pi(HoldsAt(f, t_2))| \leq 1 - \eta.$$

Remark 1666. *Here "continuity" is a regularity condition on a fluent: whenever two times are deemed similar enough (TemporalSimilarity holds), the fluents value cannot change too much (after projection by* π*). The lemma simply rewrites this in the more familiar form of an upper bound on a difference.*

This matters because it turns a similarity-based condition into an inequality that can be composed with other numerical reasoning. In effect, it lets one treat TemporalSimilarity as a kind of control on variation, linking the qualitative predicate to quantitative bounds.

Sketch. Def. 70 gives $sim_V(HoldsAt(f, t_1), HoldsAt(f, t_2)) \geq \eta$. By Def. 68, $sim_V = 1 - |\pi(\cdot) - \pi(\cdot)|$, so $1 - |\Delta| \geq \eta$, i.e. $|\Delta| \leq 1 - \eta$. □

Remark 1667. Proof sketch (strategy). *Substitute the definition of* sim_V *and rearrange.*

Key step. *The transformation from* $1 - |\Delta| \geq \eta$ *to* $|\Delta| \leq 1 - \eta$ *is purely algebraic, but it is the step that makes the condition operational.*

Intuition. *"High similarity" means "small distance," because similarity was defined as* $1 -$ *distance.*

Lemma 39 (Increasing and decreasing imply constancy)**.** *Fix* $(T, <)$ *and projection* π *(Def. 72). If* f *is both increasing and decreasing, then for all* $t_1 < t_2$*,*

$$\pi(HoldsAt(f, t_1)) = \pi(HoldsAt(f, t_2)).$$

So $\pi(HoldsAt(f, t))$ *is constant along each* $<$*-chain.*

Remark 1668. *This lemma is an order-theoretic truism with a useful interpretive punch: a quantity that never goes down and never goes up is constant. Here the quantity is the projected fluent value along the proto-time order.*

Its role is to show how qualitative monotonicity constraints collapse degrees of freedom. In a system where fluents represent properties evolving through time, imposing both monotone directions forces stasis (at least in π*), which can be used either as a diagnostic (your constraints are too strong) or as a characterization (the fluent is invariant).*

Sketch. Increasing gives $\pi(t_1) \leq \pi(t_2)$, decreasing gives $\pi(t_1) \geq \pi(t_2)$; hence equality. □

Remark 1669. Proof sketch (strategy). *Squeeze the value between itself: if $a \leq b$ and $a \geq b$, then $a = b$.*

Key step. *The lemma relies only on antisymmetry of $\leq$ on $[0, 1]$, not on any special property of proto-time.*

Intuition. *Think of a curve that is everywhere nondecreasing and everywhere nonincreasing; the only such curve is flat.*

29.7 Functorial process view: composition along proto-time

Lemma 40 (Functorial composition along proto-time)**.** *Let T be the thin category generated by $(T, <)$ (Def. 73), and let $S : T \to Sys$ be a process (functor). If $t_1 < t_2 < t_3$, then the induced transition morphisms satisfy*

$$S(t_1 \to t_3) = S(t_2 \to t_3) \circ S(t_1 \to t_2).$$

Remark 1670. *This lemma expresses, in categorical language, the minimal coherence one expects of "process" (Hyperseed-Concept 140): going from t_1 to t_3 in one step must agree with going from t_1 to t_2 and then from t_2 to t_3. The thin category associated to a strict partial order has at most one arrow between any two objects, so the only question is whether a process respects this compositional structure.*

Its importance is conceptual unity. It is one of the places where the formalism aligns with a process ontology in the Whiteheadian spirit [15]: what persists across time is not a static substance but a web of transitions, and consistency means that these transitions compose. It also complements the event-calculus fixpoint view: both are ways of ensuring that temporal evolution is not arbitrary but structure-preserving.

Sketch. In the thin category, $(t_1 \to t_3)$ is the composite of $(t_1 \to t_2)$ and $(t_2 \to t_3)$. A functor preserves identity and composition, hence the equality. □

Remark 1671. Proof sketch (strategy). *Use the defining property of a functor: it preserves composition.*

Key step. *In a thin category generated by an order, the composite arrow $(t_1 \to t_2) \circ (t_2 \to t_3)$ is* by construction *the arrow $(t_1 \to t_3)$. Functoriality transfers this identity into Sys.*

Intuition. *If a process is a lawful passage, it cannot depend on whether you regard an interval as one stretch or two consecutive stretches; the "meaning" of the passage must be compositional.*

Remark 1672. *A useful way to read the statement is that S assigns to each comparable pair $t < t'$ a morphism in Sys that can be interpreted as an* evolution map *(or transition) from the system-at-t to the system-at-t'. The lemma then says that these evolution maps are compatible with* refinement of a proto-time interval*: if one refines the passage $[t_1, t_3]$ by inserting an intermediate moment t_2, the "overall" transition is unchanged, because it is determined by composing the refined transitions.*

This is exactly the categorical notion of path-independence *in a poset-shaped index category: there may be multiple ways to witness $t_1 < t_3$ by a chain of inequalities, but in a thin category all such chains represent the same unique arrow $t_1 \to t_3$. A functor cannot distinguish between these witnesses; it must send the unique arrow to a unique morphism in Sys, forcing all corresponding composites in Sys to agree. In this sense, the lemma is not an extra axiom on top of functoriality; rather, it is an unpacking of what functoriality means when the domain is generated by an order relation.*

Remark 1673. *The identity part of functoriality, though not written in Lemma 40, is often interpreted as the "no time passes" constraint: for each t there is an identity arrow $\mathrm{id}_t : t \to t$ in T, and functoriality forces $S(\mathrm{id}_t) = \mathrm{id}_{S(t)}$. Together with composition, this says that "doing nothing" is represented by an identity morphism and that successive passages concatenate without ambiguity. In applications, these two properties typically underwrite invariance principles (what is preserved by identity) and concatenation principles (how evolutions combine).*

Corollary 5 (Iterated composition along a chain)**.** *Let T and $S : T \to Sys$ be as in Lemma 40. For any finite chain $t_0 < t_1 < \cdots < t_n$, one has*

$$S(t_0 \to t_n) = S(t_{n-1} \to t_n) \circ \cdots \circ S(t_0 \to t_1).$$

Sketch. Apply Lemma 40 repeatedly (or argue by induction on n) using associativity of composition in Sys. □

Remark 1674. *Corollary 5 makes explicit the "independence from discretization" intuition: if one approximates a passage from t_0 to t_n by inserting more intermediate proto-times, the composite of the finer-grained transition morphisms must still agree with the coarse-grained transition. This is one categorical expression of a Markovian or semigroup-like intuition, but without requiring any additional analytic structure: it is a purely structural compatibility between (i) the order-theoretic shape of proto-time and (ii) the composition law of system morphisms in Sys.*

30 Helper theorems for effort, resistance, and simplicity (Section 8)

Standing assumptions and notation. Fix a context C. Let $E := ([0,\infty], \leq_E, \bigvee_E, \otimes_E, 0)$ be the effort quantale of Def. 74, where $\leq_E$ is the reversed numerical order, $\bigvee_E = \inf$ (numerical minimum), and $\otimes_E = +$ (sequential composition of costs). In particular, $0 \in [0,\infty]$ functions as the tensor unit for $\otimes_E$, so that composing a process with a zero-effort process leaves the effort unchanged, and ∞ serves as the absorbing/impossible cost that dominates sequential composition when present. The choice of $[0,\infty]$ (rather than $[0,\infty)$) ensures that infeasible or undefined operations can be represented internally without leaving the quantale.

Let P be a set of processes with effort assignment $\mathrm{Eff}_C : P \to [0,\infty]$ (Def. 75). One should read $\mathrm{Eff}_C(p)$ as a context-dependent cost model (time, energy, data requirements, or any aggregate resource) rather than as an intrinsic property of p in isolation; changing C may change what counts as "expensive" even for the same underlying algorithmic step. The separation between the abstract process set P and the numerical valuation Eff_C is used repeatedly in later statements to phrase claims as inequalities in the quantale rather than as ad hoc estimates.

Let X be a finite universe and $\mathcal{H}_C \subseteq \mathcal{P}(X \times X)$ the admissible indistinction policies (Def. 76). For policies $H, H' \in \mathcal{H}_C$, opening/closing are as in Def. 77. Policy effort $\mathrm{Eff}_C : \mathcal{H}_C \to [0,\infty]$ is antitone w.r.t. inclusion and marginal effort is $\Delta\mathrm{Eff}_C(H \to H') := \max(0, \mathrm{Eff}_C(H') - \mathrm{Eff}_C(H))$ (Def. 78). Resistance is identified with $\Delta\mathrm{Eff}_C$ and submission is the case $\Delta\mathrm{Eff}_C(H \to H') = 0$ (Def. 79). The antitonicity convention encodes that allowing *more* indistinction (larger H) should not require *more* effort from the observer: once one relaxes discriminations, one can always "ignore" the additional distinctions for free, so the required effort is weakly smaller. The positive-part definition of $\Delta\mathrm{Eff}_C$ is important for directional comparisons: it distinguishes a genuine increase in required effort from a change that merely makes the task easier, and it makes "submission" behave like a zero-resistance edge in the policy graph (so that sequences of submissions remain submissions under addition of marginal efforts).

Simplicity $s_C(x)$ is the infimum of representation effort over admissible representations of x (Def. 80). Weakness $w(H)$ is monotone w.r.t. inclusion and satisfies the monotonic sanity theorem with effort (Thm. 7). Task adequacy $\mathrm{Adeq}_C(H)$, feasible set F_C, and MRE are as in Defs. 81–82; upward closure and the maximally open feasible policy H_b are as in Thm. 8. The infimum in the definition of $s_C(x)$ should be read operationally as "best available description under the rules of C": it permits multiple admissible representation schemes while still producing a single scalar that can be compared across objects. Monotonicity of weakness $w(H)$ with respect to inclusion matches the reading that opening a policy (adding more indistinction pairs) can only increase the space of confusions available to an adversary or learner, hence cannot decrease weakness; Thm. 7 then links this monotonicity to the effort ordering so that "easier" policies are not accidentally judged "stronger". For feasibility, the upward-closure property emphasizes that if a policy H is feasible (adequate at tolerable effort), then any further opening $H' \supseteq H$ remains feasible because it only relaxes constraints; the maximally open feasible policy H_b packages this closure into a canonical boundary object that can be used as a single representative of the feasible region.

Compositional simplicity s^*_C for a combination system $(X_C, *, e)$ with overhead t_C is Def. 84, with Prop. 4 and Thm. 9. Generalized description systems and generalized Kolmogorov complexity $K_C(x)$ are Defs. 85–86 with structural/compositional equivalence Prop. 5. The role of the overhead t_C is to isolate the "glue cost" of composition (parsing, interfacing, protocol negotiation, or other coordination burdens) from the base costs of the parts, so that s^*_C measures a compositional tradeoff rather than merely restating s_C. Prop. 4 and Thm. 9 are used later to justify that, under suitable regularity, compositional simplicity behaves like a controlled relaxation of plain simplicity: building an object from simpler parts can be cheaper, but not arbitrarily cheaper unless the overhead model permits it. Finally, the generalized description-system viewpoint provides a bridge to more classical complexity measures: $K_C(x)$ is a context-indexed analogue of description length, and Prop. 5 ensures that (within the permitted structural hypotheses) the "program-like" and "composition-like" formulations coincide up to the equivalence notion fixed there.

Remark 1675 (Intuition on the standing notation and conventions)**.** *The effort quantale E is a precise way to say: "smaller numerical cost means better / easier." This is why $\le_E$ is defined as the* reversed *numerical order: when we write $a \le_E b$ we are declaring that a is* no more effortful *than b in the sense relevant for the quantale. Concretely, if a process costs* 3 *units and another costs* 5 *units numerically, then the former should count as "larger" in the algebra of feasibility/ease; reversing the order makes the quantale joins and monotonicity statements align with that intuition (Hyperseed-Concepts 100, 158). Equivalently, one can keep the usual numerical order but then every monotonicity statement about "increasing effort" would have to be rewritten with order reversal; the present convention avoids that constant translation and lets inequalities read in the intended direction. This becomes especially convenient when effort is combined with other ordered quantities (e.g., weakness) via monotone maps: the categorical/quantale apparatus then directly reflects "harder implies no better guarantee"-type reasoning without sign changes.*

The symbol $\bigvee_E$ denotes the quantale join. Here $\bigvee_E =$ inf *(numerical minimum), reflecting the idea that when one may choose among multiple ways to achieve a result, the effective effort is the least effort among the options. The tensor $\otimes_E$ is sequential composition; here it is simply $+$, reflecting that doing p and then q generally costs the sum of the costs. These conventions place effort in the same algebraic family as the classic "tropical" or "min-plus" arithmetic often used for shortest paths; the present development uses it specifically to support the notions of resistance/submission and the effort–weakness tradeoff [3, 2] (Hyperseed-Concept 143). From this perspective, a statement such as "the effort of a composite plan is the tensor of the efforts" becomes an instance of a general algebraic law (associativity, unitality, and distributivity over joins), rather than a special-*

case arithmetic fact. Likewise, the interpretation of $\bigvee_E$ as "choose the best available option" is what allows later lemmas to take infima over families of candidate procedures without leaving the formal setting.

For policies $H \subseteq X \times X$, inclusion $H \subseteq H'$ should be read as "H' permits at least as much indistinction/coarse-graining as H." Thus an opening *is movement to a superset (loosening the observer's discriminations), while a* closing *is movement to a subset (tightening distinctions). The marginal effort $\Delta\mathrm{Eff}_C(H \to H') = \max(0, \mathrm{Eff}_C(H') - \mathrm{Eff}_C(H))$ is the positive-part operator applied to an effort difference; it formalizes the idea that only* additional *required effort counts as resistance. In particular, if $H \subseteq H'$ is an opening, then antitonicity suggests $\mathrm{Eff}_C(H') \leq \mathrm{Eff}_C(H)$ numerically, so $\Delta\mathrm{Eff}_C(H \to H')$ is typically 0; this is the formal counterpart of "relaxing constraints should not be resisted." Conversely, for a closing $H' \subseteq H$ one expects (numerically) $\mathrm{Eff}_C(H') \geq \mathrm{Eff}_C(H)$, and then $\Delta\mathrm{Eff}_C(H \to H')$ records the extra work needed to regain discriminatory power. This directional asymmetry is why resistance is defined on ordered pairs $(H \to H')$ rather than as a symmetric distance: opening and closing have different operational meanings, and the cost of moving between policies depends on the direction of change.*

30.1 Effort quantale and effort of processes

Lemma 41 (Distributivity law (cost quantale))**.** *For any $a \in [0, \infty]$ and any set $S \subseteq [0, \infty]$,*

$$a + \inf S \;=\; \inf_{s \in S}(a + s), \qquad \inf S + a \;=\; \inf_{s \in S}(s + a).$$

Remark 1676 (What the lemma says, and why it matters)**.** *This lemma states that adding a fixed cost a "commutes" with taking the best available option (the infimum) among a family of costs. In plain terms: if you must pay a no matter what, then choosing the cheapest option from S and then adding a yields the same total as adding a to each option first and then choosing the cheapest.*

This is important because it is exactly the algebraic backbone that makes the min-plus effort structure behave like a well-formed quantale: sequential composition $(+)$ distributes over choice $(\inf)$. Later arguments about infima over representations or parse trees tacitly rely on being able to "push" fixed overhead through minima.

Remark 1677. ***Edge cases and the role of*** $[0, \infty]$ *Two minor points are worth keeping in view because they occur implicitly later. First, the lemma is stated in the extended nonnegative reals $[0, \infty]$, so $\inf S$ is always defined (possibly 0 or ∞), and addition is interpreted with the usual convention $a + \infty = \infty$ for all $a \in [0, \infty]$. In particular, if $S = \varnothing$, then $\inf S = \infty$ and both sides reduce to $a + \infty = \infty$ (respectively $\infty + a = \infty$), so the identities remain valid even for empty families of options.*

Second, the statement is really about the order structure: it uses only that the map $x \mapsto a + x$ is monotone and preserves arbitrary infima. This is why analogous distributivity identities continue to hold for many other "cost" structures used in semantics, provided they are complete lattices with a compatible monoidal action.

Sketch. This is exactly the statement that $+$ distributes over arbitrary infima in Def. 74. It can also be checked directly from basic properties of infimum in $[0, \infty]$. $\square$

Remark 1678 (Proof sketch and intuition)**.** *The strategy is to use the defining property of $\inf S$: it is the greatest lower bound of S. Adding a is order-preserving in the usual numerical order, so it sends lower bounds of S to lower bounds of $\{a + s : s \in S\}$, and likewise it sends the greatest lower bound to the greatest lower bound. Geometrically, if you picture the set S as points on the number* *line, adding a simply shifts the entire set to the right by a; the leftmost point (or limiting leftmost point) shifts by the same amount.*

Remark 1679 (A slightly more explicit inequality argument)**.** *For readers who prefer to see the two inequalities separately: let $m = \inf S$. Since $m \le s$ for all $s \in S$, monotonicity gives $a + m \le a + s$ for all $s \in S$, hence $a+m$ is a lower bound of $\{a+s : s \in S\}$, so $a+m \le \inf_{s\in S}(a+s)$. Conversely, if b is any lower bound of $\{a+s : s \in S\}$, then $b \le a+s$ for all $s \in S$, so $b-a \le s$ for all $s \in S$ (in the extended-real sense), hence $b - a \le \inf S = m$, so $b \le a + m$. Taking $b = \inf_{s\in S}(a + s)$ yields $\inf_{s\in S}(a+s) \le a+m$, giving equality. The right-hand identity $\inf S + a = \inf_{s\in S}(s+a)$ is the same argument, using commutativity of $+$ in $[0,\infty]$ (or simply re-running the monotonicity argument for $x \mapsto x + a$).*

Lemma 42 (Multi-step sequential subadditivity)**.** *Assume the sequential subadditivity axiom of Def. 75: $\mathrm{Eff}_C(p; q) \le \mathrm{Eff}_C(p) + \mathrm{Eff}_C(q)$. Then for any composable sequence $p_1; \cdots ; p_n$,*

$$\mathrm{Eff}_C(p_1; \cdots ; p_n) \ \le \ \sum_{i=1}^{n} \mathrm{Eff}_C(p_i).$$

Remark 1680 (What the lemma says, and why it matters)**.** *The lemma extends a two-step bound to an n-step bound: if doing p then q never costs more than doing them separately and summing, then the same is true for any finite chain. Intuitively, "any efficiencies of composition" are allowed (the inequality points in the permissive direction), but there can be no mysterious superlinear penalty that appears only after many steps.*

This kind of inequality is the minimal tool needed to compare a complex routine to the sum of its parts, which is precisely what later compositional simplicity and description-length arguments do: they break constructions into smaller pieces and add overheads.

Remark 1681 (Associativity and parenthesization conventions)**.** *The expression $p_1; \cdots ; p_n$ implicitly assumes that sequential composition is associative up to the intended notion of equality (or at least that Eff_C is insensitive to the choice of parenthesization). Concretely, one can read $p_1; \cdots ; p_n$ as the left-associated composite $((p_1; p_2); \cdots); p_n$, which is the form used in the induction proof. This is the only place where a bookkeeping convention is needed: the inequality then follows by repeated application of the two-step axiom, regardless of whether there may be other equivalent bracketings.*

Sketch. Induct on n. The case $n = 2$ is Def. 75. For $n + 1$, apply Def. 75 to $(p_1; \cdots ; p_n); p_{n+1}$ and then apply the inductive hypothesis. □

Remark 1682 (Proof sketch and intuition)**.** *The proof is the familiar "parenthesize-and-repeat" technique. One first groups the first n steps into a single macro-process $(p_1; \cdots ; p_n)$ and then applies the given two-step inequality to append p_{n+1}. The inductive hypothesis supplies the needed bound on the macro-process. Visually, one may imagine a chain whose total length is at most the sum of segment lengths; adding one more segment preserves the bound.*

Remark 1683 (Related consequence: bounded overhead accumulation)**.** *A useful way to rephrase the lemma is that any fixed per-stage upper bound propagates linearly: if $\mathrm{Eff}_C(p_i) \le M$ for all i, then $\mathrm{Eff}_C(p_1; \cdots ; p_n) \le nM$. Later, when "effort" is used to upper-bound the resource expenditure of a composite construction, this is the step that converts local (componentwise) estimates into a global estimate for a whole pipeline.*

Lemma 43 (Nested choice collapses to a global minimum)**.** *Assume the choice axiom of Def. 75: if p is implemented by choosing between p_1 and p_2, then $\mathrm{Eff}_C(p) = \min(\mathrm{Eff}_C(p_1), \mathrm{Eff}_C(p_2))$. If p can be implemented by choosing among a finite set $\{p_i\}_{i=1}^k$ via a binary-choice tree, then*

$$\mathrm{Eff}_C(p) = \min_{1 \le i \le k} \mathrm{Eff}_C(p_i).$$

Remark 1684 (What the lemma says, and why it matters)**.** *This lemma says that if "choice" is evaluated by taking the cheaper branch, then it does not matter how one nests binary choices: after all the nesting, the effort is simply the minimum among all leaf options. A simple example is a decision procedure that chooses between algorithms A and B, and then, if it chose A, chooses between A_1 and A_2; the overall effort is just* $\min(\mathrm{Eff}(A_1), \mathrm{Eff}(A_2), \mathrm{Eff}(B))$.

The point is conceptual as much as technical: it justifies treating a finite menu of alternatives as a single "min" operation, which is the algebraic dual of saying that opening up more options cannot increase the minimal required effort. This resonates with the later policy-union construction H_b and with compositional search over parse trees.

Remark 1685 (Ties, duplicates, and "do-nothing" options)**.** *Because the evaluation is by* min*, ties between branches are harmless: if two leaves have the same effort, the overall effort is that common value, and nothing depends on which tie-breaking rule an implementation might use. Likewise, duplicates among the p_i (or syntactically different branches with the same effort) do not change the result. This matches the intended interpretation: adding redundant alternatives cannot make the best achievable effort worse, and adding an explicitly available "do-nothing" or "fallback" branch simply introduces one more candidate in the global minimum.*

Sketch. Induct on the size of the choice tree: each binary decision replaces a node effort by the minimum of its children, so the root evaluates to the minimum over all leaves. □

Remark 1686 (Proof sketch and intuition)**.** *The high-level strategy is to observe that a binary-choice tree is evaluated bottom-up: every internal node applies the operation* min *to its two children. Since* min *is associative and commutative over finite sets (in the sense that repeated pairwise minima yield the overall minimum), the final value at the root must be the minimum over all leaves. One can picture water flowing downhill in a branching channel: it will always end up at the lowest reachable point, regardless of the branching pattern.*

Remark 1687 (Connection to finite infima)**.** *Since* $\min_{1 \le i \le k}$ *is the infimum over a finite set, this lemma can also be read as the finite version of replacing nested binary infima by a single infimum over all leaves. This is exactly the form used when one enumerates a finite family of candidate representations (or parse trees) and then defines the effort of the overall procedure to be the least effort among them. In that sense, the lemma is the operational counterpart of the algebraic identity that finite infima are computed by iterated binary infima.*

30.2 Policies, opening/closing, and resistance/submission

Lemma 44 (Compositionality of opening and closing)**.** *Let $H_0, H_1, H_2 \in \mathcal{H}_C$.*

1. *If $H_0 \subseteq H_1 \subseteq H_2$, then $H_0 \to H_2$ is an opening.*
2. *If $H_2 \subseteq H_1 \subseteq H_0$, then $H_0 \to H_2$ is a closing.*

Remark 1688 (What the lemma says, and why it matters). *An "opening" is defined purely by inclusion $H \subseteq H'$, and a "closing" by reverse inclusion. This lemma observes that these notions are stable under multi-step motion: if you open in stages, you have opened overall; if you close in stages, you have closed overall. The content is logically elementary, but it matters because later we will compare marginal efforts along multi-step paths, and we must know that the qualitative direction (opening vs. closing) is well-defined for the whole path.*

Conceptually, this is the set-theoretic shadow of the more phenomenological idea that one can relax distinctions gradually without ever reversing the direction of relaxation (Hyperseed-Concepts 125, 72).

Sketch. Both are immediate from Def. 77 and transitivity of $\subseteq$. □

Remark 1689 (Proof sketch and intuition). *The proof is a one-line use of transitivity: inclusion composes. If H_0 is contained in H_1 and H_1 is contained in H_2, then H_0 is contained in H_2. Visually, if each step enlarges your permissible indistinction relation, then the endpoint is an enlargement of the starting point.*

Lemma 45 (Marginal effort for opening vs closing). *Assume policy effort is antitone (Def. 78): $H \subseteq H' \to \mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(H')$. Then:*

1. *If $H \to H'$ is an opening, then $\Delta\mathrm{Eff}_C(H \to H') = 0$.*
2. *If $H \to H'$ is a closing, then $\Delta\mathrm{Eff}_C(H \to H') = \mathrm{Eff}_C(H') - \mathrm{Eff}_C(H) \geq 0$.*

Remark 1690 (What the lemma says, and why it matters). *This lemma makes precise a guiding intuition:* opening should not cost extra effort *in the minimal model, whereas* closing may. *Under antitonicity, larger policies (more indistinction permitted) are easier/cheaper, so moving to a superset cannot increase effort. Therefore the positive part* $\max(0, \mathrm{Eff}_C(H') - \mathrm{Eff}_C(H))$ *vanishes.*

The asymmetry between opening and closing is philosophically suggestive: it encodes a directionality reminiscent of thermodynamic coarse-graining (though here it is purely definitional and order-theoretic). In the later MRE result, this is what makes the "most open feasible" policy H_b into an effort minimizer (Hyperseed-Concepts 100, 158).

Sketch. (1) Opening means $H \subseteq H'$, so antitonicity gives $\mathrm{Eff}_C(H') \leq \mathrm{Eff}_C(H)$. Thus $\max(0, \mathrm{Eff}_C(H') - \mathrm{Eff}_C(H)) = 0$. (2) Closing means $H' \subseteq H$, so antitonicity gives $\mathrm{Eff}_C(H') \geq \mathrm{Eff}_C(H)$, so the max is attained by the difference. □

Remark 1691 (Proof sketch and intuition). *The proof is a direct case analysis on the sign of the difference* $\mathrm{Eff}_C(H') - \mathrm{Eff}_C(H)$. *Antitonicity tells you the sign once you know the inclusion direction. The operator* $\max(0, \cdot)$ *then acts as a diode: negative differences are clipped to* 0 *(no resistance), positive differences pass through unchanged (resistance equals the increase). One may picture opening as "releasing a brake" and closing as "tightening a brake" (Hyperseed-Concept 183).*

Corollary 6 (All openings are submissions in the minimal model). *Under the assumptions of Lemma 45, every opening $H \to H'$ satisfies submission: $\Delta\mathrm{Eff}_C(H \to H') = 0$.*

Remark 1692 (What the corollary says, and why it matters). *This corollary identifies a clean conceptual alignment: in the minimal model, opening is not merely "non-resistant" but is literally the definition of submission (zero marginal effort). This clarifies how resistance/submission are not separate phenomenological primitives here, but arise from the effort calculus.*

This is also a warning label: if one wants a model where opening can be difficult (e.g. because letting go of distinctions can require cognitive work), then one must weaken the antitonicity assumption or refine the effort definition. The present result is therefore a baseline, not a metaphysical necessity (Hyperseed-Concepts 125, 183).

Sketch. Immediate from Lemma 45(1) and Def. 79. □

Remark 1693 (Proof sketch and intuition)**.** *The proof simply matches two definitions: Lemma 45(1) gives the numeric condition $\Delta\mathrm{Eff}_C = 0$ for openings, and Def. 79 names that condition "submission." Conceptually, the corollary says that in this model, submission is nothing over and above the absence of additional cost.*

Lemma 46 (Triangle inequality for resistance (path subadditivity))**.** *For any real numbers a, b, c,*

$$\max(0, c-a) \;\le\; \max(0, b-a) + \max(0, c-b).$$

Hence for any policies H_0, H_1, H_2,

$$\Delta\mathrm{Eff}_C(H_0 \to H_2) \;\le\; \Delta\mathrm{Eff}_C(H_0 \to H_1) \;+\; \Delta\mathrm{Eff}_C(H_1 \to H_2).$$

Remark 1694 (What the lemma says, and why it matters)**.** *The first inequality is a purely numerical statement about the "positive part" function $x \mapsto \max(0, x)$: the positive part of the total change from a to c is bounded by the sum of the positive parts of the two changes $a \to b$ and $b \to c$. Interpreted for policies, it says resistance is* subadditive along a path*: going from H_0 to H_2 directly cannot require more marginal effort than taking a detour through H_1 and paying marginal effort at each step.*

This matters because it gives resistance a weak "metric-like" behavior (though it need not be symmetric, nor satisfy identity of indiscernibles). It also connects naturally to the idea that resistance is about where effort increases*, and increases can be accounted for incrementally (Hyperseed-Concept 158).*

A useful way to read the inequality is: any decrease along the path is "free" from the perspective of resistance (since the positive part ignores negative changes), and so the only contribution comes from the segments where effort goes up. In particular, if $a \le b \le c$, then all changes are nonnegative and the inequality becomes an equality $(c-a) = (b-a) + (c-b)$; whereas if one segment goes down (say $a < b$ but $c < b$), then the total increase from a to c may be smaller than the sum of segmentwise increases because the intermediate rise can be "undone" by a later drop. The lemma asserts that even in such mixed cases, counting rises separately along the broken line $a \to b \to c$ can only overestimate (never underestimate) the rise seen by jumping directly from a to c.

Equivalently, the statement can be viewed as a triangle-inequality analogue for the one-sided "distance" $d_+(u, v) := \max(0, v-u)$ on $\mathbb{R}$: it always holds that $d_+(a, c) \le d_+(a, b) + d_+(b, c)$. When resistance is defined via d_+ applied to effort levels, this immediately yields the corresponding path subadditivity for resistance values.

Sketch. Let $x = b - a$ and $y = c - b$, so $c - a = x + y$. Note $\max(0, x) \ge x$ and $\max(0, y) \ge y$, hence $\max(0, x) + \max(0, y) \ge x + y = c - a$. Also $\max(0, x) + \max(0, y) \ge 0$, so it is at least $\max(0, c-a)$. Substitute $a = \mathrm{Eff}_C(H_0)$, $b = \mathrm{Eff}_C(H_1)$, $c = \mathrm{Eff}_C(H_2)$.

For completeness, one can also see the inequality directly by a short case split on the signs of x and y. If $x \ge 0$ and $y \ge 0$, then $\max(0, x) + \max(0, y) = x + y = \max(0, x + y)$. If $x \ge 0$ and $y < 0$, then $\max(0, x) + \max(0, y) = x$, while $\max(0, x + y) \le \max(0, x) = x$ because adding a negative amount cannot increase the positive part beyond x. The case $x < 0$ and $y \ge 0$ is symmetric, yielding $\max(0,x)+\max(0,y)=y\geq\max(0,x+y)$. Finally, if $x<0$ and $y<0$, then both sides are 0 since $x+y<0$. This is the same numerical fact expressed in the more algebraic inequalities above, but it makes explicit that the only nontrivial situation is when one increment is positive and the other is negative. $\square$

Remark 1695 (Proof sketch and intuition)**.** *The key move is to rewrite the total difference as a sum of incremental differences:* $c-a=(b-a)+(c-b)$. *The positive-part function is convex enough that* $\max(0,x)+\max(0,y)$ *always dominates both* $x+y$ *and* 0, *hence dominates* $\max(0,x+y)$. *Visually, if you graph* $f(u)=\max(0,u)$, *the inequality expresses that the "upward jump" from* a *to* c *is no bigger than the sum of the two upward jumps along the broken line* $a\to b\to c$.

In policy terms, if $\mathrm{Eff}_C(H)$ *is interpreted as the effort level required by the agent (under constraint/context* C*) to implement or sustain policy* H*, then the resistance of changing from* H_i *to* H_j *is computed by applying the positive part to the effort difference. The lemma then says that if one contemplates a transition that passes through an intermediate policy* H_1*, the total "paid" resistance is the sum of the positive parts at each step, and this can only be larger than the resistance of moving directly from* H_0 *to* H_2*. Intuitively: intermediate overexertion is still overexertion, even if the endpoint ends up being easier than the intermediate.*

A further consequence that is often used implicitly is the extension to longer chains: by iterating the same inequality, for any sequence $H_0,H_1,\dots,H_n$ *one has*

$$\max\bigl(0,\mathrm{Eff}_C(H_n)-\mathrm{Eff}_C(H_0)\bigr)\leq\sum_{k=1}^{n}\max\bigl(0,\mathrm{Eff}_C(H_k)-\mathrm{Eff}_C(H_{k-1})\bigr),$$

so resistance accumulates at most additively when one decomposes a change into multiple stages. This is exactly the sense in which resistance can be "accounted for incrementally": the model never misses an increase by splitting into smaller steps, but it may double-count increases that are later reversed by decreases, which is appropriate if increases themselves are what generate resistance.

30.3 Simplicity as minimum representational effort and weakness duality

Lemma 47 (Representation upper bound)**.** *For any* $x\in X_C$ *and any admissible representation* $r\in R_C(x)$,

$$s_C(x)\ \leq\ \mathrm{Eff}_C(r).$$

Remark 1696 (What the lemma says, and why it matters)**.** *By definition, simplicity* $s_C(x)$ *is the least effort among all admissible ways to represent* x*. This lemma merely states the obvious consequence: any particular representation cannot beat the optimum. A simple example: if* x *has two encodings costing* 10 *and* 12*, then* $s_C(x)=10$*, and indeed* $10\leq 12$ *for the second encoding.*

The usefulness is methodological: whenever one constructs a representation explicitly (a code, a proof, a parse tree), this lemma turns that construction into an upper bound on simplicity. In complexity-theoretic language, it is the basic "exhibit a program" technique (Hyperseed-Concept 169; cf. [16]).

Remark 1697 (A small but useful refinement: infimum vs. minimum)**.** *Because Def. 80 uses an infimum, one should not silently assume that an optimal representation achieving* $s_C(x)$ *necessarily exists. For example, it is consistent with the definition that there is a sequence of admissible representations* (r_n) *with* $\mathrm{Eff}_C(r_n)\downarrow s_C(x)$*, while no single* r *attains* $\mathrm{Eff}_C(r)=s_C(x)$*. The inequality in Lemma 47 therefore has the correct logical strength: it gives an upper bound from* any *exhibited* r*, without requiring a minimizer.*

In particular, the lemma supports a common style of argument: to show that $s_C(x)$ is "small", it suffices to provide one concrete representation whose effort is small, even if the true optimum is approached only asymptotically in the representation space. Conversely, when lower bounds are sought, one must reason about all *admissible $r \in R_C(x)$, since no single worst-case witness suffices.*

Sketch. By Def. 80, $s_C(x) = \inf\{\mathrm{Eff}_C(r') : r' \in R_C(x)\}$, and an infimum is bounded above by any element of the set. $\square$

Remark 1698 (Proof sketch and intuition)**.** *The proof is an instance of a general order fact: the infimum of a set is below every element of the set. Intuitively, $s_C(x)$ is what you get when you "shop around" among all representations; any one receipt r provides a concrete price tag, and the best possible price cannot be higher than that.*

Remark 1699 (Connection to "two-part codes" and model selection heuristics)**.** *Interpreting $\mathrm{Eff}_C(r)$ as a description-length-like quantity makes Lemma 47 the abstract form of the familiar guarantee that any candidate code (or hypothesis description) provides a valid upper bound on the unknown optimal code length. In MDL-style reasoning, one often decomposes a description into "model" + "data given model"; in the present notation, this corresponds to constructing a composite representation r and then immediately obtaining $s_C(x) \leq \mathrm{Eff}_C(r)$. Even when the effort functional is not literally a bit-length, the lemma justifies the same workflow: propose a representation strategy, compute its effort, and treat that number as a certified (though possibly loose) simplicity bound.*

Lemma 48 (Monotonicity in the representation set)**.** *Let $R_C(x) \subseteq R'_C(x)$ and use the same effort assignment on representations. Let s_C and s'_C be defined by Def. 80 using R_C and R'_C respectively. Then $s'_C(x) \leq s_C(x)$.*

Remark 1700 (What the lemma says, and why it matters)**.** *If you allow* more *candidate representations, the minimal effort cannot go up: more options cannot worsen the best option. For instance, if you initially only permit handwritten descriptions but later also permit a compressed digital format, the simplest description can only become simpler (or remain the same).*

This monotonicity is crucial whenever we compare different modeling choices: enlarging a representation language, adding constructors, or relaxing admissibility constraints should never artificially inflate simplicity. It also foreshadows the analogous monotonicity in policy sets and in parse-tree decompositions.

Remark 1701 (When do we get strict improvement?)**.** *Lemma 48 only asserts $\leq$, and equality is common: if every newly admitted representation in $R'_C(x) \setminus R_C(x)$ has effort at least $s_C(x)$, then nothing changes. Strict inequality $s'_C(x) < s_C(x)$ occurs precisely when the enlargement introduces at least one new admissible representation whose effort is strictly below the previous infimum.*

This observation can be operationally important: it separates representational "expressivity" (having more syntactic forms available) from representational "efficiency" (actually lowering minimal effort for the specific x under study). It also cautions that claims like "language L' is more expressive than L" do not automatically imply that all objects become simpler; monotonicity guarantees non-increase, but improvement is instance-dependent.

Sketch. The infimum over a larger set cannot be larger: $\inf_{r \in R'_C(x)} \mathrm{Eff}_C(r) \leq \inf_{r \in R_C(x)} \mathrm{Eff}_C(r)$. $\square$

Remark 1702 (Proof sketch and intuition)**.** *The proof uses the elementary fact that if $A \subseteq B$ then* $\inf B \leq \inf A$*. Geometrically, if you plot all allowed effort values on the number line, adding more points can only move the leftmost point leftward (or keep it where it is).*

Remark 1703 (Relation to admissibility constraints and "free lunches")**.** *In applications, $R_C(x)$ often depends on constraints that encode what counts as a valid explanation, derivation, or encoding (e.g., a grammar, a proof system, a resource bound, or a notion of observational access). Lemma 48 ensures that relaxing such constraints cannot perversely make an object harder to describe. However, the lemma also highlights the hidden cost of relaxation: if one changes the admissibility notion, one may also implicitly change what is being measured. The monotonicity statement therefore supports careful bookkeeping: one can enlarge $R_C(x)$ to gain smaller $s_C(x)$, but one should record that this reflects a more permissive representational regime rather than a property of x alone.*

Theorem 29 (Effort-weakness monotone tradeoff along opening/closing)**.** *Assume weakness w is monotone under inclusion and policy effort is antitone (Thm. 7 assumptions). Then for any $H \subseteq H'$ in $\mathcal{H}_C$:*

$$w(H) \leq w(H'), \qquad \mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(H').$$

So opening (moving to a superset) simultaneously increases weakness and decreases effort, while closing does the opposite.

Remark 1704 (What the theorem says, and why it matters)**.** *The theorem articulates a clean tradeoff: if H' allows more indistinction than H (so $H \subseteq H'$), then two things happen in lockstep. First, weakness increases: $w(H) \leq w(H')$. Second, effort decreases: $\mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(H')$. Thus, in this formalism, "to be weaker" is literally to be "more open" in policy space, and openness is easier in the effort sense (Hyperseed-Concepts 202, 143).*

This is important because it turns what might otherwise feel like a metaphor (weakness vs. effort) into an inference rule. It is also a conceptual hinge connecting the phenomenological primitives (effort/resistance) to the policy/observer apparatus: a monotone weakness functional is a way of measuring how much the observer permits indistinction, and the antitone effort makes that permission cheap. This monotone relationship is central in the broader "weakness is all you need" perspective [3, 2].

Remark 1705 (A boundary-case sanity check)**.** *At the extremes, the theorem behaves as expected. If H is already maximally open among the policies under consideration, there is no strict superset H', and thus no further reduction in effort via opening in that restricted policy class. If H is very closed (highly discriminating), moving to a slightly more open H' can be interpreted as allowing additional identifications (equivalences) among states or observations; the theorem then guarantees that this relaxation cannot cost* more *effort under an antitone effort functional.*

In that sense, the pair of inequalities can be read as a consistency condition on the primitives: if one adopts the normative stance that "being permissive about indistinction is easier", then antitonicity of Eff_C is the formal expression of that stance, and the theorem is the immediate payoff.

Sketch. This is exactly Thm. 7, restated as an inference rule. □

Remark 1706 (Proof sketch and intuition)**.** *No new argument is required: the proof simply invokes the previously established theorem. The underlying intuition is that the policy lattice is ordered by inclusion, while effort is contravariant and weakness is covariant with that order. One may picture policy space as a cone opening outward: moving outward (opening) broadens permissible indistinction, which by design counts as weaker but costs less.*

Remark 1707 (How to use the tradeoff as a design principle)**.** *In practice, Theorem 29 can be used in either direction. If one has a target effort budget, opening the policy (moving to a larger H') is a principled way to reduce $\mathrm{Eff}_C(H)$ at the price of increased weakness. Dually, if one needs* *a stricter notion of distinction (smaller weakness), closing the policy (moving to a smaller H) is guaranteed to raise the required effort.*

This is also the point where the "duality" language becomes operational: the partial order simultaneously organizes two quantities with opposite variance. As a result, inclusion chains $H_0 \subseteq H_1 \subseteq \cdots$ *automatically produce monotone sequences* $w(H_0) \leq w(H_1) \leq \cdots$ *and* $\mathrm{Eff}_C(H_0) \geq \mathrm{Eff}_C(H_1) \geq \cdots$*, which can be interpreted as Pareto-front trajectories in the* (w, Eff) *plane.*

30.4 Minimum representational effort (MRE) as maximal opening

Lemma 49 (Maximally open feasible policy is a greatest element)**.** *Assume the feasible set* $F_C := \{H \in \mathcal{H}_C : \mathrm{Adeq}_C(H)\}$ *is upward closed (Thm. 8 assumption):* $H \in F_C$ *and* $H \subseteq H' \to H' \in F_C$*. Define* $H_b := \bigcup_{H \in F_C} H$*. Then* $H_b \in F_C$ *and for all* $H \in F_C$*,* $H \subseteq H_b$*. Hence* H_b *is a greatest element of* $(F_C, \subseteq)$*.*

Remark 1708 (What the lemma says, and why it matters)**.** *This lemma says that if feasibility is stable under opening (upward closed), then there exists a single "most open" feasible policy* H_b*, obtained by unioning all feasible policies. In concrete terms: if every time a policy is adequate, any policy that forgets* even more *distinctions is also adequate, then the policy that forgets all distinctions that are forgettable while staying adequate is simply the union of all adequate forgettings.*

This is the order-theoretic heart of the MRE principle in this setting: it identifies a canonical extremal point of the feasible region, so optimization over F_C *reduces to selecting this extremal policy. The construction is intentionally simple: it uses the lattice structure of* $\mathcal{P}(X \times X)$ *under* $\subseteq$*.*

It is also worth making explicit how "opening" is encoded by $\subseteq$*. In this framework, a policy* $H \subseteq X \times X$ *is a set of allowed identifications (or "indistinguishabilities"); enlarging* H *means declaring* more *pairs indistinguishable, i.e., representing the world with fewer distinctions. Thus the inclusion order is aligned with an "openness" or "forgetfulness" order:* $H \subseteq H'$ *reads as "*H' *is at least as open as* H*."*

Finally, one minor edge case is that if $F_C = \varnothing$ *then the union* $\bigcup_{H \in F_C} H$ *is the empty set by convention, and the conclusion* $H_b \in F_C$ *is not automatic. In typical applications of Thm. 8 one implicitly has at least one adequate baseline policy (e.g., a maximally discriminating or otherwise trivially adequate policy), so* F_C *is nonempty and the lemma applies in its intended (nonvacuous) form.*

Sketch. This is Thm. 8(1–2): upward closure makes the union feasible, and union contains each member. □

Remark 1709 (Proof sketch and intuition)**.** *The proof uses two facts about unions. First,* $\bigcup_{H \in F_C} H$ *contains every* $H \in F_C$*, hence is above them in the inclusion order. Second, upward closure means that anything above a feasible element is feasible; since* H_b *is above every feasible element, it is feasible in particular. Visually, imagine stacking translucent sheets (each sheet a feasible policy); their overlay is the union, and upward closure says the overlay remains feasible.*

From an order-theoretic standpoint, what is being used is that $(\mathcal{P}(X \times X), \subseteq)$ *is a complete lattice, so any subset has a join (supremum), given concretely by union. The lemma is precisely the statement that when* F_C *is an* upper set *(i.e., upward closed), its join is not merely an upper bound but remains inside* F_C*, thereby becoming a greatest element.*

Corollary 7 (MRE reduces to choosing H_b)**.** *Under the assumptions of Lemma 49 and antitonicity of* Eff_C*,* H_b *is an effort minimizer over* F_C *(Thm. 8(3)). Moreover, if weakness* w *is monotone,* H_b *is also a weakness maximizer over* F_C *(Thm. 8(4)).*

Remark 1710 (What the corollary says, and why it matters)**.** *Once H_b is known to be the greatest feasible policy, the optimization becomes almost tautological: if effort is antitone, then greater policies have lower effort, hence the greatest feasible policy has the least effort. If weakness is monotone, then greater policies have greater weakness, hence the same H_b maximizes weakness among feasible policies.*

This is an instance of a general pattern: when an objective is monotone and the feasible set has an extremal element, optimization is solved by selecting that extremal element. The corollary therefore ties together feasibility (adequacy), effort (minimization), and weakness (maximization) in a single stroke [9, 3] (Hyperseed-Concepts 202, 100).

Intuitively, the antitonicity of Eff_C *formalizes the idea that representing* more *distinctions costs* more *representation: if $H \subseteq H'$ then H enforces at least as many distinctions as H', and therefore demands at least as much representational effort. The adequacy constraint* Adeq_C *then restricts how far one can open while still meeting the context C; the lemma identifies the farthest open point that remains feasible, and the corollary states that any monotone objective must take its optimum there.*

In particular, this "monotone objective + extremal feasible element" structure is what makes the MRE conclusion robust to many possible choices of effort functional: one does not need a detailed analytic form of Eff_C*, only its order-compatibility with opening. This is why the result reads as a structural theorem about the poset $(F_C, \subseteq)$ rather than as a computation.*

Sketch. If $H \subseteq H_b$ and Eff_C is antitone, then $\mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(H_b)$. Similarly monotonicity of w gives $w(H) \leq w(H_b)$. ☐

Remark 1711 (Proof sketch and intuition)**.** *The proof is a direct application of monotonicity/antitonicity along the inclusion order. The key step is recognizing that Lemma 49 provides $H \subseteq H_b$ for every feasible H; the rest is just pushing inequalities through monotone functions. One may picture F_C as a region in the poset with a "top" element; any monotone quantity reaches an extreme at the top (or bottom, depending on variance).*

A helpful way to read the inequalities is as a comparison principle: any feasible policy H is dominated (in openness) by H_b, and so any antitone cost is dominated (in value) by its value at H_b. In the same way, any monotone "capacity to fail gracefully" or "weakness" quantity is maximized at the same dominating policy. No additional combinatorics about F_C is needed beyond the existence of this top element.

Lemma 50 (Uniqueness under strict antitonicity)**.** *Assume strict antitonicity: if $H \subset H'$ then* $\mathrm{Eff}_C(H) > \mathrm{Eff}_C(H')$*. Then under the assumptions of Lemma 49, H_b is the unique effort minimizer in F_C.*

Remark 1712 (What the lemma says, and why it matters)**.** *The previous corollary identified H_b as an effort minimizer, but it allowed ties. This lemma says that if opening* strictly *reduces effort (not just weakly), then there can be no tie: only the most open feasible policy achieves the minimum.*

This uniqueness is useful when one wants determinacy in the theory: it means that "the" minimum representational effort policy is well-defined, rather than being a choice among several incomparable minimizers. It also clarifies which assumption is doing the work: uniqueness does not come from feasibility but from strictness of the effort decrease.

Conceptually, strict antitonicity rules out "flat directions" in the effort landscape: whenever one can strictly open a policy (move to a strict superset), one must strictly decrease effort. In contexts where effort is derived from, e.g., description length, memory usage, or constraint count, strictness corresponds to the claim that every additional allowed identification eliminates some representational burden rather than merely leaving it unchanged.

Sketch. Let $H \in F_C$ with $H \neq H_b$. Then $H \subset H_b$ (since H_b is greatest), so strict antitonicity implies $\mathrm{Eff}_C(H) > \mathrm{Eff}_C(H_b)$. Thus no other H can tie the minimum. $\square$

Remark 1713 (Proof sketch and intuition). *The proof is a standard extremal-element argument. Any feasible $H \neq H_b$ must lie strictly below the greatest element H_b, and strict antitonicity turns "strictly below" into "strictly higher effort." Visually, there is a strictly descending slope of effort as one moves upward in the policy poset, so only the top point can be lowest in effort.*

Equivalently, strict antitonicity makes Eff_C an order-embedding (up to reversal) on comparable elements: comparability $H \subset H_b$ is transported to a strict inequality of effort values. Since Lemma 49 guarantees that every feasible H is comparable to H_b (indeed, below it), the strict comparison applies to all competitors, yielding uniqueness without needing any additional structure on F_C (such as convexity, finiteness, or chain conditions).

30.5 Compositional simplicity: parse trees, monotonicity, and optimal substructure

Lemma 51 (Parse-tree upper bound). *Assume the setting of Defs. 83–84 and nonnegative overhead $t_C \geq 0$. For any full binary parse tree T evaluating to x with internal-node costs given by t_C,*

$$s_C^*(x) \;\leq\; \mathrm{cost}(T).$$

Remark 1714 (What the lemma says, and why it matters). *Compositional simplicity $s_C^*(x)$ is defined as the least effort required to build x from primitives by binary composition, paying an overhead t_C at each composition step (Hyperseed-Concept 82). A parse tree T is a concrete witness of one particular way to build x; this lemma says that the optimal cost is no more than the cost of that witness.*

As a simple example, if $x = (a * b) * c$ and you have a tree that first combines a, b (paying $t_C(a,b)$) and then combines the result with c (paying $t_C(a*b,c)$), then $s_C^*(x)$ is bounded above by the sum of the leaf costs (here 0 for the unit e in the simplest base case) plus those overheads. This lemma is the core "certificate gives an upper bound" principle that makes dynamic programming and optimal-substructure reasoning possible; it is the same structural idea used in dependency tower analyses [8].

Sketch. Proceed by structural induction on T. If T is a leaf labeled by e, then $x = e$ and $s_C^*(e) = 0 = \mathrm{cost}(T)$ (Def. 84). If T has root children T_1, T_2 evaluating to y, z with $y * z = x$, then Prop. 4 gives $s_C^*(x) \leq s_C^*(y) + s_C^*(z) + t_C(y,z)$. Apply the induction hypothesis to bound $s_C^*(y) \leq \mathrm{cost}(T_1)$ and $s_C^*(z) \leq \mathrm{cost}(T_2)$, and note $\mathrm{cost}(T) = \mathrm{cost}(T_1) + \mathrm{cost}(T_2) + t_C(y,z)$. $\square$

Remark 1715 (Proof sketch and intuition). *The strategy is structural induction, which mirrors the recursive nature of parse trees. At each internal node, one uses the compositional inequality from Prop. 4 to relate the simplicity of the parent to the simplicities of the children plus overhead. The induction hypothesis then converts those child simplicities into the concrete subtree costs. A helpful mental picture is that cost accumulates locally at each internal node; the global bound is obtained by summing those local contributions along the tree.*

Corollary 8 (Minimum parse tree characterization (finite case)). *In the finite case of Thm. 9, $s_C^*(x)$ equals the minimum $\mathrm{cost}(T)$ over all parse trees T for x.*

Remark 1716 (What the corollary says, and why it matters). *The previous lemma provides an inequality $s_C^*(x) \leq \mathrm{cost}(T)$ for every tree T for x. This corollary says that, in the finite case, this* *inequality is tight:* $s^*_C(x)$ *is not merely bounded by tree costs, it is* exactly *the minimal tree cost. Thus compositional simplicity can be computed (in principle) by searching over parse trees.*

This is a pivotal bridge between a fixed-point/least-solution definition (Def. 84, Thm. 9) and a combinatorial optimization view (minimization over trees). The latter view enables algorithmic intuition: optimal substructure, pruning, and monotonicity in overhead.

Sketch. Lemma 51 shows $s^*_C(x)$ is at most any tree cost. Thm. 9 states that the least solution of Def. 84 achieves the minimum parse-tree cost, i.e. the bound is tight. □

Remark 1717 (Proof sketch and intuition)**.** *The proof is a two-sided squeeze: (i) every tree gives an upper bound on* $s^*_C(x)$*, so* $s^*_C(x)$ *is at most the minimum tree cost; (ii) Thm. 9 ensures that the recursive definition does not leave a gap: the least fixed point corresponds to actually attaining that minimum. One may think of Thm. 9 as ensuring that the recursive "Bellman-style" equations faithfully encode the global optimization.*

Lemma 52 (Optimal substructure)**.** *Assume the finite case of Thm. 9. Let* T *be a minimum-cost parse tree for* x *with root split* $x = y * z$ *and subtrees* T_1, T_2 *for* y, z*. Then* T_1 *is minimum-cost among parse trees for* y*, and* T_2 *is minimum-cost among parse trees for* z*.*

Remark 1718 (What the lemma says, and why it matters)**.** *Optimal substructure is the classic principle behind dynamic programming: an optimal whole is built from optimal parts. Here it says: if* T *is the cheapest way to build* x*, and the root decomposes* x *into* y *and* z*, then the chosen subtree for* y *must be the cheapest way to build* y *(and similarly for* z*). Otherwise, we could swap in a cheaper subtree and improve* T*.*

This lemma matters because it legitimizes bottom-up computation of s^*_C*: one can compute best costs for smaller components and reuse them, rather than enumerating all global trees naively. In the broader program, this resonates with how complex systems reuse optimal subassemblies, and how dependency structures enforce local optimality constraints [8] (Hyperseed-Concept 94).*

Sketch. If T_1 were not optimal for y, replace it by a cheaper tree T_1' for y. This strictly decreases the cost of the full tree for x, contradicting optimality of T. Similarly for T_2. □

Remark 1719 (Proof sketch and intuition)**.** *The proof is by contradiction via local improvement: assume a subtree is not optimal, then perform a local surgery (replace* T_1 *by a cheaper* T_1'*) that leaves the root combination structure intact but strictly lowers total cost, contradicting minimality. Geometrically, one can think of the full tree cost as the sum of independent contributions from disjoint subtrees plus the root overhead; lowering one disjoint contribution lowers the whole.*

One way to formalize the "local surgery" is: fix a parse tree T *for* x *and identify a node whose associated subexpression evaluates to some intermediate object* u*. The subtree below that node is itself a parse tree for* u*, contributing a well-defined additive amount to the total cost of* T *(the sum of the overheads on the subtree's internal nodes, plus whatever base/leaf costs are part of the model). If there exists another parse tree* T_u' *for the same* u *with strictly smaller cost, then substituting* T_u' *in place of the old subtree produces a new parse tree for* x *with the same outer shape above that node and strictly smaller total cost. The only requirement for this substitution argument is that the cost functional be additive across disjoint subtrees together with the overhead at the parent node—i.e., that the cost of a full tree decomposes as "root overhead + cost(left subtree) + cost(right subtree)" (and similarly recursively). This is the standard "optimal substructure" property familiar from dynamic programming: global optimality forces local optimality of every component.*

It is also worth noting why strict improvement is available: if the subtree is not optimal, then by definition there is some alternative with strictly smaller cost, so the replacement decreases the *total by at least the gap between the two subtree costs. If there are ties (multiple distinct subtrees with the same minimal cost), the argument still goes through with "$\leq$" but yields non-uniqueness rather than a contradiction; the contradiction requires the assumption that one has chosen a globally minimal tree and then found a strict local improvement.*

Lemma 53 (Monotonicity in overhead and in available decompositions)**.** *Assume the finite case of Thm. 9.*

1. *If $t'_C(y,z) \leq t_C(y,z)$ for all (y,z), then the corresponding compositional simplicities satisfy $s^*_{C,t'}(x) \leq s^*_{C,t}(x)$ for all x.*
2. *If the decomposition set is enlarged (more admissible pairs (y,z) with $y * z = x$), then $s^*_C(x)$ cannot increase.*

Remark 1720 (What the lemma says, and why it matters)**.** *Part (1) says: if you make composition cheaper everywhere, then the optimal compositional cost cannot go up. Part (2) says: if you allow more ways to decompose/build things, you may find cheaper constructions, but you cannot be forced into a more expensive optimum. Both are sanity checks that the formalism respects the everyday logic of optimization.*

These monotonicity principles are also philosophically important: they express that simplicity is not an intrinsic property of x alone, but of x relative to a constructive regime (allowed decompositions, overhead schedule). Changing the regime changes simplicity in a directionally predictable way (Hyperseed-Concept 82).

A useful way to read (1) is pointwise monotonicity of the objective: each parse tree T induces a real number $\mathrm{cost}_t(T)$, and switching from t to t' moves every one of these real numbers downward (or leaves it unchanged). Since the optimum is an infimum/ minimum over the same set of trees, it cannot move upward. In particular, if $t'_C < t_C$ on at least one overhead actually used by every optimal tree under t, then one expects a strict decrease in s^*; but the lemma correctly states only the weak inequality because it may happen that the only decreases occur on decompositions that no optimal construction ever uses.

Likewise, (2) is monotonicity in the feasible set: enlarging the admissible decomposition relation enlarges the set of realizable parse trees. The cost function itself does not become worse; there are simply more candidate trees to compare. Thus the optimal value can only stay the same or drop. This captures an important modeling intuition: granting the agent an extra construction rule cannot rationally make its best achievable simplicity worse, even if the agent chooses to ignore the new rule. (The statement is about the optimal *cost, not about what a particular algorithm might output if it were constrained to use the new rule.)*

Finally, the finiteness assumption in Thm. 9 matters only to justify "minimum" rather than merely "infimum": in an infinite setting one would typically restate the lemma with inf *over all parse trees. The same order-theoretic logic would apply, but one must be slightly more careful about whether the optimal value is attained by an actual tree.*

Sketch. Both are immediate from the minimum-parse-tree characterization: decreasing per-node costs or adding new candidate trees can only decrease (or preserve) the minimum.

More explicitly, fix x and let $\mathcal{T}(x)$ denote the set of admissible parse trees for x under the given regime. For (1), the hypothesis $t'_C \leq t_C$ implies $\mathrm{cost}_{t'}(T) \leq \mathrm{cost}_t(T)$ for every $T \in \mathcal{T}(x)$, because the total cost is a sum of node overheads (and other nonnegative components, if present) evaluated at the same node labels and child pairs. Taking minima over the same set $\mathcal{T}(x)$ yields $\min_{T\in\mathcal{T}(x)} \mathrm{cost}_{t'}(T) \leq \min_{T\in\mathcal{T}(x)} \mathrm{cost}_t(T)$, i.e., $s^*_{C,t'}(x) \leq s^*_{C,t}(x)$. For (2), if $\mathcal{T}(x) \subseteq \mathcal{T}'(x)$ after enlarging the decomposition set, then $\min_{T\in\mathcal{T}'(x)} \mathrm{cost}(T) \leq \min_{T\in\mathcal{T}(x)} \mathrm{cost}(T)$ by the elementary fact that the minimum over a superset cannot exceed the minimum over a subset. $\square$

Remark 1721 (Proof sketch and intuition)**.** *The proof reduces everything to minimization over a set of real numbers: the set of parse-tree costs. In (1), every tree's cost weakly decreases when node overheads decrease, hence the minimum weakly decreases. In (2), adding decompositions enlarges the set of available trees, and the minimum over a larger set cannot be larger. This is the same order fact used earlier for representation sets (Lemma 48).*

It can be helpful to keep separate the two "directions" in which monotonicity may act:

- *Changing t_C changes the* cost assigned to each fixed tree *(the feasible set stays the same).*
- *Changing the admissible decompositions changes the* feasible set of trees *(the cost assignment stays the same).*

Both are instances of the same basic principle: if you make some options cheaper, or you provide additional options, an optimum defined as a minimum cannot worsen. The lemma thus functions as a consistency check on the definition of s^*_C: it behaves like an honest optimization objective rather than an ad hoc complexity score.

As a concrete mental model, consider building x from two parts y and z with overhead $t_C(y, z)$. If one decreases all such overheads by a constant $\delta \geq 0$, then every *internal node becomes cheaper by at most δ, so the total cost of any fixed tree decreases by (at most) δ times the number of internal nodes. The optimal tree may change when costs change, but the optimum value cannot increase. Similarly, if one adds a new admissible decomposition $x = y * z$ that was previously forbidden, then one has strictly more candidate trees for x; if the added decomposition is never beneficial, the optimum stays the same, and if it is beneficial, the optimum drops.*

In this sense, Lemma 53 is the compositional analogue of the monotonicity properties one expects from shortest paths: lowering edge weights cannot increase the shortest-path distance, and adding edges cannot increase it. Here, parse trees play the role of paths, and node overheads play the role of local weights.

30.6 Generalized Kolmogorov complexity and structural complexity

Lemma 54 (Description upper bound)**.** *For any generalized description system (Def. 85) and any $d \in D_C$ with $\mathrm{Dec}_C(d) = x$,*

$$K_C(x) \;\leq\; \mathrm{Eff}_C(d).$$

Remark 1722 (What the lemma says, and why it matters)**.** *This is the direct analogue of Lemma 47, now in the setting of generalized Kolmogorov complexity: $K_C(x)$ is defined as the infimum effort among descriptions that decode to x, so any particular description gives an upper bound. In the classical setting of Kolmogorov complexity, the slogan is: "any program that prints x shows $K(x)$ is at most the program's length" [16] (Hyperseed-Concept* **??***).*

The lemma is useful whenever we design a description language: it allows one to bound complexity by constructing explicit descriptions, and it provides the basic comparison principle used in the compositional bound below.

Concretely, one can read the statement as separating two tasks: (i) exhibit a description d that works *(i.e., decodes to the target object x), and (ii) evaluate or upper bound the effort* $\mathrm{Eff}_C(d)$ *in the chosen effort model. The lemma then turns (ii) into an immediate bound on $K_C(x)$. This is typically how upper bounds are proved in practice: instead of reasoning directly about the infimum over all possible descriptions, one presents a structured family of candidate descriptions and analyzes their effort.*

Note that nothing in the lemma requires optimality, uniqueness, or even computability of the infimum: it is purely an order-theoretic consequence of defining $K_C(x)$ as an infimum over the set

$\{ \mathrm{Eff}_C(d) : d \in D_C,\ \mathrm{Dec}_C(d) = x \}$. *In particular, if there are many distinct descriptions of x (e.g., many programs that output the same string), each yields a possibly different upper bound, and the best such upper bound is precisely $K_C(x)$.*

Sketch. Immediate from Def. 86: $K_C(x)$ is the infimum of $\mathrm{Eff}_C(d)$ over all descriptions decoding to x. ☐

Remark 1723 (Proof sketch and intuition)**.** *As before, the proof is the general order fact that an infimum is below every element of its set. Intuitively: the "best possible" description cannot be worse than any particular description you already have in hand.*

It is sometimes helpful to spell out the quantifiers explicitly: Def. 86 says

$$K_C(x) = \inf\{\mathrm{Eff}_C(d) : d \in D_C,\ \mathrm{Dec}_C(d) = x\}.$$

Fixing any particular d with $\mathrm{Dec}_C(d) = x$ simply means $\mathrm{Eff}_C(d)$ is one element of this set, so the infimum cannot exceed it. This remains true even when the infimum is not attained (i.e., even if there is no single description whose effort equals $K_C(x)$).

Lemma 55 (Compositional upper bound under a homomorphism assumption)**.** *Assume there is a binary constructor/concatenation $\cdot$ on descriptions such that $\mathrm{Eff}_C(d_1 \cdot d_2) \le \mathrm{Eff}_C(d_1) + \mathrm{Eff}_C(d_2)$ (Def. 85), and additionally assume a decoder compatibility (homomorphism) condition:*

$$\mathrm{Dec}_C(d_1) = x,\ \mathrm{Dec}_C(d_2) = y \ \rightarrow\ \mathrm{Dec}_C(d_1 \cdot d_2) = x * y.$$

Then

$$K_C(x * y) \ \le\ K_C(x) + K_C(y).$$

Remark 1724 (What the lemma says, and why it matters)**.** *This lemma says that complexity is subadditive under composition: if you can describe x and describe y, then you can describe their composite $x * y$ with effort at most the sum of efforts (up to the constructor overhead encoded in the inequality for $\cdot$). The extra assumption $\mathrm{Dec}_C(d_1 \cdot d_2) = x * y$ is a homomorphism condition ensuring that "concatenate the descriptions" really corresponds to "compose the objects."*

This is a generalized version of a familiar fact from algorithmic information theory: $K(x, y) \le K(x) + K(y) + O(1)$, where the $O(1)$ accounts for pairing/concatenation overhead [16]. Here the overhead is absorbed into the effort inequality for $\cdot$. The lemma is also a conceptual precursor to the equivalence theorem below: it suggests that description complexity and parse-tree (compositional) complexity obey the same algebra.

The compatibility assumption can be viewed as a correctness constraint on the description language: the syntax-level operation $\cdot$ must implement the intended semantic operation $*$ after decoding. Without such a constraint, one could still have a subadditive effort inequality on raw descriptions, but it would not translate into any bound on the complexity of semantic composites $x * y$. In other words, the lemma isolates the two minimal ingredients needed to inherit subadditivity at the level of decoded objects: a low-overhead way to combine descriptions, and a decoder that respects that combination.

Depending on the application, the effort inequality $\mathrm{Eff}_C(d_1 \cdot d_2) \le \mathrm{Eff}_C(d_1) + \mathrm{Eff}_C(d_2)$ can be interpreted in different concrete ways. If Eff_C measures bit-length, it says concatenation does not increase total length beyond the sum (often up to a fixed delimiter cost). If Eff_C measures time or energy, it says the work to execute the combined description is no worse than running the two parts sequentially (again, up to the stipulated overhead encoded in Def. 85).

Remark 1725 (How it connects to earlier results). *Compare the inequality $K_C(x * y) \le K_C(x) + K_C(y)$ with the compositional recursion for s^*_C and with Lemma 42: all are manifestations of the same principle that sequential/constructive composition should not create superlinear effort by fiat. In that sense, this lemma is the "description-language" counterpart of compositional simplicity.*

From the perspective of dynamic programming or optimal substructure, the lemma can also be read as stating that if an object is formed by a binary composition, then a near-optimal description of the whole can be obtained by stitching together near-optimal descriptions of the parts, provided the description system is designed so that such stitching is valid and does not introduce disproportionate overhead. This is exactly the kind of closure property one wants when relating "how objects are built" to "how objects are described."

Sketch. Fix $\epsilon > 0$. Choose d_1, d_2 with $\mathrm{Dec}_C(d_1) = x$, $\mathrm{Dec}_C(d_2) = y$ and $\mathrm{Eff}_C(d_1) \le K_C(x) + \epsilon$, $\mathrm{Eff}_C(d_2) \le K_C(y) + \epsilon$ (approximate infimum). Then $\mathrm{Dec}_C(d_1 \cdot d_2) = x * y$ and $\mathrm{Eff}_C(d_1 \cdot d_2) \le \mathrm{Eff}_C(d_1) + \mathrm{Eff}_C(d_2) \le K_C(x) + K_C(y) + 2\epsilon$. Apply Lemma 54 to $d_1 \cdot d_2$ and let $\epsilon \to 0$. $\square$

Remark 1726 (Proof sketch and intuition). *The strategy is the standard "ϵ-approximate minimizer" technique: because $K_C(x)$ is an infimum, we may not have a literal minimizer, but we can get arbitrarily close. We then compose two near-optimal descriptions and use the assumed subadditivity of effort under $\cdot$ to bound the composite's effort. Finally, we remove the slack by sending $\epsilon \to 0$.*

A useful picture is that of two funnels: one funnel collects all descriptions of x and narrows down to $K_C(x)$; similarly for y. By choosing points close to each funnel's narrowest part and then combining them, we land close to the narrowest part of the funnel for $x * y$.

Formally, the only subtlety relative to a minimum-attaining setting is that one cannot necessarily pick d_1 with $\mathrm{Eff}_C(d_1) = K_C(x)$ exactly. The ϵ-argument is the standard replacement: for every tolerance $\epsilon > 0$ there exists a witness within ϵ of the infimum. The final limit step uses that the bound holds for all $\epsilon > 0$, hence also in the limit, yielding the inequality without slack.

Theorem 30 (Structural/compositional equivalence as an inference bridge). *Under the generation assumptions of Prop. 5 (finite primitives + binary constructor corresponding to $*$ with overhead),*

$$K_C(x) \text{ coincides with } s^*_C(x) \text{ up to fixed base costs.}$$

Hence helper theorems for s^*_C (parse-tree bounds, monotonicity, optimal substructure) can be re-used for K_C.

Remark 1727 (What the theorem says, and why it matters). *This theorem states that, under the specified generation assumptions, the two notions of complexity in this section are essentially the same quantity computed in two different languages. On one side, $s^*_C(x)$ measures the cheapest way to assemble x via binary composition (a "construction history" represented by a parse tree). On the other, $K_C(x)$ measures the cheapest description that decodes to x. The theorem says these coincide up to fixed base costs, meaning that differences are absorbed into constant offsets attributable to the choice of primitives and representation conventions.*

The phrase "fixed base costs" is meant to parallel the ubiquitous $O(1)$ terms in classical Kolmogorov complexity: changing the universal machine changes $K(x)$ by at most an additive constant independent of x. Here, once the set of primitives and the constructor overhead are fixed (as in Prop. 5), the conversion between "a parse tree that constructs x" and "a description that decodes to x" incurs only constant-size scaffolding: delimiters, tags indicating which constructor node is being used, and a uniform decoding convention. These costs do not scale with the size or internal complexity of x; they depend only on the agreed-upon representation scheme.

Operationally, the inference bridge works in both directions. A parse-tree upper bound on $s^*_C(x)$ yields an explicit construction plan, which can be compiled into a description d with $\mathrm{Dec}_C(d) = x$, giving an upper bound on $K_C(x)$ via Lemma 54. Conversely, if one has a short/low-effort description of x in the generalized Kolmogorov sense, the generation assumptions ensure that the description can be interpreted (perhaps after a constant-cost normalization) as specifying a finite composition tree over the primitives, thereby bounding $s^*_C(x)$ by essentially the same value.

In particular, once this equivalence is in place, any structural lemma proved for s^*_C can be transported to K_C without repeating the full argument at the level of descriptions. This is the main methodological payoff: one may reason in the more convenient domain (parse trees or descriptions) while obtaining conclusions about the other domain "for free," up to the stipulated constant offsets.

Remark 1728 (Why an equivalence theorem is plausible under Prop. 5)**.** *Prop. 5 posits a finite generating basis together with a binary constructor aligned with $*$, and it controls overhead at each composition step. Under these assumptions, any construction of x determines a finite rooted binary tree whose leaves are primitives and whose internal nodes are applications of $*$. Encoding such a tree as a description is a matter of choosing a traversal and adding a fixed amount of syntax to indicate branching structure; conversely, any description that decodes via repeated application of the constructor can be unfolded into such a tree. The effort model then assigns comparable total cost to both representations because both are built from the same local ingredients: primitive costs at leaves plus per-node overhead at internal constructor applications.*

Remark 1729. *This is important because it allows a transfer of results: any optimization or monotonicity statement proved for parse trees becomes a statement about description complexity. Philosophically, it supports a Russell-style moral about definitions: apparently different descriptions of "simplicity" can converge when they are forced to respect the same structural constraints [16]. In the broader Hyperseed frame, it links compositional construction (Hyperseed-Concept 82) with structural complexity (Hyperseed-Concept 181) through a rigorous equivalence. More concretely, it justifies treating a shortest description (in the generalized Kolmogorov sense) and a cheapest construction (in the parse-tree sense) as two presentations of the same minimization problem, differing at most by the bookkeeping conventions used to account for composition. In particular, once a fixed encoding of constructors and arguments is chosen, the "overhead" of describing how parts are combined can be made uniform across descriptions, so that the remaining variability is exactly the structural choice of how to decompose x. This is the point at which the usual invariance intuition from Kolmogorov complexity becomes relevant: changes of description language affect costs only up to a controlled translation penalty, while the structural constraints determine the leading behavior of the minimum [16].*

Remark 1730 (How it connects to the surrounding theory)**.** *This equivalence is the technical reason the document can speak fluidly about "simplicity" both as minimal effort of assembly and as minimal effort of description, without constantly reproving parallel lemmas. It is also aligned with the perspective that dependency structures (parse trees, construction graphs) are not mere bookkeeping, but the geometry of complexity itself [8]. Operationally, it means that any lemma stated for the effort functional on trees (e.g., that refining a decomposition cannot reduce cost under a monotone overhead model, or that certain normal forms are optimal) can be reinterpreted as a lemma about description length for a decoder that implements the same constructors. Conversely, lower bounds stated in terms of unavoidable description length can be viewed as constraints on the minimal achievable assembly effort. This is especially helpful when later sections mix viewpoints: one can argue in the tree language when exploiting compositionality and in the description language when appealing to information-theoretic intuitions, while relying on this equivalence to ensure the two arguments are genuinely about the same quantity.*

Sketch. Prop. 5: each description induces a parse tree whose effort is the sum of base and overhead costs, and taking the infimum over descriptions equals taking the minimum over parse trees; then apply Thm. 9. More explicitly, fix a decoding convention in which a description is parsed into (i) literals or base symbols and (ii) constructor calls that combine previously produced subobjects. Reading such a description left-to-right (or via its own syntactic parse) yields a tree whose leaves correspond to base symbols and whose internal nodes correspond to constructor applications; by design, the description cost splits into the base costs of the leaves plus a per-node overhead for each constructor application. Minimizing description cost therefore reduces to choosing the best tree shape together with the best leaf labels, which is exactly the tree minimization problem. The passage from "infimum" to "minimum" is justified in the finite/compact setting assumed by Prop. 5 (e.g., finitely many admissible constructors at each step and discrete costs), while in more general settings one keeps the infimum and obtains equality up to the same limiting argument. Thm. 9 then identifies the resulting tree minimum with the corresponding fixed-point/minimum characterization required for the statement. □

Remark 1731 (Proof sketch and intuition)**.** *The proof strategy is to build a two-way correspondence between descriptions and parse trees. One direction maps a description to a parse tree witnessing how the decoder constructs x; the effort of the description decomposes into base costs plus per-composition overhead, matching the tree cost. The other direction maps a parse tree to a composed description built by repeated application of the binary constructor. Once these mappings preserve (or tightly relate) costs, taking an infimum over descriptions becomes equivalent to taking a minimum over trees (in the finite case), and Thm. 9 supplies the fixed-point/minimum identification needed to conclude. A useful way to view the "tightness" condition here is that the encoding of tree structure (which node combines which subresults, and in what order) is required to have a predictable cost: it is either counted explicitly as overhead at each internal node or absorbed into a uniform additive constant determined by the chosen description formalism. In this sense, the equivalence is not merely existential; it depends on the modeling choice that descriptions must respect the same admissible composition rules as the parse trees they are being compared to.*

The geometric intuition is that both descriptions and parse trees are coordinate systems on the same underlying constructive space: they slice the same object x into parts and record the gluing operations. The theorem says that, once the slicing rules are aligned, the measured "length" of the shortest route to x is independent of which coordinate system you use. One can also read this as a statement about where complexity "lives": if two descriptions differ only by superficial syntactic rearrangements but induce the same dependency graph, then they have essentially the same effort, whereas genuinely different decompositions correspond to different routes through the constructive space and can change the minimum. This explains why later arguments can treat the parse tree as the primary carrier of structure and treat description length as a derived measurement attached to that structure, rather than as an unrelated notion of succinctness.

31 Helper theorems for patterns, properties, emergence, and blending (Section 9)

Standing assumptions and notation. Fix a context C with: (i) entities E_C, (ii) a (partial) static combination $*_C$ on E_C, (iii) a description language L_C and decoder $\mathrm{Dec}_C : L_C \to E_C$, (iv) a cost functional $\mathrm{cost}_C : L_C \to \mathbb{R}_{\geq 0} \cup \{\infty\}$, (v) a baseline encoder $\mathrm{base}_C : E_C \to L_C$ with $\mathrm{Dec}_C(\mathrm{base}_C(x)) = x$.

The role of the context C is to package the "model of description" (the pair (L_C, Dec_C)), the "notion of resource" used to score descriptions (the functional cost_C), and the admissible way of composing entities (the partial operation $*_C$). The operation $*_C$ is allowed to be partial to accommodate domains where not every pair of entities can be meaningfully combined, and the qualifier "static" emphasizes that $*_C$ is treated as a fixed operation of the context (rather than something optimized over within a theorem).

Let $s_C(x) := \inf\{\mathrm{cost}_C(\ell) : \ell \in L_C,\ \mathrm{Dec}_C(\ell) = x\}$ (Def. 87), and $s_C^{\mathrm{base}}(x) := \mathrm{cost}_C(\mathrm{base}_C(x))$ (Def. 93).

Thus $s_C(x)$ is the best achievable (infimal) cost of any valid description of x in C, whereas $s_C^{\mathrm{base}}(x)$ is a distinguished reference cost obtained from the baseline encoder. In particular, by the defining property $\mathrm{Dec}_C(\mathrm{base}_C(x)) = x$, the set over which the infimum defining $s_C(x)$ is taken is nonempty whenever $\mathrm{base}_C(x)$ is defined, and one always has the basic upper bound $s_C(x) \leq s_C^{\mathrm{base}}(x)$ (possibly with both sides infinite). The use of inf rather than min permits contexts where optimal descriptions may not exist but can be approached arbitrarily well.

A compositional witness for x is $P = (y, z, t)$ with $x = y *_C z$ and overhead $t \geq 0$ (Def. 94), with composite cost $h_C(P) := s_C(y) + s_C(z) + t$ (Def. 94).

Intuitively, a witness P certifies that x can be obtained by combining constituents y and z at an additional nonnegative overhead t, where t is intended to account for glue code, alignment/typing constraints, coordination information, or any other extra description needed to make the composition well-formed in the given context. The quantity $h_C(P)$ should be read as the total cost of describing x via the route "describe y, describe z, and then pay t to combine them," with the understanding that the constituents are scored using their intrinsic description costs $s_C(y)$ and $s_C(z)$ rather than their baseline costs. (In later arguments, this separation allows one to compare direct baselines against potentially more efficient compositional encodings.)

Scalar intensity (Def. 95) is

$$I_C(\ell; x) = \max\left(0, \frac{s_C^{\mathrm{base}}(x) - \mathrm{cost}_C(\ell)}{s_C^{\mathrm{base}}(x)}\right) \in [0,1], \quad I_C(P; x) = \max\left(0, \frac{s_C^{\mathrm{base}}(x) - h_C(P)}{s_C^{\mathrm{base}}(x)}\right) \in [0,1].$$

This normalization makes intensity a relative improvement over the baseline: $I_C(\ell; x)$ (respectively $I_C(P; x)$) is positive exactly when the candidate description ℓ (respectively the compositional explanation P) beats the baseline cost for x, and it saturates at 1 in the extreme case where the candidate cost is 0. The outer $\max(0, \cdot)$ enforces that "no improvement" is represented as intensity 0 rather than a negative number, so the scale is compatible with viewing intensities as fuzzy membership values. When $s_C^{\mathrm{base}}(x)$ is finite and positive, the formula is literal; in degenerate cases (e.g. $s_C^{\mathrm{base}}(x) = 0$ or $s_C^{\mathrm{base}}(x) = \infty$), one typically treats the displayed expression as a conventionally normalized score and restricts attention to settings where the baseline is informative enough to serve as a denominator.

A property-set is $\mathrm{Prop}_C(x) : P_C \to [0,1]$ given by $\mathrm{Prop}_C(x)(Q) := I_C(Q; x)$ for a chosen pattern vocabulary P_C (Def. 97), with mass $\|\mathrm{Prop}_C(x)\|_1 := \sum_{Q \in P_C} \mathrm{Prop}_C(x)(Q)$ (Def. 98). Here the pattern vocabulary P_C is an externally fixed collection of "candidate explanations" or "recognizable regularities" (e.g. descriptions ℓ, compositional witnesses P, or other structured patterns Q) whose intensities are evaluated against the target entity x. The mass $\|\mathrm{Prop}_C(x)\|_1$ is the total amount of recognized structure from P_C present in x according to this scoring; in applications one often chooses P_C so that this sum is finite (for example by restricting to a finite vocabulary, to patterns below a cost threshold, or to patterns supported by a finite dataset), ensuring that the ℓ^1-quantity is well-defined and comparable across entities.

Inheritance is the preorder

$$A \preceq_C B \quad :\Longleftrightarrow \quad \mathrm{Prop}_C(A)(Q) \geq \mathrm{Prop}_C(B)(Q) \ \forall Q \in P_C \qquad \text{(Def. 99).}$$

This order reads "A inherits B" (or A is at least as pattern-rich as B relative to P_C) in the sense that every pattern in the vocabulary is present in A with intensity at least as large as it is present in B. Because the definition is pointwise over $Q \in P_C$, it is immediate that $\preceq_C$ is reflexive and transitive (hence a preorder), and it becomes a partial order after quotienting by the induced equivalence relation of mutual inheritance.

Association is fuzzy Jaccard (Def. 100):

$$\operatorname{assoc}_C(A, B) := \frac{\sum_{Q \in P_C} \min(\operatorname{Prop}_C(A)(Q), \operatorname{Prop}_C(B)(Q))}{\sum_{Q \in P_C} \max(\operatorname{Prop}_C(A)(Q), \operatorname{Prop}_C(B)(Q))} \quad \text{with } 0/0 := 0.$$

This is the standard Jaccard similarity generalized from crisp sets to fuzzy membership weights, where min plays the role of intersection and max plays the role of union. The convention $0/0 := 0$ corresponds to declaring two entities to have association 0 when neither exhibits any pattern from the vocabulary (so both numerator and denominator vanish). When the denominator is nonzero, $\operatorname{assoc}_C(A, B) \in [0, 1]$, achieving 1 exactly when the property profiles coincide pointwise on P_C and approaching 0 when their overlap is negligible compared to their union.

Emergence is defined by weights $w_C(A), w_C(B)$ from baseline costs (Def. 101), surplus $\operatorname{Sur}_C(Q; A, B)$ and emergent intensity $\operatorname{Emer}_C(Q; A, B) := \max(0, \operatorname{Sur}_C(Q; A, B))$ (Def. 102). The conceptual intent is that $w_C(A)$ and $w_C(B)$ calibrate how much the constituents A and B should contribute to the baseline expectation for a combined object (for instance, to avoid double-counting improvements that are already explained by one constituent alone). A positive surplus $\operatorname{Sur}_C(Q; A, B)$ indicates that the pattern Q is exhibited by the joint entity more strongly than can be accounted for by the weighted contributions of A and B separately, and the truncation to $\operatorname{Emer}_C(Q; A, B)$ ensures that only genuinely new (nonnegative) gains are counted as emergence. In later helper theorems, these definitions are used to bound how pattern masses, inheritances, and associations behave under composition and to isolate conditions under which emergent structure must appear.

31.1 Pattern intensity algebra

Lemma 56 (Intensity as truncated relative savings)**.** *Assume $s_C^{\text{base}}(x) > 0$. Then for any witness with cost-value $u \in [0, \infty]$ (either $u = \operatorname{cost}_C(\ell)$ or $u = h_C(P)$),*

$$I_C(\cdot; x) = \max\left(0, 1 - \frac{u}{s_C^{\text{base}}(x)}\right).$$

In particular:

$$I_C(\cdot; x) > 0 \iff u < s_C^{\text{base}}(x), \qquad I_C(\cdot; x) = 0 \iff u \geq s_C^{\text{base}}(x).$$

Sketch. Immediate algebra from Def. 95 and the max-clamp. More explicitly, Def. 95 defines intensity as a normalized savings fraction relative to the baseline scale $s_C^{\text{base}}(x)$, with the outer $\max(0, \cdot)$ ensuring nonnegativity even when a proposed witness is no better than baseline. When $u = \infty$ (i.e., an unusable or undefined witness cost), the expression inside the clamp is $-\infty$, hence $I_C(\cdot; x) = 0$ as expected. □

Lemma 57 (Recovering cost from positive intensity)**.** *Assume $s_C^{\text{base}}(x) > 0$ and $I_C(\cdot; x) > 0$. Then the witness cost is exactly*

$$u = s_C^{\text{base}}(x) \cdot (1 - I_C(\cdot; x)).$$

Sketch. If $I > 0$, the clamp is inactive, so $I = 1 - u/s_{\text{base}}$ and rearrange. Note that the assumption $I_C(\cdot; x) > 0$ is essential: at intensity 0 the clamp discards information about how large u is beyond the threshold $s_C^{\text{base}}(x)$, so u cannot be uniquely recovered from $I = 0$ alone. □

Lemma 58 (Monotonicity: cheaper witnesses yield higher intensity)**.** *Assume $s_C^{\mathrm{base}}(x) > 0$. If two witnesses of x have costs $u \le v$, then $I(u;x) \ge I(v;x)$.*

Sketch. The map $u \mapsto \max(0, 1 - u/s)$ is monotone decreasing in u for fixed $s > 0$. Equivalently, before truncation the expression is affine with slope $-1/s_C^{\mathrm{base}}(x)$, and the truncation at 0 preserves the order because it is itself monotone. □

Lemma 59 (Lipschitz control: intensity changes at most linearly with cost)**.** *Assume $s_C^{\mathrm{base}}(x) > 0$. Then for any two witness costs $u, v \in [0, \infty]$,*

$$\big|I(u;x) - I(v;x)\big| \;\le\; \frac{|u-v|}{s_C^{\mathrm{base}}(x)},$$

with the convention that the right-hand side is ∞ if one of u, v is ∞.

Sketch. On the region where the clamp is inactive, $I(u;x) = 1 - u/s_C^{\mathrm{base}}(x)$ is affine with slope magnitude $1/s_C^{\mathrm{base}}(x)$. Applying $\max(0, \cdot)$ cannot increase distances (it is 1-Lipschitz on $\mathbb{R}$), so the same bound holds globally after truncation. □

Lemma 60 (Overhead sensitivity bound (compositional witnesses))**.** *Assume $s_C^{\mathrm{base}}(x) > 0$ and let $P = (y, z, t)$ witness x. For $\Delta \ge 0$, define $P' := (y, z, t + \Delta)$ (same parts, larger glue bound). Then*

$$I_C(P';x) \;\ge\; I_C(P;x) - \frac{\Delta}{s_C^{\mathrm{base}}(x)}.$$

Sketch. $h_C(P') = h_C(P) + \Delta$. Apply Lemma 56 and use that truncation at 0 can only increase the left-hand side. Concretely, before truncation the intensity drops by exactly $\Delta/s_C^{\mathrm{base}}(x)$, and if this pushes the value below 0 the clamp sets it back to 0, so the realized decrease can only be smaller in magnitude than the linear prediction. □

Lemma 61 (Baseline dominates optimal complexity)**.** *For all $x \in E_C$,*

$$s_C(x) \le s_C^{\mathrm{base}}(x).$$

Consequently, if $s_C^{\mathrm{base}}(x) > 0$ then the best achievable *normalized compression fraction is at least*

$$I_C^\star(x) := \max\!\left(0, \frac{s_C^{\mathrm{base}}(x) - s_C(x)}{s_C^{\mathrm{base}}(x)}\right) \in [0,1],$$

and every witness intensity is bounded by $I_C(\cdot;x) \le I_C^\star(x)$.

Sketch. $\mathrm{base}_C(x)$ is a witness for x, so the infimum defining $s_C(x)$ is $\le \mathrm{cost}_C(\mathrm{base}_C(x))$. For the bound, note $u \ge s_C(x)$ for any witness cost u, then apply Lemma 56. In particular, if $s_C(x) = s_C^{\mathrm{base}}(x)$ then $I_C^\star(x) = 0$ and no witness can achieve positive intensity (the baseline is already optimal under the cost model), whereas if $s_C(x) = 0$ then $I_C^\star(x) = 1$, matching the interpretation that perfect compression relative to a positive baseline would yield unit intensity. □

31.2 Properties and inheritance

Theorem 31 (Inheritance via properties is a preorder)**.** *The relation $\preceq_C$ from Def. 99 is reflexive and transitive on E_C.*

Sketch. Reflexive: $\mathrm{Prop}_C(A)(Q) \geq \mathrm{Prop}_C(A)(Q)$ pointwise. Transitive: if $\mathrm{Prop}_C(A) \geq \mathrm{Prop}_C(B)$ and $\mathrm{Prop}_C(B) \geq \mathrm{Prop}_C(D)$ pointwise, then $\mathrm{Prop}_C(A) \geq \mathrm{Prop}_C(D)$ pointwise. In other words, $\preceq_C$ is precisely the product (pointwise) order on property-vectors $\mathrm{Prop}_C(\cdot) \in [0,1]^{P_C}$ pulled back along the map $\mathrm{Prop}_C \colon E_C \to [0,1]^{P_C}$, so reflexivity and transitivity reduce to the corresponding facts about $\geq$ on $[0,1]$ evaluated coordinatewise. Note that antisymmetry need not hold on E_C: it is possible that $A \preceq_C B$ and $B \preceq_C A$ while $A \neq B$ as entities, provided they induce the same property function (cf. Lemma 66 for an equality criterion at the level of Prop_C). □

Lemma 62 (Threshold inheritance rule)**.** *If $A \preceq_C B$ and $\mathrm{Prop}_C(B)(Q) \geq \tau$, then $\mathrm{Prop}_C(A)(Q) \geq \tau$. Equivalently, any property holding strongly of B holds at least as strongly of A.*

Sketch. Immediate from the pointwise inequality in Def. 99. Concretely, $A \preceq_C B$ means $\mathrm{Prop}_C(A)(Q) \geq \mathrm{Prop}_C(B)(Q)$ for each fixed $Q \in P_C$; chaining this with $\mathrm{Prop}_C(B)(Q) \geq \tau$ yields $\mathrm{Prop}_C(A)(Q) \geq \tau$. This is the basic mechanism by which property-level constraints propagate "downward" along $\preceq_C$ at any chosen cutoff $\tau \in [0,1]$. □

Lemma 63 (Mass monotonicity under inheritance)**.** *Assume P_C is finite or countable so the ℓ^1 mass is defined. If $A \preceq_C B$, then $\|\mathrm{Prop}_C(A)\|_1 \geq \|\mathrm{Prop}_C(B)\|_1$.*

Sketch. Sum the pointwise inequalities $\mathrm{Prop}_C(A)(Q) \geq \mathrm{Prop}_C(B)(Q)$ over $Q \in P_C$. Because all terms are nonnegative, the (finite or countable) sum preserves inequalities, so the aggregate "amount of property evidence" (total mass) cannot decrease when moving from B to an inheritor A in the sense of $\preceq_C$. In particular, if $\|\mathrm{Prop}_C(B)\|_1$ is finite then $\|\mathrm{Prop}_C(A)\|_1$ is also finite and bounded below by it. □

31.3 Association (fuzzy Jaccard) calculus

The quantity $\mathrm{assoc}_C(A,B)$ used below is the standard fuzzy Jaccard similarity of the property profiles $\mathrm{Prop}_C(A)$ and $\mathrm{Prop}_C(B)$: it measures overlap via min (soft intersection) normalized by max (soft union). The $0/0 := 0$ convention ensures the definition is total even when both entities carry zero total property mass, i.e. when $\mathrm{Prop}_C(A)$ and $\mathrm{Prop}_C(B)$ are both identically 0 on P_C.

Lemma 64 (Association bounds and symmetry)**.** *For all $A, B \in E_C$,*

$$0 \leq \mathrm{assoc}_C(A,B) \leq 1, \qquad \mathrm{assoc}_C(A,B) = \mathrm{assoc}_C(B,A).$$

Sketch. Numerator and denominator are sums of nonnegative terms, and $\min(u,v) \leq \max(u,v)$ pointwise, giving the $[0,1]$ bound. More explicitly, for each Q one has $0 \leq \min(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q)) \leq \max(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q))$, hence after summing over Q the numerator is between 0 and the denominator. If the denominator is 0 then both numerator and denominator are 0 (since $\min \leq \max$ and both are nonnegative), and the convention $0/0 := 0$ yields the stated bounds as well. Symmetry holds because min and max are symmetric in their arguments, so both numerator and denominator are unchanged under swapping A and B. □

Lemma 65 (Intersection/union rewrite)**.** *Define the* intersection mass

$$M_\cap(A,B) := \sum_{Q \in P_C} \min(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q)).$$

Then

$$\sum_{Q\in P_C} \max(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q)) = \|\mathrm{Prop}_C(A)\|_1 + \|\mathrm{Prop}_C(B)\|_1 - M_\cap(A,B),$$

and if the denominator is nonzero,

$$\mathrm{assoc}_C(A,B) = \frac{M_\cap(A,B)}{\|\mathrm{Prop}_C(A)\|_1 + \|\mathrm{Prop}_C(B)\|_1 - M_\cap(A,B)}.$$

Sketch. Use the pointwise identity $\max(u,v) = u + v - \min(u,v)$ and sum over Q. It is sometimes convenient to name the denominator as a "union mass" $M_\cup(A,B) := \sum_{Q\in P_C} \max(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q))$, in which case the displayed equality reads $M_\cup(A,B) = \|\mathrm{Prop}_C(A)\|_1 + \|\mathrm{Prop}_C(B)\|_1 - M_\cap(A,B)$ and $\mathrm{assoc}_C(A,B) = M_\cap(A,B)/M_\cup(A,B)$ whenever $M_\cup(A,B) > 0$. □

Lemma 66 (When is association 1?)**.** *If* $\|\mathrm{Prop}_C(A)\|_1 > 0$ *or* $\|\mathrm{Prop}_C(B)\|_1 > 0$*, then*

$$\mathrm{assoc}_C(A,B) = 1 \iff \mathrm{Prop}_C(A) = \mathrm{Prop}_C(B) \textit{ pointwise.}$$

If both masses are 0, then $\mathrm{assoc}_C(A,B) = 0$ *by the* $0/0 := 0$ *convention.*

Sketch. If assoc = 1 and denominator is nonzero, then numerator equals denominator, so min = max termwise, hence the two property functions agree pointwise. To justify the termwise conclusion: if $a_Q := \min(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q))$ and $b_Q := \max(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q))$, then $0 \le a_Q \le b_Q$ for all Q and $\sum_Q a_Q = \sum_Q b_Q$ forces $a_Q = b_Q$ for each Q (otherwise some strict inequality would remain after summing nonnegative differences). Conversely, if they agree pointwise and have nonzero mass, then min = max termwise and the ratio is 1. The separate zero-mass case rules out the degenerate situation where both numerator and denominator vanish; under the stated convention this yields similarity 0 rather than 1, which aligns with the interpretation that there is no positive evidence of shared properties. □

Lemma 67 (Association lower-bounds shared property mass)**.** *Assume the denominator is nonzero and let* $\alpha := \mathrm{assoc}_C(A,B) \in (0,1]$*. Then the intersection mass satisfies*

$$M_\cap(A,B) = \frac{\alpha}{1+\alpha}\Big(\|\mathrm{Prop}_C(A)\|_1 + \|\mathrm{Prop}_C(B)\|_1\Big).$$

In particular, if $\mathrm{assoc}_C(A,B) \ge \tau$ *then*

$$M_\cap(A,B) \;\ge\; \frac{\tau}{1+\tau}\Big(\|\mathrm{Prop}_C(A)\|_1 + \|\mathrm{Prop}_C(B)\|_1\Big).$$

Sketch. Solve the equation in Lemma 65 for $M_\cap$. Indeed, from $\alpha = M_\cap/(\|\mathrm{Prop}_C(A)\|_1 + \|\mathrm{Prop}_C(B)\|_1 - M_\cap)$ one obtains $\alpha(\|\mathrm{Prop}_C(A)\|_1 + \|\mathrm{Prop}_C(B)\|_1 - M_\cap) = M_\cap$, hence $\alpha(\|\mathrm{Prop}_C(A)\|_1 + \|\mathrm{Prop}_C(B)\|_1) = (1+\alpha)M_\cap$, yielding the displayed formula. The monotone implication for $\mathrm{assoc}_C(A,B) \ge \tau$ follows since the map $\alpha \mapsto \alpha/(1+\alpha)$ is increasing on $[0,\infty)$. □

Lemma 68 (Finite-vocabulary witness of shared patterns)**.** *Assume* P_C *is finite with* $|P_C| = N$*. If* $M_\cap(A,B) \ge \epsilon > 0$*, then there exists some pattern* $Q \in P_C$ *such that*

$$\min(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q)) \;\ge\; \epsilon/N.$$

Sketch. If every term were $< \epsilon/N$, the sum of N terms would be $< \epsilon$. Equivalently, this is a pigeonhole/averaging argument: the average value of the N nonnegative numbers $\min(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q))$ is $M_\cap(A,B)/N \ge \epsilon/N$, so at least one coordinate attains at least the average. Thus positive intersection mass in a finite vocabulary necessarily yields a concrete "witness" pattern shared to a quantitatively bounded degree. □

31.4 Emergence calculus

This subsection collects elementary algebraic facts about the emergence quantities introduced earlier, with an emphasis on inequalities and simplifications that can be used as plug-in steps inside longer arguments. Throughout, C denotes the ambient context, P_C the property space, E_C the space of eligible entities, and $I_C(Q;\cdot)$ the (normalized) degree to which an entity instantiates the property Q. The definitions of Sur_C and Emer_C are arranged so that Sur_C measures "excess property instantiation" of the composite relative to a baseline mixture of the parts, while $\mathrm{Emer}_C = \max(0, \mathrm{Sur}_C)$ retains only the positive (i.e., genuinely emergent) component. In particular, the weights $w_C(A), w_C(B)$ encode how strongly each part contributes to the baseline, so the baseline is a convex combination whenever the total baseline mass is nonzero.

Lemma 69 (Emergence weights form a convex pair)**.** *Assume $s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B) > 0$. Then the weights from Def. 101 satisfy*

$$w_C(A) \geq 0, \quad w_C(B) \geq 0, \quad w_C(A) + w_C(B) = 1.$$

Sketch. Immediate from Def. 101 as ratios of nonnegative numbers with common positive denominator. □

The condition $s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B) > 0$ is precisely what ensures that the normalization used to define $(w_C(A), w_C(B))$ is well-posed. When this hypothesis holds, $w_C(A)$ and $w_C(B)$ can be read as barycentric coordinates: any weighted baseline term of the form $w_C(A)\,x + w_C(B)\,y$ lies between $\min\{x, y\}$ and $\max\{x, y\}$, a fact that is repeatedly used implicitly when comparing Sur_C to $I_C(Q; A *_C B)$.

Lemma 70 (Basic emergence bounds)**.** *For any $Q \in P_C$ and $A *_C B$ defined:*

$$0 \leq \mathrm{Emer}_C(Q; A, B) \leq I_C(Q; A *_C B) \leq 1.$$

Sketch. By definition $\mathrm{Emer} = \max(0, \mathrm{Sur}) \geq 0$. Also $\mathrm{Emer} \leq \max(0, I_C(Q; A * B)) \leq I_C(Q; A * B)$ since the baseline term is nonnegative. Finally $I_C(\cdot;\cdot) \in [0, 1]$ by Def. 95 / Prop. 6. □

To make the middle inequality explicit, recall that $\mathrm{Sur}_C(Q; A, B)$ subtracts a baseline mixture of $I_C(Q; A)$ and $I_C(Q; B)$ (with weights from Lemma 69) from $I_C(Q; A *_C B)$. Since the baseline mixture is pointwise ≥ 0 whenever $I_C(\cdot;\cdot) \geq 0$, one has

$$\mathrm{Sur}_C(Q; A, B) \leq I_C(Q; A *_C B),$$

and therefore $\mathrm{Emer}_C(Q; A, B) = \max(0, \mathrm{Sur}_C(Q; A, B)) \leq \max(0, I_C(Q; A *_C B)) = I_C(Q; A *_C B)$ using $I_C(Q; A *_C B) \geq 0$. The upper bound by 1 is the normalization built into I_C, and it propagates to emergence because Emer_C never exceeds the composite score.

Lemma 71 (Equal-part simplification)**.** *Assume $s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B) > 0$ and $I_C(Q; A) = I_C(Q; B) = q$. Then*

$$\mathrm{Sur}_C(Q; A, B) = I_C(Q; A *_C B) - q, \qquad \mathrm{Emer}_C(Q; A, B) = \max(0, I_C(Q; A *_C B) - q).$$

Sketch. Use Lemma 69 to replace the weighted average by $w_C(A)q + w_C(B)q = q$. □

This simplification is often the fastest route to a usable estimate: whenever the two parts are indistinguishable with respect to the queried property Q, the entire baseline collapses to that common value q, independent of how the baseline weights split between A and B. In particular, in the equal-part regime, positivity of emergence for Q is equivalent to the single inequality $I_C(Q; A *_C B) > q$, i.e., the composite must score strictly above either part (since both parts share the same score).

Theorem 32 (Symmetry under commutative combination)**.** *If $*_C$ is commutative and $A *_C B$ is defined, then*

$$\mathrm{Emer}_C(Q; A, B) = \mathrm{Emer}_C(Q; B, A) \quad \textit{for all } Q \in P_C.$$

Sketch. This is Proposition 7 in Section 9: commutativity implies $A * B = B * A$ and the weights swap, leaving the surplus unchanged. □

Concretely, the Sur_C expression depends on (A, B) through (i) the composite $A *_C B$ and (ii) a weighted baseline that is affine in the pair of numbers $\big(I_C(Q; A), I_C(Q; B)\big)$. Under commutativity, the composite term is invariant, while exchanging (A, B) simply permutes the two weight–score products in the baseline, so the baseline sum is unchanged. Since Emer_C is obtained from Sur_C by applying $\max(0, \cdot)$ pointwise, the same invariance transfers immediately from surplus to emergence.

Lemma 72 (Collective-property-set monotonicity)**.** *Let $\mathcal{B} \subseteq E_C$ be a reference class and define*

$$\mathrm{Prop}_C^{\mathrm{coll}}(A)(Q) := \sup_{B \in \mathcal{B}} \mathrm{Emer}_C(Q; A, B) \qquad \textit{(Def. 103).}$$

Then:

1. $\mathrm{Prop}_C^{\mathrm{coll}}(A)(Q) \geq \mathrm{Emer}_C(Q; A, B)$ *for all $B \in \mathcal{B}$.*
2. *If $\mathcal{B} \subseteq \mathcal{B}'$, then $\mathrm{Prop}_{C,\mathcal{B}}^{\mathrm{coll}}(A)(Q) \leq \mathrm{Prop}_{C,\mathcal{B}'}^{\mathrm{coll}}(A)(Q)$.*

Sketch. (1) Supremum dominates each element. (2) Supremum over a larger set cannot decrease. □

The use of sup (rather than max) allows $\mathcal{B}$ to be infinite and also covers the common case where the "best" partner B is only approached by an improving sequence of candidates but not attained by any single $B \in \mathcal{B}$. Part (1) states that $\mathrm{Prop}_C^{\mathrm{coll}}(A)(Q)$ is an upper envelope of the family of functions $B \mapsto \mathrm{Emer}_C(Q; A, B)$ indexed by the reference class; part (2) is the corresponding isotonicity with respect to enlarging the admissible comparison set. Together these properties justify interpreting $\mathrm{Prop}_C^{\mathrm{coll}}(A)$ as a reference-class-dependent "potential for emergence" of A across possible blends with elements of $\mathcal{B}$, in the sense that giving oneself more admissible partners cannot reduce the measured potential.

31.5 Blend score calculus

Lemma 73 (Blend score bounds and symmetry)**.** *Let $\mathrm{blendscore}_C(C; A, B)$ be as in Def. 104. Then $0 \leq \mathrm{blendscore}_C(C; A, B) \leq 1$ and it is symmetric in (A, B).*

Sketch. The overlap term uses $\min(\mathrm{Prop}_C(C), \max(\mathrm{Prop}_C(A), \mathrm{Prop}_C(B))) \leq \mathrm{Prop}_C(C)$ pointwise, so $\mathrm{ov}_C(C; A, B) \leq \|\mathrm{Prop}_C(C)\|_1$, giving the ≤ 1 bound when mass is nonzero. Nonnegativity is immediate. Symmetry holds because $\max(\mathrm{Prop}(A), \mathrm{Prop}(B))$ is symmetric.

More explicitly, for each $Q \in P_C$ we have

$$0 \;\le\; \min\Big(\mathrm{Prop}_C(C)(Q),\, \max(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q))\Big) \;\le\; \mathrm{Prop}_C(C)(Q),$$

so summing over Q (or integrating, depending on the ambient model underlying $\|\cdot\|_1$) yields

$$0 \;\le\; \mathrm{ov}_C(C; A, B) \;\le\; \|\mathrm{Prop}_C(C)\|_1.$$

Dividing by $\|\mathrm{Prop}_C(C)\|_1$ (under the standing nonzero-mass condition in Def. 104) gives $0 \le \mathrm{blendscore}_C(C; A, B) \le 1$. The symmetry statement follows pointwise from

$$\max(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q)) = \max(\mathrm{Prop}_C(B)(Q), \mathrm{Prop}_C(A)(Q)),$$

hence the entire integrand (and therefore the overlap mass and the score) is unchanged by swapping A and B. □

Lemma 74 (Trivial blends (full property coverage))**.** *Assume* $\|\mathrm{Prop}_C(C)\|_1 > 0$*. If for all* $Q \in P_C$*,*

$$\mathrm{Prop}_C(C)(Q) \le \max(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q)),$$

then $\mathrm{blendscore}_C(C; A, B) = 1$ *(hence C is a blend at every threshold $\theta \le 1$). In particular, if $C = A$ or $C = B$ and* $\|\mathrm{Prop}_C(C)\|_1 > 0$*, then* $\mathrm{blendscore}_C(C; A, B) = 1$.

Sketch. Under the assumption, the min in Def. 104 equals $\mathrm{Prop}_C(C)(Q)$ for every Q, so $\mathrm{ov}_C = \|\mathrm{Prop}_C(C)\|_1$.

To spell out the pointwise step: the hypothesis says that for each Q,

$$\mathrm{Prop}_C(C)(Q) \;\le\; \max(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q)),$$

so the smaller of the two quantities $\mathrm{Prop}_C(C)(Q)$ and $\max(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q))$ is necessarily $\mathrm{Prop}_C(C)(Q)$, i.e.

$$\min\Big(\mathrm{Prop}_C(C)(Q),\, \max(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q))\Big) = \mathrm{Prop}_C(C)(Q).$$

Summing over $Q \in P_C$ gives $\mathrm{ov}_C(C; A, B) = \|\mathrm{Prop}_C(C)\|_1$, hence the normalized score in Def. 104 equals 1. The special case $C = A$ (or $C = B$) is immediate because then $\max(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q)) \ge \mathrm{Prop}_C(A)(Q) = \mathrm{Prop}_C(C)(Q)$ pointwise, so the coverage condition holds without further assumptions beyond $\|\mathrm{Prop}_C(C)\|_1 > 0$. □

Lemma 75 (Blend score monotonicity under stronger sources)**.** *Assume* $\|\mathrm{Prop}_C(C)\|_1 > 0$*. If* $A' \preceq_C A$ *and* $B' \preceq_C B$*, then*

$$\mathrm{blendscore}_C(C; A', B') \;\ge\; \mathrm{blendscore}_C(C; A, B).$$

Sketch. $A' \preceq_C A$ means $\mathrm{Prop}_C(A') \ge \mathrm{Prop}_C(A)$ pointwise, similarly for B'. Therefore $\max(\mathrm{Prop}(A'), \mathrm{Prop}(B')) \ge \max(\mathrm{Prop}(A), \mathrm{Prop}(B))$ pointwise, so the overlap mass in Def. 104 cannot decrease, while the denominator $\|\mathrm{Prop}(C)\|_1$ is unchanged.

Concretely, fix any $Q \in P_C$. From $A' \preceq_C A$ and $B' \preceq_C B$ we have

$$\mathrm{Prop}_C(A')(Q) \ge \mathrm{Prop}_C(A)(Q), \qquad \mathrm{Prop}_C(B')(Q) \ge \mathrm{Prop}_C(B)(Q),$$

hence

$$\max(\mathrm{Prop}_C(A')(Q), \mathrm{Prop}_C(B')(Q)) \;\ge\; \max(\mathrm{Prop}_C(A)(Q), \mathrm{Prop}_C(B)(Q)).$$

Applying $\min(\mathrm{Prop}_C(C)(Q), \cdot)$ to both sides preserves the inequality, so the integrand defining $\mathrm{ov}_C(C; \cdot, \cdot)$ in Def. 104 is pointwise larger (or equal) for (A', B') than for (A, B). Summation then yields

$$\mathrm{ov}_C(C; A', B') \;\geq\; \mathrm{ov}_C(C; A, B).$$

Dividing by the common positive normalization $\|\mathrm{Prop}_C(C)\|_1$ gives the claimed monotonicity of $\mathrm{blendscore}_C$. $\square$

It is sometimes helpful to read Lem. 75 as a kind of "antitonicity" in the preorder symbols: moving to A', B' that dominate A, B in the $\preceq_C$ sense (i.e. that have pointwise *larger* Prop_C values) can only increase the achievable overlap with the fixed target C. In particular, whenever one source is strengthened while the other is held fixed, the blend score cannot go down.

31.6 Lifting instance relations to groups

Lemma 76 (Singleton consistency)**.** *For an instance relation $C(\cdot, \cdot) : X \times Y \to [0, 1]$ and singletons $A = \{a\}$, $B = \{b\}$, the three lifts from Def. 106 satisfy*

$$C_{\mathrm{avg}}(A, B) = C_{\forall\exists}(A, B) = C_{\exists\forall}(A, B) = C(a, b).$$

Sketch. Each definition collapses to the unique entry $C(a, b)$ when $|A| = |B| = 1$. More explicitly, every aggregation involved in the three lifts is taken over an index set of size one: any average over $A \times B = \{(a, b)\}$ equals the single summand, any $\max_{b' \in B}$ equals evaluation at $b' = b$, and any $\min_{a' \in A}$ equals evaluation at $a' = a$. Thus no information is lost in lifting from instances to singleton groups: all three group-level scores coincide with the original instance score. $\square$

Lemma 77 (Minimax inequality for lifted relations)**.** *For finite nonempty $A \subseteq X$, $B \subseteq Y$:*

$$C_{\exists\forall}(A, B) \;\leq\; C_{\forall\exists}(A, B).$$

Sketch. This is the standard minimax inequality: $\max_b \min_a C(a, b) \leq \min_a \max_b C(a, b)$ for real matrices. To see the inequality directly, write $m(b) := \min_{a \in A} C(a, b)$ and $M(a) := \max_{b \in B} C(a, b)$. For any fixed pair $(a, b) \in A \times B$, we have $m(b) \leq C(a, b) \leq M(a)$, because $m(b)$ is the minimum in column b and $M(a)$ is the maximum in row a. Taking $\max_{b \in B}$ of the left inequality yields $\max_{b \in B} m(b) \leq C(a, b)$ for all a, b, and taking $\min_{a \in A}$ of the right inequality yields $C(a, b) \leq \min_{a \in A} M(a)$ for all a, b. Combining these bounds gives $\max_{b \in B} \min_{a \in A} C(a, b) \leq \min_{a \in A} \max_{b \in B} C(a, b)$, which is exactly the stated claim after matching to the definitions of $C_{\exists\forall}$ and $C_{\forall\exists}$. The finiteness and nonemptiness assumptions ensure these minima and maxima are attained and well-defined without additional conventions. $\square$

Lemma 78 (Monotonicity in group inclusion for the quantifier-like lifts)**.** *Let $A \subseteq A' \subseteq X$ and $B \subseteq B' \subseteq Y$ be finite nonempty. Then:*

$$C_{\forall\exists}(A', B) \leq C_{\forall\exists}(A, B), \qquad C_{\forall\exists}(A, B) \leq C_{\forall\exists}(A, B'),$$

and similarly

$$C_{\exists\forall}(A', B) \leq C_{\exists\forall}(A, B), \qquad C_{\exists\forall}(A, B) \leq C_{\exists\forall}(A, B').$$

Sketch. For $\forall\exists$: enlarging A adds more terms to a minimum (can only decrease), enlarging B adds more options to a maximum (can only increase). For $\exists\forall$: enlarging A decreases each inner minimum, enlarging B increases the outer maximum. Spelling out one representative inequality, for $C_{\forall\exists}$ we have

$$C_{\forall\exists}(A,B) = \min_{a\in A}\ \max_{b\in B} C(a,b), \qquad C_{\forall\exists}(A',B) = \min_{a\in A'}\ \max_{b\in B} C(a,b).$$

Since $A \subseteq A'$, the set of candidate values $\{\max_{b\in B} C(a,b) : a \in A'\}$ contains (at least) the set $\{\max_{b\in B} C(a,b) : a \in A\}$, so taking a minimum over the larger index set A' cannot produce a larger value; hence $C_{\forall\exists}(A',B) \le C_{\forall\exists}(A,B)$. For monotonicity in B, note that if $B \subseteq B'$ then for each fixed a,

$$\max_{b\in B} C(a,b) \ \le\ \max_{b\in B'} C(a,b),$$

and therefore taking $\min_{a\in A}$ on both sides yields $C_{\forall\exists}(A,B) \le C_{\forall\exists}(A,B')$. The corresponding statements for $C_{\exists\forall}$ follow by the same two elementary monotonicity facts for extrema: (i) enlarging the index set of a minimum can only decrease (or leave unchanged) the minimum, and (ii) enlarging the index set of a maximum can only increase (or leave unchanged) the maximum; applied in the correct order to

$$C_{\exists\forall}(A,B) = \max_{b\in B}\ \min_{a\in A} C(a,b).$$

Intuitively, $C_{\forall\exists}$ behaves like a "for all a there exists a good b" score, so adding more required a's makes the constraint stricter, while adding more available b's makes it easier; $C_{\exists\forall}$ behaves like "there exists a b that works for all a," so enlarging A makes each candidate b harder to satisfy and enlarging B offers more candidates b to choose from. □

31.7 Combinatorial-categorical closure (rule-based substitution)

Setup. Fix finite instances S and finite category domain W (Def. 107). A membership state is $m : S \to 2^W$. Given a theory T of rules $(x \in A) \wedge (y \in B) \to (z \in C)$ (Def. 108), define an immediate-consequence operator Φ_T on states by: for each $z \in S$,

$$\Phi_T(m)(z) := m(z) \cup \{\, C \in W : \exists \text{ rule } (x \in A)\wedge(y \in B) \to (z \in C) \in T \text{ with } A \in m(x), B \in m(y) \,\}.$$

Then the closure state m_T in Def. 109 is the least fixed point above m_0.

In more explicit lattice-theoretic terms, the space of all states is the finite product

$$\mathcal{M} := (2^W)^S,$$

ordered pointwise by $m \le m'$ iff $m(s) \subseteq m'(s)$ for all $s \in S$. With this order, $\mathcal{M}$ is a finite complete lattice: joins and meets are computed componentwise, e.g.,

$$\Big(\bigvee_i m_i\Big)(s) = \bigcup_i m_i(s), \qquad \Big(\bigwedge_i m_i\Big)(s) = \bigcap_i m_i(s).$$

The operator $\Phi_T : \mathcal{M} \to \mathcal{M}$ is precisely the usual "one-step consequence" operator familiar from forward-chaining: it leaves all existing labels in place and adds exactly those consequent labels C whose antecedents A, B are already present at the specified source instances x, y. Because S and W are finite, each state can be identified with a finite set of labeled facts $\{(s,\omega) : \omega \in m(s)\} \subseteq S \times W$, and Φ_T can be viewed as repeatedly saturating this set under the rules in T.

Lemma 79 (Monotonicity and extensivity of Φ_T)**.** *For all states m, m':*

$$m \le m' \implies \Phi_T(m) \le \Phi_T(m'), \qquad m \le \Phi_T(m),$$

where $m \le m'$ means $m(s) \subseteq m'(s)$ for all $s \in S$.

Sketch. If $m \leq m'$, any rule antecedent satisfied under m is also satisfied under m', so all added labels under m are also added under m'. Extensivity holds because $\Phi_T(m)(z)$ includes $m(z)$ by definition. $\square$

It is sometimes useful to spell out the monotonicity check componentwise: fix $z \in S$. If $C \in \Phi_T(m)(z)$, then either $C \in m(z)$ (hence $C \in m'(z) \subseteq \Phi_T(m')(z)$), or else C is justified by some rule $(x \in A) \wedge (y \in B) \to (z \in C)$ with $A \in m(x)$ and $B \in m(y)$. But $m \leq m'$ implies $A \in m'(x)$ and $B \in m'(y)$, so the same rule witnesses $C \in \Phi_T(m')(z)$. Thus $\Phi_T(m)(z) \subseteq \Phi_T(m')(z)$ for all z, i.e. $\Phi_T(m) \leq \Phi_T(m')$.

Lemma 80 (Finite convergence bound)**.** *Because S and W are finite and Φ_T is monotone and extensive, the iterative sequence $m_{n+1} := \Phi_T(m_n)$ starting from m_0 stabilizes after at most $|S| \cdot |W|$ strict label-additions. The limit is the least fixed point m_T (Def. 109).*

Sketch. Each strict step adds at least one new pair (s, ω) with $\omega \in m(s)$, and there are only $|S| \cdot |W|$ such pairs. By monotone iteration on a finite complete lattice, the limit is the least fixed point above m_0. $\square$

Concretely, extensivity implies a chain

$$m_0 \leq m_1 \leq m_2 \leq \cdots, \qquad \text{where } m_{n+1} = \Phi_T(m_n),$$

so no label ever disappears. Writing $E_n := \{(s, \omega) : \omega \in m_n(s)\} \subseteq S \times W$, each strict step satisfies $E_n \subsetneq E_{n+1}$ and therefore increases $|E_n|$ by at least 1. Since $|S \times W| = |S| \cdot |W|$, there can be at most $|S| \cdot |W|$ such strict increases before stabilization. At a stabilized stage N we have $m_{N+1} = m_N$, hence m_N is a fixed point of Φ_T.

Moreover, in this finite setting one can equivalently describe the resulting closure as the union of all iterates:

$$m_T = \bigvee_{n \geq 0} m_n, \qquad \text{that is, } m_T(s) = \bigcup_{n \geq 0} m_n(s) \text{ for each } s \in S,$$

and the union is attained at some finite N by the stabilization argument above. This is the usual Kleene construction for least fixed points specialized to finite lattices.

Lemma 81 (Monotonicity of closure in data and theory)**.** *If $m_0 \leq m'_0$ then $m_T \leq m'_T$. If $T \subseteq T'$ then $m_T \leq m_{T'}$ (same S, W, m_0).*

Sketch. Both follow from Lemma 79 and standard monotone-iteration / least-fixpoint arguments. $\square$

For the first claim, one can compare the two Kleene sequences $m_{n+1} = \Phi_T(m_n)$ and $m'_{n+1} = \Phi_T(m'_n)$ with $m_0 \leq m'_0$: Lemma 79 gives by induction that $m_n \leq m'_n$ for all n, hence also $\bigvee_n m_n \leq \bigvee_n m'_n$, i.e. $m_T \leq m'_T$. For the second claim, define Φ_T and $\Phi_{T'}$ from the two rule sets; then $T \subseteq T'$ implies $\Phi_T(m) \leq \Phi_{T'}(m)$ for every state m (since T' can only add more rule-justified consequents at each step). Iterating from the same m_0 preserves the inequality at each stage, yielding $m_T \leq m_{T'}$ at the stabilized limits.

Lemma 82 (Idempotence of closure)**.** *Let m_T be the closure of (T, S, m_0) (Def. 109). Then applying closure again does nothing:*

$$\Phi_T(m_T) = m_T.$$

Sketch. By definition, m_T is a fixed point of rule-application and is obtained as the least fixed point reached by iteration. $\square$

In particular, Lemma 82 says that m_T is already "saturated" under T: every consequent label that is derivable from the labels present in m_T is already included in m_T itself. Equivalently, if one views closure as the endofunction $\mathrm{cl}_T : \mathcal{M} \to \mathcal{M}$ defined by $\mathrm{cl}_T(m_0) := m_T$, then the three properties

$$m \leq \mathrm{cl}_T(m), \qquad m \leq m' \Rightarrow \mathrm{cl}_T(m) \leq \mathrm{cl}_T(m'), \qquad \mathrm{cl}_T(\mathrm{cl}_T(m)) = \mathrm{cl}_T(m),$$

are exactly extensivity, monotonicity, and idempotence of a closure operator on the lattice $\mathcal{M}$. This makes the construction compatible with standard notions of closure in algebra and logic: the closed states are precisely the fixed points of Φ_T, and m_T is the smallest closed state extending the initial data m_0.

Finally, because the rules are purely additive (no negation, no deletion), the computation of m_T can be organized as forward chaining: repeatedly scan for rules whose antecedents are satisfied and insert the missing consequent labels, halting when a full pass adds nothing. Lemma 80 ensures termination in the finite setting, and Lemma 81 ensures robustness under adding initial labels or enlarging the theory.

31.8 Combination systems, interpreters, and causal validity

Lemma 83 (Interpreter homomorphism extends to all parse trees)**.** *Let $(S, *, \mathrm{Dec})$ be an interpreted combination system (Def. 112) with syntax-composition $\cdot$. For any well-formed expression e built from $\cdot$ and atomic symbols, the value $\mathrm{Dec}(e)$ equals the result of evaluating the corresponding binary parse tree by $*$ (when defined). Moreover, when $*$ is a partial operation, the statement is to be read with the usual convention that only those parse-tree evaluations in which every internal node operation is defined are considered, and in that case the evaluation yields a unique element of S independent of any notational bracketing of e consistent with the given binary parse tree.*

Sketch. Structural induction on expressions: base case atoms is trivial; inductive step uses Def. 112: $\mathrm{Dec}(e_1 \cdot e_2) = \mathrm{Dec}(e_1) * \mathrm{Dec}(e_2)$. Concretely, for the induction hypothesis assume that for each immediate subexpression e_i the value $\mathrm{Dec}(e_i)$ agrees with the $*$-evaluation of the parse subtree rooted at e_i (when that subtree evaluation is defined). The parse tree for $e = e_1 \cdot e_2$ has root corresponding to $\cdot$ with left and right subtrees for e_1 and e_2, so evaluating the full tree is exactly applying $*$ to the two subtree values. Def. 112 provides precisely this compatibility between Dec and the syntactic constructor $\cdot$, and thus the root value produced by tree evaluation matches $\mathrm{Dec}(e)$. If $*$ is partial, then definedness of the full-tree evaluation is equivalent to definedness of the two subtree evaluations together with definedness of $\mathrm{Dec}(e_1) * \mathrm{Dec}(e_2)$, matching the recursive clause above. $\square$

Lemma 84 (Combination-preserving maps extend to composites)**.** *Let $f : D \to S$ be combination-preserving (Def. 113) between $(D, **)$ and $(S, *)$. Then for any composite term E built from elements of D using $**$ (when defined), $f(E)$ equals the corresponding composite of the f-images in $(S, *)$. Equivalently, if E is represented by a binary tree whose internal nodes are labeled by $**$ and whose leaves are labeled by elements of D, then applying f after evaluating the D-tree yields the same result as first mapping all leaves by f and then evaluating the resulting S-tree using $*$, provided each intermediate composition required is defined.*

Sketch. Induction on the composite structure using Def. 113 as the induction step. In the base case where E is a single element $d \in D$, the claim is $f(d) = f(d)$. For the inductive step, write $E = E_1 ** E_2$ with E_1, E_2 smaller composites and assume the claim holds for E_1 and E_2. Then

$$f(E) = f(E_1 ** E_2) = f(E_1) * f(E_2),$$

where the last equality is exactly the combination-preservation clause of Def. 113 (under the relevant definedness assumptions). Substituting the induction hypotheses for $f(E_1)$ and $f(E_2)$ identifies the right-hand side with the composite of the f-images, yielding the desired extension to all composite terms. $\square$

Theorem 33 (Validity implies factorization through the representation quotient)**.** *Let $\Gamma : D^3 \to [0,1]$ be a combinational dynamical causal model (Def. 114), and let $f : D \to S$ be a combination-preserving representational mapping (Def. 113). Assume Γ is valid relative to f (Def. 114). Define an equivalence relation $a \sim a'$ iff $f(a) = f(a')$. Then there exists a unique function $\overline{\Gamma} : (f(D))^3 \to [0,1]$ such that*

$$\Gamma(a,b,c) = \overline{\Gamma}(f(a), f(b), f(c)) \quad \textit{for all } a,b,c \in D.$$

In particular, Γ depends on (a,b,c) only through their representational images $(f(a), f(b), f(c))$, so any two triples (a,b,c) and (a',b',c') with the same f-images necessarily receive the same causal score.

Sketch. Define $\overline{\Gamma}(s_1, s_2, s_3) := \Gamma(a,b,c)$ for any a,b,c with $f(a) = s_1, f(b) = s_2, f(c) = s_3$. Validity ensures this is well-defined (independent of chosen representatives). Uniqueness is immediate. To spell out the well-definedness argument: suppose (a,b,c) and (a',b',c') are two choices with $f(a) = f(a') = s_1$, $f(b) = f(b') = s_2$, and $f(c) = f(c') = s_3$. By validity relative to f (Def. 114), replacing any argument of Γ by another element with the same f-image does not change the value, so one obtains $\Gamma(a,b,c) = \Gamma(a',b,c) = \Gamma(a',b',c) = \Gamma(a',b',c')$. Hence the definition of $\overline{\Gamma}(s_1,s_2,s_3)$ does not depend on the representatives chosen from each equivalence class. For uniqueness, if $\widetilde{\Gamma} : (f(D))^3 \to [0,1]$ also satisfies $\Gamma(a,b,c) = \widetilde{\Gamma}(f(a), f(b), f(c))$ for all a,b,c, then for any $(s_1,s_2,s_3) \in (f(D))^3$ choose representatives a,b,c with those images and conclude $\widetilde{\Gamma}(s_1,s_2,s_3) = \Gamma(a,b,c) = \overline{\Gamma}(s_1,s_2,s_3)$. $\square$

31.9 Specific entities as temporally coherent pattern bundles

Lemma 85 (Association threshold implies shared property mass)**.** *Let $x_t, x_{t'} \in E_C$ be two time-slices in an occurrence stream (Def. 115) and suppose the association is computed by Def. 100. If $\mathrm{assoc}_C(x_t, x_{t'}) \geq \tau > 0$ and the denominator is nonzero, then*

$$M_\cap(x_t, x_{t'}) \;\geq\; \frac{\tau}{1+\tau}\Big(\|\mathrm{Prop}_C(x_t)\|_1 + \|\mathrm{Prop}_C(x_{t'})\|_1\Big),$$

so "near-time similarity" (Def. 116) entails a quantitative lower bound on shared property overlap. In particular, the right-hand side scales linearly with the total property mass of the two slices (as measured by the ℓ_1-norm), so a fixed association threshold τ rules out the degenerate situation where x_t and $x_{t'}$ have large total property mass but negligible overlap. The condition that the denominator is nonzero is the standard well-definedness requirement in ratio-style similarity scores: it excludes the case where both slices carry no property mass at all (so that both $\|\mathrm{Prop}_C(x_t)\|_1$ and $\|\mathrm{Prop}_C(x_{t'})\|_1$ vanish and association becomes undefined or vacuous, depending on the chosen convention). Equivalently, for any fixed $\tau > 0$, association above τ forces $M_\cap(x_t, x_{t'})$ to be a nontrivial fraction $\tau/(1+\tau)$ of the combined mass $\|\mathrm{Prop}_C(x_t)\|_1 + \|\mathrm{Prop}_C(x_{t'})\|_1$, making the notion of "temporal coherence" operationally testable via overlap computations.

Sketch. Apply Lemma 67 with $A = x_t$ and $B = x_{t'}$. The inequality is the same statement specialized to two slices of a single occurrence stream; the proof obligation is therefore only to check that the association score used here is exactly the one referenced in Lemma 67 (Def. 100) and that the nonzero-denominator hypothesis matches the hypotheses of that lemma. $\square$

Lemma 86 (Finite-vocabulary: near-time similarity yields at least one shared strong pattern)**.** *Assume P_C is finite with $|P_C| = N$, and that $M_\cap(x_t, x_{t'}) \ge \epsilon > 0$. Then there exists some pattern $Q \in P_C$ such that Q is present in both slices with*

$$\mathrm{Prop}_C(x_t)(Q) \ge \epsilon/N \quad \textit{and} \quad \mathrm{Prop}_C(x_{t'})(Q) \ge \epsilon/N.$$

The content is a simple but important discretization principle: if the total *shared mass across a finite list of patterns is at least ϵ, then some* individual *pattern must contribute at least an ϵ/N share on both sides. This converts a global overlap guarantee (a single scalar lower bound on $M_\cap$) into the existence of a concrete witness pattern Q that can be used downstream as an explicit "identity carrier" (e.g., a named feature that persists across t and t') in logic-engine implementations.*

Sketch. Combine Lemma 68 with the definition of $M_\cap$ as a sum of mins. Concretely, writing $M_\cap(x_t, x_{t'}) = \sum_{R \in P_C} \min(\mathrm{Prop}_C(x_t)(R), \mathrm{Prop}_C(x_{t'})(R))$, the assumption $M_\cap(x_t, x_{t'}) \ge \epsilon$ implies that at least one summand satisfies $\min(\mathrm{Prop}_C(x_t)(Q), \mathrm{Prop}_C(x_{t'})(Q)) \ge \epsilon/N$; otherwise all N summands would be $< \epsilon/N$ and the total would be $< \epsilon$, contradicting the hypothesis. Unpacking the minimum then yields both inequalities $\mathrm{Prop}_C(x_t)(Q) \ge \epsilon/N$ and $\mathrm{Prop}_C(x_{t'})(Q) \ge \epsilon/N$. $\square$

Engineering note (logic-engine friendliness). Defs. 115–116 describe specific-entity identity as graded satisfaction of coherence rules. Lemmas 85–86 provide direct inference rules from an assoc threshold to guaranteed shared pattern overlap, which is often the most useful computable proxy for "temporal coherence" in automated reasoning. In practice, these lemmas support a two-stage strategy: first, use $\mathrm{assoc}_C(x_t, x_{t'}) \ge \tau$ as a fast filter to certify that overlap must be present at scale (Lemma 85); second, when P_C is finite (as is typical in engineered feature vocabularies), extract a concrete witness pattern Q that is provably shared above a known quantitative floor (Lemma 86). This is particularly helpful when subsequent rules require an explicit shared predicate rather than a real-valued similarity score: the witness Q can be reified as the common handle anchoring the two slices to a single temporally coherent bundle. Moreover, the bounds are monotone in the thresholds: increasing τ (or ϵ) strengthens the guaranteed overlap and thus reduces the risk that "identity links" are supported only by diffuse low-level noise spread across many patterns. .

32 Helper theorems for Section 10 (Information, uncertainty, and ineffability)

Standing conventions. Throughout, X is finite (or has been reduced to a finite partition of blocks), log is the natural logarithm, and we use the standard convention $0 \log 0 := 0$. An "indistinction weight" is a function $\iota(x, y) \in [0, 1]$; a reconstruction is a distribution $q \in \Delta(X)$. When log is taken to be natural, entropies and divergence-like quantities are measured in nats; changing the logarithm base merely rescales these quantities by a fixed constant, so statements that compare such values (e.g. inequalities or minimization principles) are invariant under this choice. The phrase "reduced to a finite partition of blocks" should be read literally: in many arguments the only structure that matters is the σ-algebra generated by an observer's coarse partition, and a finite partition ensures that all relevant objects may be represented by finite vectors and matrices (for example, by passing from microstates to block-labels). In particular, if X is replaced by a set of blocks $\{B_1, \ldots, B_k\}$, then a distribution on the reduced space is equivalently a distribution that is constant on each block of the original space, making explicit the idea that the observer cannot (or will not) resolve distinctions within a block.

Remark 1732. *The finiteness assumption on X is not merely a technical convenience: it ensures that all sums are finite and that σ-algebras generated by partitions behave in the simplest possible way. In the main text, X often stands for a world of possibilities available to an observer or modeling system; reducing to a finite partition amounts to a deliberate coarse-graining, i.e. a choice to treat many microstates as indistinguishable. This is one clean mathematical avatar of* uncertainty *(Hyperseed-Concept 195) and of the way* information *(Hyperseed-Concept* **??***) depends on what distinctions an observer is able or willing to draw. Equally importantly, finiteness avoids measure-theoretic pathologies that can obscure the intended interpretation: conditional probabilities and entropies on finite spaces can be handled by explicit finite sums, and statements about refinement/coarsening of partitions reduce to elementary combinatorics on blocks. When X is infinite but replaced by a finite partition, the loss of resolution is not an afterthought but part of the modeling stance: two microstates that lie in the same block are, by stipulation, observationally identical for the purposes of the theory being developed in Section 10. Thus, when later notions depend on what an agent can "say" or encode, the finitary reduction makes the dependence on representational granularity explicit rather than implicit.*

Remark 1733. *The convention $0 \log 0 := 0$ is a disciplined way of expressing the idea that events assigned probability 0 contribute no uncertainty: the limit $\lim_{t \downarrow 0} t \log t = 0$ makes the formula for Shannon entropy continuous at the boundary of the simplex. The symbol $\Delta(X)$ denotes the probability simplex on X, i.e. the set of functions $q : X \to [0,1]$ with $\sum_{x \in X} q(x) = 1$ (Hyperseed-Concept 139). An "indistinction weight" $\iota(x,y) \in [0,1]$ may be read as a graded notion of "x could be taken for y" (Hyperseed-Concept 98); it is the soft, quantitative cousin of the crisp equivalence relation behind a partition (Hyperseed-Concept* **??***). Such weights are the raw material from which we later define fidelity and ineffability (Hyperseed-Concept* **??***) in observer-relative terms. It is useful to keep in mind that, unless explicitly assumed later, ι need not be symmetric and need not satisfy transitivity: an agent might reliably mistake x for y without equally mistaking y for x (asymmetric confusability), and "could be taken for" may fail to propagate cleanly along chains of resemblance. Requiring only that $\iota(x,y) \in [0,1]$ keeps the framework broad enough to encompass both hard partitions (recoverable by setting ι to be 1 on a block and 0 across blocks) and more graded perceptual or representational limitations. Similarly, calling $q \in \Delta(X)$ a reconstruction emphasizes an intended role: q is not merely any distribution but a candidate posterior, guess, or synthesized representation of what the world could be, given limited access to distinctions. In later helper theorems, q typically appears as a variable over which some functional is minimized or maximized, formalizing the idea that an agent chooses (or is forced into) the "best available" representation under its constraints.*

Remark 1734. *For orientation, one may view many forthcoming quantities as functionals on $\Delta(X)$ assembled from finite sums of elementary terms such as $q(x) \log q(x)$ or $p(x) \log\big(p(x)/q(x)\big)$, possibly modified by an indistinction kernel $\iota(x,y)$ that blurs the contribution of specific states. The standing conventions above guarantee that all such expressions are well-defined without additional measurability hypotheses and that boundary cases (where some probabilities vanish) can be handled uniformly. This uniformity is especially helpful when formal claims about "ineffability" are meant to be robust under coarse-graining: replacing X by a partition should change the values in an interpretable way, rather than introducing technical exceptions.*

32.1 Observer-indexed coarse-graining facts

Lemma 87 (Partition-generated observables are exactly unions of blocks)**.** *Suppose $\Sigma_O \subseteq 2^X$ is generated by a partition $\pi_O = \{B_1, \ldots, B_k\}$. Then an event $A \subseteq X$ is O-observable (i.e. $A \in \Sigma_O$) iff A is a union of blocks of π_O. Equivalently, if $\alpha : X \to \{1, \ldots, k\}$ maps $x \mapsto i$ when $x \in B_i$, then $A \in \Sigma_O$ iff $A = \alpha^{-1}(S)$ for some $S \subseteq \{1, \ldots, k\}$. Moreover, in this finite-partition setting, Σ_O contains exactly 2^k events (one for each choice of subcollection of blocks), and Σ_O may be identified with the full power set $2^{\{1,\ldots,k\}}$ via $S \mapsto \alpha^{-1}(S)$.*

Remark 1735. *Intuitively, a partition π_O specifies exactly which distinctions the observer O can make. If O can only tell which block B_i the true state lies in, then the only well-posed yes/no questions are those whose answers depend only on the block-label, not on the fine-grained element within the block. In this sense, Σ_O is the algebra of "questions that make sense to O" given their perceptual or representational granularity (Hyperseed-Concept 134, and more broadly Hyperseed-Concept 86). One can also read this as a statement about invariance: A is O-observable exactly when it is constant on each block (i.e. whenever x, y lie in the same B_i, either both are in A or both are not in A). In that sense, π_O induces an "indistinguishability" relation on X, and O-observables are precisely those events that respect that relation.*

Remark 1736. *This lemma is a small but essential bridge between qualitative epistemology and quantitative information theory: once observables are characterized as unions of blocks, one can push probability distributions forward along α and compute entropies on the coarse space $\{1, \ldots, k\}$. This is one of the cleanest ways to see how information is* observer-indexed *rather than absolute. Concretely, if $(X, \Sigma, \mathbb{P})$ is a probability space with $\Sigma_O \subseteq \Sigma$, then α becomes a random variable taking values in $\{1, \ldots, k\}$, and $\mathbb{P}(\alpha = i) = \mathbb{P}(B_i)$. Any O-observable event A corresponds to a subset $S \subseteq \{1, \ldots, k\}$, so that $\mathbb{P}(A) = \mathbb{P}(\alpha \in S) = \sum_{i \in S} \mathbb{P}(B_i)$. Thus probabilities of O-events depend only on the block-masses, not on any finer distribution inside each B_i, which is exactly what it means for the observer to be insensitive to within-block structure.*

Remark 1737. *Before the proof, note the role of the symbols. The set 2^X is the power set of X (all events). A σ-algebra Σ_O is a collection of events closed under complements and countable unions; in the finite case, "countable unions" reduces to finite unions. The map $\alpha : X \to \{1, \ldots, k\}$ is simply the "block ID" map, and $\alpha^{-1}(S)$ is the event that the block ID lies in S. It is often helpful to note that Σ_O can also be written as $\sigma(\alpha)$, the σ-algebra generated by the random variable (measurable map) α; equivalently, $\Sigma_O = \{\alpha^{-1}(S) : S \subseteq \{1, \ldots, k\}\}$ when the codomain carries the discrete σ-algebra (which, for a finite set, is just its power set). This repackages the lemma into a standard measurability fact: an event is measurable with respect to α exactly when it is a preimage of an event in the codomain.*

Sketch. The σ-algebra generated by a partition is, by definition, the smallest σ-algebra containing each block; closure under complements and countable unions forces inclusion of all unions of blocks, and nothing else is needed (finite case). More explicitly, let

$$\mathcal{U} \;=\; \Big\{ \bigcup_{i \in S} B_i \;:\; S \subseteq \{1, \ldots, k\} \Big\}.$$

Then $\mathcal{U}$ contains each B_i (take $S = \{i\}$), contains $\emptyset$ (take $S = \emptyset$), and contains X (take $S = \{1, \ldots, k\}$). If $A = \bigcup_{i \in S} B_i \in \mathcal{U}$, then its complement is

$$X \setminus A \;=\; \bigcup_{i \notin S} B_i \in \mathcal{U},$$

so $\mathcal{U}$ is closed under complements. If $A_n = \bigcup_{i \in S_n} B_i \in \mathcal{U}$ is any sequence, then

$$\bigcup_{n=1}^{\infty} A_n \;=\; \bigcup_{n=1}^{\infty} \bigcup_{i \in S_n} B_i \;=\; \bigcup_{i \in \cup_n S_n} B_i \in \mathcal{U},$$

so $\mathcal{U}$ is closed under countable unions as well (and in the present finite setting, this closure is equivalent to closure under finite unions). Hence $\mathcal{U}$ is a σ-algebra containing the blocks, so by minimality of the generated σ-algebra we have $\Sigma_O \subseteq \mathcal{U}$. Conversely, since Σ_O contains each block and is closed under unions, it must contain every union of blocks, so $\mathcal{U} \subseteq \Sigma_O$. Therefore $\Sigma_O = \mathcal{U}$, proving the "union of blocks" characterization. The equivalence with $A = \alpha^{-1}(S)$ follows by observing that $\alpha^{-1}(S) = \bigcup_{i \in S} B_i$ by definition of α and the partition. □

Remark 1738. Proof sketch. *The strategy is purely structural: show that the family of all unions of blocks is itself a σ-algebra containing each block, and then use minimality of the generated σ-algebra to conclude equality.* □

The key step is that closure under complements turns a union of blocks into a union of the remaining blocks, while closure under unions composes unions-of-blocks into unions-of-blocks. Visually, one may imagine the blocks as "pixels"; the only shapes expressible to O are those made by selecting whole pixels, never by cutting a pixel in half. An equivalent visualization is via quotienting: the partition induces a quotient set $X/\!\sim$, where $x \sim y$ iff they lie in the same block. The map α is (up to relabeling) the quotient map, and Σ_O consists precisely of the events that are inverse images of subsets downstairs. So an O-observable event is one that is well-defined on equivalence classes, i.e. it makes sense to ask it without specifying which representative inside the class is realized.

Remark 1739. *Two small corollaries are often useful in later information-theoretic manipulations. First, every O-observable event A is determined by the* index set $S_A = \{i : B_i \subseteq A\}$, *and conversely $A = \bigcup_{i \in S_A} B_i$. Second, if one works with indicator functions, then $\mathbf{1}_A$ is Σ_O-measurable iff $\mathbf{1}_A = f \circ \alpha$ for some $f : \{1, \ldots, k\} \to \{0, 1\}$, i.e. iff the truth value of A is a function of the coarse label alone. This provides a convenient functional form of the same idea that will align with later uses of random variables and coarse-grained statistics.*

32.2 Shannon identities that are useful as rewrite rules

Lemma 88 (Cross-entropy decomposition)**.** *For distributions p, q on X with $q(x) > 0$ whenever $p(x) > 0$,*

$$H(p, q) \;=\; H(p) \;+\; D_{\mathrm{KL}}(p \| q).$$

In particular, $H(p, q) \geq H(p)$ with equality iff $p = q$.

Remark 1740. *This identity says: the expected code-length of using the "wrong" model q when the truth is p equals the intrinsic uncertainty of p plus a nonnegative penalty measuring how far q deviates from p. In philosophical terms, $H(p)$ is the ineliminable opacity in the source itself, whereas $D_{\mathrm{KL}}(p \| q)$ is the price of an epistemic misfit between representation and reality (Hyperseed-Concept* **??**, *Hyperseed-Concept* **??***). This decomposition is standard in information theory and underlies many minimum-cross-entropy and maximum-likelihood principles; it also resonates with algorithmic perspectives on description and model mismatch [16]. One can also read the identity as a "rewrite rule" for optimizing models: minimizing cross-entropy $H(p, q)$ over q is equivalent to minimizing $D_{\mathrm{KL}}(p \| q)$, since $H(p)$ does not depend on q. In this way, KL divergence measures the* excess *description length beyond what is unavoidable given the source p itself. Finally, the numerical value depends on the base of the logarithm: base 2 gives bits, base e gives nats, and the identity holds verbatim in any base as long as it is used consistently in all three quantities.*

Remark 1741. *A simple example: let $X = \{0, 1\}$ and $p(1) = 1/2$ (a fair coin), but you insist on using $q(1) = 0.9$. Then $H(p)$ is $\log 2$, while $H(p, q)$ is larger because your model predicts 1 too often; the gap is exactly $D_{\mathrm{KL}}(p\|q) > 0$. Thus, even when the world is maximally uncertain (fair coin), you can still do strictly worse by holding an incorrect belief. If we take base-2 logarithms to make the code-length interpretation literal (in bits), then*

$$H(p, q) = -\tfrac{1}{2}\log_2(0.9) - \tfrac{1}{2}\log_2(0.1) = \tfrac{1}{2}\log_2\left(\tfrac{1}{0.09}\right) = \tfrac{1}{2}\log_2(11.\overline{1}) \approx 1.736,$$

whereas $H(p) = 1$. Hence $D_{\mathrm{KL}}(p\|q) = H(p, q) - H(p) \approx 0.736$ bits: on average, using the wrong model costs roughly three quarters of a bit per outcome relative to the optimal code matched to the fair coin. This makes vivid that the penalty term is not merely qualitative; it is an explicit and operationally meaningful loss.

Remark 1742. *Before the proof, recall the meaning of the notation: $H(p)$ is Shannon entropy $-\sum_x p(x)\log p(x)$; $H(p, q)$ is cross-entropy $-\sum_x p(x)\log q(x)$; and $D_{\mathrm{KL}}(p\|q)$ is the Kullback–Leibler divergence $\sum_x p(x)\log\frac{p(x)}{q(x)}$. The support condition $q(x) > 0$ whenever $p(x) > 0$ ensures that $\log\frac{p(x)}{q(x)}$ never evaluates to $\log\frac{\text{positive}}{0}$. Equivalently, it ensures that $H(p, q)$ is finite: if some event has $p(x) > 0$ but $q(x) = 0$, then the term $-p(x)\log q(x)$ contributes $+\infty$, reflecting that a code optimized for q would assign infinite length to an event that actually occurs with positive probability under p. In this sense, the support condition is not an artificial technicality: it encodes the minimal requirement that the model q does not declare genuinely possible outcomes to be impossible. For completeness, one typically adopts the convention $0\log 0 := 0$ (as a limit) in Shannon entropy, so terms with $p(x) = 0$ do not cause difficulties in $H(p)$; the real obstruction is only when $q(x) = 0$ on the support of p.*

Sketch. Expand definitions: $D_{\mathrm{KL}}(p\|q) = \sum_x p(x)\log\frac{p(x)}{q(x)} = \sum_x p(x)\log p(x) - \sum_x p(x)\log q(x) = -H(p) + H(p, q)$. Rearrange. The inequality follows from $D_{\mathrm{KL}} \geq 0$. To connect this directly to the intended "rewrite" usage: the displayed computation is precisely the algebraic step that allows one to replace an expression involving $H(p, q)$ by one involving $H(p)$ and $D_{\mathrm{KL}}(p\|q)$ (or vice versa), whichever is more convenient for subsequent bounds or conceptual interpretation. ☐

Remark 1743. Proof sketch. *Compute $D_{\mathrm{KL}}(p\|q)$ and observe it is exactly the difference between cross-entropy and entropy; then appeal to the general fact $D_{\mathrm{KL}} \geq 0$.* ☐

The algebra works because $\log\frac{p}{q} = \log p - \log q$, so the sum splits into two sums, one being $-H(p)$ and the other being $H(p, q)$. Geometrically, D_{KL} is a kind of directed "separation" between distributions, so it is natural that it measures the excess cost of coding under the wrong model. It is worth stressing the "directed" aspect: typically $D_{\mathrm{KL}}(p\|q) \neq D_{\mathrm{KL}}(q\|p)$, so the penalty depends on which distribution is the data-generating truth and which distribution is the assumed model. This asymmetry matches the operational story: data are drawn from p, but the coder chooses q, so the expectation is taken with respect to p. As a practical rewrite rule, the identity is often used in the form

$$H(p, q) - H(p) = D_{\mathrm{KL}}(p\|q),$$

i.e. "excess average codelength equals divergence." In arguments about uncertainty and ineffability, this can be read as: some portion of opacity is irreducible ($H(p)$), while the rest is an avoidable artifact of misrepresentation ($D_{\mathrm{KL}}(p\|q)$).

Lemma 89 (Entropy bounds via uniform comparison)**.** *Let $|X| = n$ and let u be uniform on X. Then $0 \leq H(p) \leq \log n$. Moreover, $H(p) = 0$ iff p is a point-mass, and $H(p) = \log n$ iff $p = u$.*

Remark 1744. *This lemma formalizes two extremes of uncertainty (Hyperseed-Concept 195). At one end, a point-mass distribution corresponds to complete certainty: there is no surprise, no freedom of outcome, hence entropy* 0*. At the other end, the uniform distribution spreads belief evenly across* n *possibilities, maximizing ignorance subject to the finite support constraint, hence entropy* $\log n$*. The result is also a moral: entropy is not "disorder" in the abstract; it is a measure of how evenly probability mass is distributed across the distinguishable alternatives (Hyperseed-Concept* **??***). A further useful perspective is that the upper bound* $\log n$ *is not merely a numerical ceiling but the entropy of the maximally symmetric state on a set of* n *labeled alternatives. Thus, whenever an argument bounds some complicated distribution by comparing it to uniform, it is implicitly appealing to symmetry as the criterion for maximal uncertainty.*

Remark 1745. *A concrete example: with* $n = 4$ *equiprobable outcomes,* $H = \log 4 = 2\log 2$*. If instead all mass is on one outcome,* $H = 0$*. If mass is split* $(1/2, 1/2, 0, 0)$*, then* $H = \log 2$*; one may read this as "only one bit of uncertainty remains" after coarse elimination of two possibilities. One can also see the concavity of entropy numerically here: averaging two point-masses (certainty in one of two outcomes) yields the mixed distribution* $(1/2, 1/2, 0, 0)$*, whose entropy* $\log 2$ *is larger than the average entropy* 0 *of the extremes. This is the same mechanism, in miniature, behind why the uniform distribution is the unique maximizer on the simplex.*

Remark 1746. *Before the proof, note that comparing to uniform is a standard technique:* $D_{\mathrm{KL}}(p\|u) \geq 0$ *is equivalent to* $H(p) \leq H(u) = \log n$*. This is one place where the cross-entropy decomposition of Lemma 88 functions as a rewrite rule: by choosing a particular* q*, one obtains inequalities for* $H(p)$*. In fact, specializing Lemma 88 to* $q = u$ *yields an identity (not only an inequality):*

$$H(p) = H(u) - D_{\mathrm{KL}}(p\|u) = \log n - D_{\mathrm{KL}}(p\|u),$$

which makes the upper bound transparent: entropy falls short of $\log n$ *by exactly the amount of non-uniformity measured by* $D_{\mathrm{KL}}(p\|u)$*. This form is often useful when one wants a quantitative stability statement: if* p *is close to uniform in KL divergence, then* $H(p)$ *is close to its maximum.*

Sketch. Nonnegativity: $H(p) = -\sum_x p(x)\log p(x)$ and $\log p(x) \leq 0$. Upper bound: $D_{\mathrm{KL}}(p\|u) \geq 0$ gives $\sum_x p(x)\log\frac{p(x)}{1/n} \geq 0$, i.e. $\sum_x p(x)\log p(x) + \log n \geq 0$, so $H(p) \leq \log n$. Equality conditions are the standard equality cases of Gibbs' inequality. For the lower bound, one may also note explicitly that each term satisfies $-p(x)\log p(x) \geq 0$ for $p(x) \in [0, 1]$ (with $0\log 0 := 0$), so the sum cannot be negative. For the upper bound, the equality case $D_{\mathrm{KL}}(p\|u) = 0$ occurs exactly when $p = u$, yielding $H(p) = \log n$, whereas entropy 0 occurs exactly at the vertices of the simplex, i.e. point masses. ☐

Remark 1747. Proof sketch. *Show* $H(p) \geq 0$ *termwise, and show* $H(p) \leq \log n$ *by comparing* p *to the uniform distribution using KL divergence.* ☐

The key mechanism is convexity (hidden inside Gibbs' inequality): uniform is the maximizer of entropy because it is the unique distribution that does not privilege any outcome. One may visualize the simplex $\Delta(X)$*: entropy is a concave function on this simplex, achieving its maximum at the center (uniform) and minima at the vertices (point masses). Another standard route to the same conclusion (consistent with the "rewrite rule" framing) is to maximize* $H(p)$ *under the constraint* $\sum_x p(x) = 1$ *via Lagrange multipliers: the stationarity condition forces* $p(x)$ *to be constant in* x*, hence uniform. The KL-divergence method is often preferred because it yields both the bound and a canonical measure of the gap to optimality:* $\log n - H(p) = D_{\mathrm{KL}}(p\|u)$*. In later arguments, it is frequently helpful to remember that these inequalities are tight and structural: they are not artifacts of a loose estimate, but rather reflect the geometry of the probability simplex together with the strict concavity of the entropy functional.*

32.3 Mutual and interaction information: algebraic normal forms

Lemma 90 (Mutual information: nonnegativity and independence test)**.** *For finite random variables (X, Y) with joint $p(x, y)$,*

$$I(X;Y) \;=\; D_{\mathrm{KL}}(p(x,y)\,\|\,p(x)p(y)) \;\geq\; 0,$$

and $I(X;Y) = 0$ iff $p(x,y) = p(x)p(y)$ (i.e. X and Y are independent).

Remark 1748. *It is often useful to keep in mind the equivalent entropy identities (all for finite variables)*

$$I(X;Y) = H(X) + H(Y) - H(X,Y) = H(X) - H(X|Y) = H(Y) - H(Y|X),$$

which make explicit the interpretation of mutual information as a "reduction in uncertainty." These equalities are compatible with the KL-divergence definition because, expanding $D_{\mathrm{KL}}(p(x,y)\|p(x)p(y))$ as a sum $\sum_{x,y} p(x,y) \log \frac{p(x,y)}{p(x)p(y)}$ and collecting terms, one recovers precisely the entropy combination above. In particular, the unit of $I(X;Y)$ (bits vs. nats) is determined by the base of the logarithm used in $H(\cdot)$ and $D_{\mathrm{KL}}(\cdot\|\cdot)$.

Remark 1749. *Mutual information measures the extent to which knowing X reduces uncertainty about Y (and symmetrically). It is the quantitative shadow of the intuitive idea of* constraint *or* coupling *between variables: if the joint distribution factors, then the variables do not constrain one another, and the mutual information vanishes. If the joint cannot be factored, the mutual information is strictly positive, encoding precisely how far the world is from being decomposable into independent parts (Hyperseed-Concept 117).*

Remark 1750. *A simple example: if $Y = X$ for a fair bit, then $I(X;Y) = H(X) = \log 2$; all uncertainty about Y is resolved by observing X. If X and Y are independent fair bits, then $I(X;Y) = 0$. Thus mutual information behaves like a measure of "shared structure" between two descriptions of reality, and it is foundational both in classical information theory and in algorithmic analogues [16].*

Remark 1751. *Before the proof, note that $p(x)p(y)$ denotes the product of the marginals, i.e. the joint distribution one would have if X and Y were independent. The identity in the lemma therefore states that mutual information is precisely the KL divergence between the true joint and the closest "independent-world" model obtained by fixing marginals.*

Remark 1752. *To avoid any ambiguity about domains: since we assumed (X, Y) are finite, all sums below are over finite supports. As usual in information theory, terms with $p(x,y) = 0$ contribute 0 to expressions of the form $p(x,y)\log(\cdot)$, while $D_{\mathrm{KL}}(p\|q)$ is defined to be $+\infty$ if there exists an atom with $p > 0$ but $q = 0$. In the present lemma, $q(x,y) = p(x)p(y)$, so this pathology cannot occur unless one allows marginals with zeros that exclude points where $p(x,y) > 0$; for ordinary discrete random variables, $p(x,y) > 0$ implies $p(x) > 0$ and $p(y) > 0$, hence $q(x,y) > 0$.*

Sketch. Immediate from the KL expression and $D_{\mathrm{KL}} \geq 0$, with equality iff the two distributions coincide. □

Remark 1753. Proof sketch. *Rewrite $I(X;Y)$ as a KL divergence, then use the general theorem that KL divergence is always nonnegative and is zero exactly when its arguments match.* □

The decisive step is conceptual: once mutual information is recognized as a KL divergence, its basic order-theoretic behavior (nonnegativity and equality case) becomes automatic. The geometry is that the set of independent distributions $p(x)p(y)$ forms a curved submanifold inside the simplex of all joint distributions, and $I(X;Y)$ quantifies departure from that submanifold.

Remark 1754. *If one wants a more explicit inequality behind $D_{\mathrm{KL}} \geq 0$, one can appeal to the log-sum inequality or to Jensen's inequality applied to the convex function $t \mapsto t \log t$. Concretely, writing $D_{\mathrm{KL}}(p\|q) = \sum_{x,y} p(x,y) \log \frac{p(x,y)}{q(x,y)}$ and using $\log u \leq u - 1$ (equivalently $-\log u \geq 1 - u$) with $u = q/p$ yields*

$$D_{\mathrm{KL}}(p\|q) \;=\; \sum_{x,y} p(x,y) \log \frac{p(x,y)}{q(x,y)} \;\geq\; \sum_{x,y} \big(p(x,y) - q(x,y)\big) = 0,$$

and the equality condition forces $p(x,y) = q(x,y)$ for all (x,y) with $p(x,y) > 0$, i.e. precisely the independence condition in this case.

Lemma 91 (Mutual information upper bounds)**.** *For finite (X,Y),*

$$I(X;Y) \leq H(X) \qquad \textit{and} \qquad I(X;Y) \leq H(Y).$$

Remark 1755. *This lemma states an epistemic sanity constraint: the information X can provide about Y cannot exceed the total uncertainty in X itself (and vice versa). One cannot extract more "shared information" than there is information to share. In contexts where X is interpreted as a message or measurement, the bound reads as: the channel cannot transmit more than the entropy of its input.*

Remark 1756. *A slightly different but equivalent viewpoint is obtained from the identity $I(X;Y) = H(X) - H(X|Y)$. Since conditional entropy is nonnegative, $H(X|Y) \geq 0$, one immediately gets $I(X;Y) \leq H(X)$, with equality precisely when $H(X|Y) = 0$, i.e. when X is a deterministic function of Y (almost surely). Symmetrically, $I(X;Y) \leq H(Y)$, with equality when Y is (a.s.) a function of X. This makes clear that the upper bounds are tight and characterize the "noiseless decoding" extremes.*

Remark 1757. *Before the proof, recall that the chain rule expresses $H(X,Y)$ as $H(X)+H(Y|X)$ and also as $H(Y)+H(X|Y)$, where conditional entropies are always ≥ 0. The inequality $H(X,Y) \geq H(X)$ is precisely the statement that joint uncertainty cannot be smaller than uncertainty in a marginal.*

Sketch. Use the standard chain-rule identity $H(X,Y) = H(X) + H(Y|X) \geq H(X)$ and also $H(X,Y) \geq H(Y)$. Then $I(X;Y) = H(X)+H(Y)-H(X,Y) \leq H(X)$ and symmetrically $\leq H(Y)$. (Any preferred proof of $H(X,Y) \geq H(X)$ can be used, e.g. via log-sum inequality.) ☐

Remark 1758. Proof sketch. *Use the chain rule to lower bound $H(X,Y)$ by $H(X)$ and $H(Y)$; then substitute into $I(X;Y) = H(X) + H(Y) - H(X,Y)$.* ☐

The key move is recognizing conditional entropy as a nonnegative remainder term. Visually, if one imagines entropy as "volume" of uncertainty, then $H(X,Y)$ is a volume in the product space, which must dominate the projection volumes $H(X)$ and $H(Y)$.

Remark 1759. *The upper bounds can also be read as a constraint on correlation structure: if $H(X)$ is small (for instance, X is nearly deterministic), then regardless of how complicated Y is, the shared information cannot exceed that small budget. This is one reason mutual information is often more robust than correlation coefficients when comparing variables with different alphabets or different degrees of intrinsic randomness: the entropy caps automatically normalize what is even possible.*

Lemma 92 (Interaction information as an alternating sum of entropies)**.** *Assuming the standard conditional-mutual-information identity $I(X;Y|Z) = H(X|Z)+H(Y|Z)-H(X,Y|Z)$ (equivalently $I(X;Y|Z) = H(X,Z) + H(Y,Z) - H(Z) - H(X,Y,Z)$), the interaction information satisfies the symmetric expansion*

$$I(X;Y;Z) = H(X) + H(Y) + H(Z) - H(X,Y) - H(X,Z) - H(Y,Z) + H(X,Y,Z).$$

In particular, $I(X;Y;Z)$ is invariant under permutation of (X,Y,Z).

Remark 1760. *One common definition (equivalent to the expansion above, given the stated identities) is*

$$I(X;Y;Z) \;=\; I(X;Y) - I(X;Y|Z),$$

which makes explicit that interaction information compares the X–Y dependence "before" and "after" revealing Z. From this viewpoint, the alternating-sum normal form is obtained simply by substituting $I(X;Y) = H(X)+H(Y)-H(X,Y)$ and the given expression for $I(X;Y|Z)$, and then collecting like entropy terms. The permutation invariance is then a consequence of the fact that the resulting polynomial in joint entropies is manifestly symmetric.

Remark 1761. *Interaction information $I(X;Y;Z)$ is a higher-order quantity: it measures how the dependence between X and Y changes when one conditions on Z. Unlike ordinary mutual information, it can be positive or negative, reflecting the subtlety of three-way constraint: Z can either explain away a correlation (yielding negative interaction information in some conventions) or create synergy where the pair (X,Y) together carries information about Z not present in either alone (Hyperseed-Concept* **??***).*

Remark 1762. *The sign can be sanity-checked on canonical examples. If Z is a common cause that renders X and Y conditionally independent (so $I(X;Y|Z) = 0$ but $I(X;Y) > 0$), then $I(X;Y;Z) = I(X;Y) > 0$ under the convention $I(X;Y;Z) = I(X;Y) - I(X;Y|Z)$. Conversely, if X and Y are marginally independent but become dependent after conditioning on Z (a collider pattern), then $I(X;Y) = 0$ while $I(X;Y|Z) > 0$, producing $I(X;Y;Z) < 0$. These examples illustrate why interaction information is not a simple "amount of dependence" but rather an interference term measuring how dependencies compose.*

Remark 1763. *The alternating-sum normal form is important because it allows one to compute and transform interaction information using only entropies of various marginals. This makes it a convenient "algebraic normal form" for proofs and for deriving identities: once expanded, symmetry under permutation becomes visible by inspection rather than by argument.*

Remark 1764. *A practical advantage of the alternating-sum form is that it makes cancellations transparent in proofs that involve adding and subtracting information quantities. For instance, when comparing two interaction-information terms that share marginals (e.g. replacing Z by (Z,W)), many entropy terms cancel immediately, leaving a small remainder that can often be recognized as a conditional mutual information. This "algebraic bookkeeping" role is analogous to how inclusion–exclusion turns set-cardinality calculations into an alternating sum of intersections.*

Remark 1765. *Before the proof, observe the bookkeeping: the formula is an inclusion–exclusion pattern in which single-variable entropies appear with $+$, pairwise entropies with $-$, and the triple entropy with $+$. This is a signature that interaction information is, in a precise sense, a third-order correction term measuring what is* not *captured by all lower-order marginals.*

Sketch. Start from the definition $I(X;Y;Z) = I(X;Y) - I(X;Y|Z)$. Replace $I(X;Y)$ by $H(X) + H(Y) - H(X,Y)$, and replace $I(X;Y|Z)$ by the entropy form above, then simplify by cancellation. The final expression is manifestly symmetric. □

Remark 1766. Proof sketch. *Expand the definition in terms of $I(X;Y)$ and $I(X;Y|Z)$, rewrite each in terms of entropies, and cancel like terms to obtain an inclusion–exclusion expression.* □

The cancellation works because conditioning on Z replaces each entropy term by a corresponding term that includes Z (e.g. $H(X|Z) = H(X,Z) - H(Z)$). The geometric intuition is that the alternating sum is analogous to subtracting overlaps between sets: pairwise overlaps are removed, but then the triple overlap must be added back.

32.4 Logical entropy, graphtropy, and their links to fidelity

Lemma 93 (Logical entropy monotone under refinement)**.** *Let π' refine π (every block of π is a union of blocks of π'). Then for any distribution p on X,*

$$h(\pi, p) \;\le\; h(\pi', p).$$

Remark 1767. *Logical entropy $h(\pi, p)$ (Hyperseed-Concept 105) is the probability that two independent draws from p fall into* different *blocks of the partition π; it is, in Ellerman's terminology, a measure of distinctions rather than surprises [17]. A refinement π' makes* more *distinctions, so it is natural that it can only increase the chance that two samples are separated.*

Remark 1768. *As an example, if π has two blocks $\{a, b\}$ and $\{c, d\}$ under the uniform distribution, then $h(\pi, p) = 1 - (1/2)^2 - (1/2)^2 = 1/2$. If one refines $\{a, b\}$ into $\{a\}$ and $\{b\}$ while leaving $\{c, d\}$ intact, then the block masses become $(1/4, 1/4, 1/2)$ and $h(\pi', p) = 1 - (1/4)^2 - (1/4)^2 - (1/2)^2 = 5/8 > 1/2$.*

Remark 1769. *Before the proof, note the refinement relation: writing $\pi = \{B_i\}$ and $\pi' = \{B'_j\}$, refinement means each B_i is a disjoint union of some subcollection of the B'_j. Thus the coarse block mass p_i is the sum of the fine block masses p'_j over those j in the subcollection.*

Sketch. Let coarse block masses be $p_i = \sum_{j \in J_i} p'_j$ where p'_j are fine masses. Then by convexity of $t \mapsto t^2$, $(\sum_{j \in J_i} p'_j)^2 \ge \sum_{j \in J_i} (p'_j)^2$. Summing over i gives $\sum_i p_i^2 \ge \sum_j (p'_j)^2$. Since $h(\cdot, p) = 1 - \sum (\cdot)^2$, the inequality reverses as stated. □

Remark 1770. Proof sketch. *Express coarse masses as sums of fine masses and apply convexity of the square function to show $\sum p_i^2$ decreases under refinement; since $h = 1 - \sum p_i^2$, h increases.* □

The key step is that squaring punishes concentration: merging probabilities (coarsening) increases the sum of squares, while splitting probabilities (refinement) decreases it. Visually, refinement spreads mass across more bins, which increases the chance that two draws land in different bins.

Lemma 94 (Logical entropy maximum on k blocks)**.** *If π has k blocks with block masses $(p_1, \dots, p_k)$, then*

$$0 \le h(\pi, p) = 1 - \sum_{i=1}^{k} p_i^2 \le 1 - \frac{1}{k},$$

with equality $h(\pi, p) = 1 - \frac{1}{k}$ iff $p_i = \frac{1}{k}$ for all i.

Remark 1771. *This is the logical-entropy analogue of the Shannon statement "entropy is maximized by uniform". Here the maximum distinction-rate is achieved when the observer's coarse blocks are equiprobable: then two random samples are most likely to fall into different blocks. The bound $1-1/k$ is also intuitively satisfying: with k equally likely blocks, the chance of matching blocks is $1/k$, so the chance of a distinction is $1-1/k$.*

Remark 1772. *Before the proof, notice that the constraint $\sum_i p_i = 1$ places (p_i) on the standard simplex, and $\sum_i p_i^2$ is minimized (hence h maximized) at the barycenter. Cauchy–Schwarz provides a one-line certificate of that minimization.*

Sketch. By Cauchy–Schwarz, $\sum_i p_i^2 \geq \frac{(\sum_i p_i)^2}{k} = \frac{1}{k}$. Thus $h = 1 - \sum_i p_i^2 \leq 1 - \frac{1}{k}$. Equality in Cauchy–Schwarz gives p_i all equal. $\square$

Remark 1773. Proof sketch. *Use Cauchy–Schwarz to lower bound $\sum_i p_i^2$ by $1/k$, then translate to an upper bound on $h = 1 - \sum_i p_i^2$.* $\square$

The proof works because Cauchy–Schwarz captures the idea that, among nonnegative numbers with fixed sum, the sum of squares is minimized when the numbers are equal. One may picture h as the amount of "separation" created by the partition under p; equal block masses are the configuration that makes the partition maximally separating in expectation.

Lemma 95 (Graphtropy is expected distinction error under the "prior" reconstruction)**.** *Let G be an indistinction structure with weights $\iota_G(x,y) \in [0,1]$ and let $p \in \Delta(X)$. Define the distinction error* $\mathrm{Err}_G(x,q) = \sum_y q(y)\,(1-\iota_G(x,y))$ *and fidelity* $\mathrm{Fid}_G(x,q) = \sum_y q(y)\,\iota_G(x,y)$*. Then*

$$GT(G,p) \;=\; \mathbb{E}_{x\sim p}\big[\mathrm{Err}_G(x,p)\big] \qquad \textit{and} \qquad 1 - GT(G,p) \;=\; \mathbb{E}_{x\sim p}\big[\mathrm{Fid}_G(x,p)\big].$$

Remark 1774. *Graphtropy (Hyperseed-Concept **??**) generalizes logical entropy from crisp partitions to graded indistinction graphs. The lemma tells us that graphtropy is literally an expected* distinction error *when one uses the "prior" p as the reconstruction of a state drawn from p. In other words, it quantifies how much indistinction structure G fails to support faithful self-reconstruction, when no additional evidence beyond the prior is used. This connects the combinatorial notion of "distinctions" directly to an epistemic notion of representation quality (Hyperseed-Concept 157).*

Remark 1775. *A simple sanity check: if $\iota_G(x,y) = 1$ for all (x,y) (everything is indistinguishable), then $\mathrm{Err}_G(x,q) = 0$ and $GT(G,p) = 0$; perfect indistinction yields no distinction errors precisely because the scoring rule never penalizes confusion. At the other extreme, if $\iota_G(x,y) = \mathbf{1}[x=y]$ (the crisp identity relation), then $\mathrm{Err}_G(x,p) = 1 - p(x)$ and $\mathbb{E}_{x\sim p}[1-p(x)] = 1 - \sum_x p(x)^2$, recovering logical entropy as expected mismatch. This illustrates how graphtropy interpolates between classical partitions and graded similarity structures, as discussed in broader pattern-theoretic settings [5]. In particular, one can read ι_G as a (possibly asymmetric) "confusability profile": the closer $\iota_G(x,y)$ is to 1, the less costly it is to confuse x with y under Err_G. Thus, as ι_G is made sharper (mass concentrated nearer the diagonal $x=y$), the same distribution p yields larger expected error and hence larger graphtropy, reflecting that the underlying notion of distinction has become more discriminating.*

Remark 1776. *Before the proof, unpack the notation: $\mathbb{E}_{x\sim p}[\cdot]$ denotes expectation when x is drawn according to p. The functions Err_G and Fid_G are linear in q and sum the (in)distinction weights against a reconstruction distribution. The identity $\mathrm{Fid}_G(x,q) = 1 - \mathrm{Err}_G(x,q)$ is immediate from $\iota_G(x,y) \in [0,1]$ and $(1-\iota_G(x,y))$ being complementary at each pair (x,y). Equivalently, for fixed x the quantity $\sum_y q(y)\iota_G(x,y)$ is an average similarity of the reconstruction $y \sim q$ to the* *target x, and $\sum_y q(y)(1-\iota_G(x,y))$ is the corresponding average dissimilarity; the complementarity holds pointwise before taking any expectation over x. This also highlights that the construction does not assume $q=p$: one can interpret $\mathrm{Err}_G(x,q)$ as the expected "distinction loss" when x is encoded/approximated by a distribution q, and the main identity specializes this to the self-consistent case $q=p$.*

Sketch. Expand: $\mathbb{E}_{x\sim p}[\mathrm{Err}_G(x,p)] = \sum_x p(x)\sum_y p(y)(1-\iota_G(x,y)) = 1-\sum_{x,y} p(x)p(y)\iota_G(x,y) = GT(G,p)$. The fidelity identity is the complement. For avoidance of doubt, the step from $\sum_x p(x)\sum_y p(y)(1-\iota_G(x,y))$ to the double sum $\sum_{x,y} p(x)p(y)(1-\iota_G(x,y))$ is just Fubini/Tonelli for finite (or absolutely summable) expressions, and it makes explicit that (x,y) are being sampled independently from p. □

Remark 1777. Proof sketch. *Write the expectation as a double sum over (x,y) drawn independently from p, then recognize the definition of $GT(G,p)$ (and its complement) inside the algebra.* □

The decisive maneuver is exchanging the order of summation: expectation over x of a q-average over y is just the expectation over independent (x,y). Geometrically, this is averaging a "blurring kernel" ι_G over the product measure $p\otimes p$, so graphtropy is a global property of how p sits inside the indistinction geometry induced by G. In particular, if p concentrates on a region where $\iota_G(x,y)$ is typically large (many pairs are mutually indistinct), then $\sum_{x,y} p(x)p(y)\iota_G(x,y)$ is large and $GT(G,p) = 1-\sum_{x,y} p(x)p(y)\iota_G(x,y)$ is small; conversely, if p spreads mass across mutually distinct regions, then the expected indistinction drops and graphtropy rises. This mirrors the usual partition picture: "spread out over many blocks" increases the probability that two independent draws fall in different blocks.

Corollary 9 (Entropy–distinction conversion bounds)**.** *Let π be a partition with block masses (p_i) and logical entropy $h(\pi,p) = 1-\sum_i p_i^2$. Then the quadratic entropy $H_2 := -\log\sum_i p_i^2$ satisfies*

$$H(\pi) \geq H_2 = -\log(1-h(\pi,p)).$$

Equivalently, any lower bound $h(\pi,p)\geq h_0$ implies $H(\pi)\geq -\log(1-h_0)$. In this partition setting, $\sum_i p_i^2$ is also the collision probability (the probability that two independent draws land in the same block), so the bound can be read as: if collisions are sufficiently unlikely, then Shannon entropy must be large. The monotonicity of $x\mapsto -\log x$ on $(0,1]$ explains why a lower bound on h (i.e., an upper bound on $\sum_i p_i^2$) turns directly into a lower bound on H_2, and then on H.

Remark 1778. *This corollary provides a translation dictionary between two ways of speaking about "how much is distinguished." Logical entropy measures distinctions directly as a probability of inequality of blocks, while Shannon entropy measures average surprise. The inequality says that a sufficiently high distinction-rate forces a nontrivial Shannon entropy lower bound. Thus, even though H and h encode different intuitions, they constrain one another, and one may use whichever is easier to bound in a given argument [17]. One practical point is that $h(\pi,p)$ is quadratic and often admits direct estimation or bounding by Cauchy–Schwarz-type arguments, while $H(\pi)$ involves a logarithm and can be harder to handle algebraically. The corollary lets one turn such quadratic control into an information-theoretic lower bound without committing to a particular coding interpretation beyond the standard meaning of Shannon entropy.*

Remark 1779. *Before the proof, note that H_2 is the order-2 Rényi ("quadratic") entropy, and it is often algebraically simpler because it depends on $\sum_i p_i^2$ rather than $\sum_i p_i\log p_i$. The identity $\sum_i p_i^2 = 1-h(\pi,p)$ makes the conversion particularly transparent. Also recall that for a fixed* *distribution, Rényi entropies are nonincreasing in the order parameter, so $H(\pi) \geq H_2$ is consistent with the general fact $H = H_1 \geq H_2$; here we are simply extracting the explicit dependence on $h(\pi, p)$ via $\sum_i p_i^2$.*

Sketch. This is the partition specialization of the Shannon-vs-quadratic bound $H \geq H_2$ (derived via KL nonnegativity by comparing p to $p^2/\sum p^2$), followed by the identity $\sum_i p_i^2 = 1 - h(\pi, p)$. Concretely, letting $r_i := p_i^2/\sum_j p_j^2$ and using $D_{\mathrm{KL}}(p\|r) \geq 0$ yields $\sum_i p_i \log p_i \geq \sum_i p_i \log r_i = \sum_i p_i(2 \log p_i - \log \sum_j p_j^2)$, which rearranges to $-\sum_i p_i \log p_i \geq -\log \sum_j p_j^2$. □

Remark 1780. Proof sketch. *Use a known inequality $H \geq H_2$ (provable via KL divergence), then substitute $\sum_i p_i^2 = 1 - h(\pi, p)$ to express the quadratic entropy bound in terms of logical entropy.* □

The proof works because KL nonnegativity is a versatile engine: one compares p to a carefully chosen distribution built from p itself (here proportional to p^2), extracting an inequality between two functionals. The logarithm then turns multiplicative concentration (captured by $\sum p_i^2$) into an additive lower bound on H. It is worth emphasizing that the comparison distribution $p^2/\sum p^2$ biases toward heavier blocks, so $D_{\mathrm{KL}}(p\|p^2/\sum p^2) \geq 0$ is precisely measuring the impossibility of p being "more spread out" than its own squared reweighting; the resulting inequality formalizes the intuition that if p has low collision probability then it must also have high average surprise.

32.5 Effability / ineffability: monotonicity and optimization forms

Lemma 96 (Fidelity is a bounded linear functional)**.** *For fixed x and G, the map $q \mapsto \mathrm{Fid}_G(x, q) = \sum_y q(y)\iota_G(x, y)$ is linear in q, and satisfies $0 \leq \mathrm{Fid}_G(x, q) \leq 1$.*

Remark 1781. *This lemma expresses a comforting fact: fidelity is an expectation value. Given x, the number $\iota_G(x, y)$ is the degree to which y counts as an acceptable reconstruction of x under the indistinction structure G. If one randomizes reconstructions according to q, fidelity is simply the average acceptability. Linearity means that mixing strategies mixes fidelities with no hidden nonlinearity, and boundedness means fidelity is a genuine "score" in $[0, 1]$. This is the basic quantitative substrate for talking about effability and ineffability (Hyperseed-Concept **??**) as optimization problems over descriptions.*

Remark 1782. *Example: if $\iota_G(x, y) = \mathbf{1}[x = y]$, then $\mathrm{Fid}_G(x, q) = q(x)$, the probability of reconstructing x exactly. If instead $\iota_G(x, y)$ gives partial credit to near-misses, then $\mathrm{Fid}_G(x, q)$ is expected partial credit, still linear in q.*

Remark 1783. *Before the proof, note that linearity is with respect to the vector space structure on functions $q : X \to \mathbb{R}$; restricting to $\Delta(X)$ makes $\mathrm{Fid}_G(x, q)$ an affine functional on the simplex. The bound $[0, 1]$ comes from the fact that q is a convex combination and $\iota_G(x, \cdot)$ takes values in $[0, 1]$.*

Sketch. Linearity is immediate from the sum. Since $\iota_G(x, y) \in [0, 1]$ and q is a probability distribution, $\mathrm{Fid}_G(x, q)$ is a convex combination of numbers in $[0, 1]$. □

Remark 1784. Proof sketch. *View $\mathrm{Fid}_G(x, q)$ as an inner product of q with the vector $\iota_G(x, \cdot)$, and use that convex combinations preserve bounds.* □

The key step is recognizing "probability-weighted average" as the archetype of a bounded linear functional. Geometrically, for fixed x, $\mathrm{Fid}_G(x, \cdot)$ is a hyperplane functional on the simplex, so its extrema over $\Delta(X)$ occur at vertices (pure reconstructions), a useful fact for optimization intuition even when the formal optimization is constrained by description budgets.

Remark 1785. *A small strengthening that is often implicitly used in later arguments is the following: because* $\mathrm{Fid}_G(x,\cdot)$ *is linear on the ambient vector space and* $\Delta(X)$ *is convex, the image* $\mathrm{Fid}_G(x,\Delta(X))$ *is an interval in* $\mathbb{R}$*. In particular, once one knows the maximum achievable fidelity over a feasible set of posteriors/reconstructions, all smaller fidelities are automatically achievable by mixing with a low-fidelity reconstruction. This "interval property" is what makes threshold-style definitions of effability natural: there is a single frontier value, and any tolerance* ε *simply asks whether that frontier lies above* $1-\varepsilon$*.*

Remark 1786. *In finite* X*, one can make the "extrema occur at vertices" remark fully explicit: writing* $q = \sum_y q(y)\,\delta_y$*, linearity gives* $\mathrm{Fid}_G(x,q) = \sum_y q(y)\mathrm{Fid}_G(x,\delta_y)$*, so the maximum over all* $q \in \Delta(X)$ *equals* $\max_y \iota_G(x,y)$*. This is the special case where the reconstruction distribution* q *itself is unconstrained; later, when* q *must arise as* $\mathrm{dec}_O(d)$ *from a description* d *under a budget* $\sigma_O(d) \le K$*, the feasible set is typically nontrivial, and the maximizer need not be a delta distribution even though the objective remains linear.*

Lemma 97 (Effability is monotone in tolerance ε)**.** *Fix* O,K,G*. If* $0<\varepsilon\le\varepsilon'<1$*, then*

$$\mathrm{Eff}_O(\varepsilon,K;G) \subseteq \mathrm{Eff}_O(\varepsilon',K;G).$$

Remark 1787. *This lemma says that if you relax your standards, more things become expressible. Effability is an observer-relative notion of what can be said (or encoded) about* x *given a limited expressive budget* K*; increasing* ε *corresponds to tolerating lower fidelity. The monotonicity is thus conceptually inevitable: allowing more error cannot reduce the set of acceptable descriptions. Here ineffability (Hyperseed-Concept* **??***) is not mystical but operational: it is the complement of an attainable fidelity region under constraints.*

Remark 1788. *Before the proof, keep track of inequalities:* $\varepsilon \le \varepsilon'$ *implies* $1-\varepsilon' \le 1-\varepsilon$*. Thus any description meeting the stricter fidelity threshold* $1-\varepsilon$ *automatically meets the weaker one* $1-\varepsilon'$*.*

Sketch. If x has a description d with $\sigma_O(d) \le K$ and $\mathrm{Fid}_G(x,\mathrm{dec}_O(d)) \ge 1-\varepsilon$, then also $\mathrm{Fid}_G(x,\mathrm{dec}_O(d)) \ge 1-\varepsilon'$ because $1-\varepsilon' \le 1-\varepsilon$. □

Remark 1789. Proof sketch. *Reuse the same witnessing description* d*: the only thing that changes is the threshold, and the threshold becomes easier to satisfy.* □

The proof is a single inequality chase. The visual intuition is that for fixed budget K*, each* x *has an achievable fidelity interval* $[0,\mathrm{Fid}^\star(x;K)]$*; increasing* ε *lowers the required fidelity and therefore expands the feasible set.*

Remark 1790. *One can also read Lemma 97 contrapositively: if* x *is ineffable at a more permissive tolerance* ε'*, then it is ineffable at every stricter tolerance* $\varepsilon \le \varepsilon'$*. This emphasizes that "ineffability" is stable under tightening requirements: once the available descriptions fail even a lenient target, there is no hope of meeting a more demanding one without changing the resource bound* K *or the indistinction structure* G*.*

Lemma 98 (Effability as a best-achievable-fidelity threshold)**.** *Fix* O,G *and define the best achievable fidelity at budget* K *by*

$$\mathrm{Fid}^\star_{O,G}(x;K) \;:=\; \sup\{\mathrm{Fid}_G(x,\mathrm{dec}_O(d)) :\; d\in D_O,\; \sigma_O(d)\le K\}.$$

Then x *is* (ε,K)*-effable (relative to* G*) iff*

$$\mathrm{Fid}^\star_{O,G}(x;K) \;\ge\; 1-\varepsilon.$$

Moreover, $\mathrm{Fid}^\star_{O,G}(x;K)$ *is nondecreasing in* K*, and nondecreasing under coarse-graining of* G *(in the sense* $\iota_G \le \iota_{G'}$ *pointwise).*

Remark 1791. *This lemma repackages an existential definition ("there exists a description meeting a threshold") into an optimization statement ("the best possible score exceeds the threshold"). This is more than cosmetic: it lets one bring to bear the tools and intuitions of optimization, duality, and monotone resource tradeoffs. In the language of cognition, K is a resource bound on representation, and* $\mathrm{Fid}^\star$ *is the best attainable alignment between what is and what can be said about it (Hyperseed-Concept 157, Hyperseed-Concept* **??***).*

Remark 1792. *The definition of* $\mathrm{Fid}^\star_{O,G}(x;K)$ *is intentionally phrased as a supremum rather than a maximum: depending on the structure of the description space D_O and the decoder* dec_O*, the set of achievable fidelities need not contain its top element (for instance, if increasingly long descriptions approximate a limit behavior). In many discrete settings (finite D_O under the constraint $\sigma_O(d) \le K$, or compactness/continuity hypotheses), the supremum is attained and one may replace* sup *by* max *without changing the value. Even when it is not attained, the threshold characterization remains operational:* $\mathrm{Fid}^\star_{O,G}(x;K) \ge 1-\varepsilon$ *means that for every $\delta > 0$ there exists a description achieving fidelity at least $1-\varepsilon-\delta$.*

Sketch. For the threshold equivalence, unwind the definitions. By definition, x is (ε, K)-effable (relative to G) iff there exists some description $d \in D_O$ with $\sigma_O(d) \le K$ such that $\mathrm{Fid}_G(x, \mathrm{dec}_O(d)) \ge 1-\varepsilon$. This holds iff the supremum over all such descriptions is at least $1-\varepsilon$, i.e. iff $\mathrm{Fid}^\star_{O,G}(x;K) \ge 1-\varepsilon$.

For monotonicity in K, note that if $K \le K'$ then the feasible set $\{d : \sigma_O(d) \le K\}$ is contained in $\{d : \sigma_O(d) \le K'\}$, so taking a supremum over the larger set cannot decrease the value: $\mathrm{Fid}^\star_{O,G}(x;K) \le \mathrm{Fid}^\star_{O,G}(x;K')$.

For monotonicity under coarse-graining, assume $\iota_G \le \iota_{G'}$ pointwise. Then for every reconstruction distribution q,

$$\mathrm{Fid}_G(x,q) = \sum_y q(y)\iota_G(x,y) \;\le\; \sum_y q(y)\iota_{G'}(x,y) = \mathrm{Fid}_{G'}(x,q),$$

and in particular for every description d we have $\mathrm{Fid}_G(x, \mathrm{dec}_O(d)) \le \mathrm{Fid}_{G'}(x, \mathrm{dec}_O(d))$. Taking suprema over the same feasible set $\{d : \sigma_O(d) \le K\}$ yields $\mathrm{Fid}^\star_{O,G}(x;K) \le \mathrm{Fid}^\star_{O,G'}(x;K)$. ☐

Remark 1793. *The two monotonicities in Lemma 98 encode distinct "knobs." The resource knob K enlarges the admissible description set, so it can only improve best-case fidelity. The granularity knob G changes what counts as "close enough"; replacing G by a coarser indistinction structure G' (larger ι pointwise) weakens the success criterion, so any fixed decoding strategy scores at least as well. This clean separation is useful when analyzing tradeoffs: one can ask whether increasing K (better descriptions) or coarse-graining G (lower-resolution standards) is the more plausible route to effability for a given class of objects.*

Remark 1794. *A convenient way to visualize the threshold statement is to treat* $\mathrm{Fid}^\star_{O,G}(x;K)$ *as a "frontier function" of the resource K. Then the effability predicate $x \in \mathrm{Eff}_O(\varepsilon, K; G)$ is simply the superlevel condition* $\mathrm{Fid}^\star_{O,G}(x;K) \ge 1-\varepsilon$*. As K increases, the frontier moves upward (never downward), and as ε increases, the horizontal cutoff $1-\varepsilon$ moves downward. This is the basic geometry behind later statements that effability regions are nested in both parameters.*

Remark 1795. *The two monotonicity statements encode two different philosophical levers. Increasing K expands the expressive repertoire of the observer O, so attainable fidelity cannot decrease. Coarse-graining G (increasing indistinction weights so that more outcomes count as acceptable reconstructions) also cannot decrease fidelity. The second monotonicity captures a form of "forgiving* *semantics": if you decide to treat more things as the same, you make it easier to speak truthfully within your new, blurred ontology. In more operational terms, monotonicity in K is a claim about* resources *(how long/complex a description may be), whereas monotonicity in G is a claim about* evaluation *(how strictly reconstructions are judged). Both are order-theoretic statements: one is induced by inclusion of feasible-description sets, and the other by pointwise enlargement of the kernel used to score reconstructions.*

Remark 1796. *Before the proof, interpret the symbols: D_O is the description space available to observer O, $\sigma_O(d)$ is the description cost/size, and $\mathrm{dec}_O(d)$ is the reconstruction distribution induced by decoding d. The supremum is used rather than maximum because the feasible set may not contain an optimizer (e.g. if description costs are real-valued and the fidelity approaches a limit). Concretely, if $\mathrm{Fid}_G(x, \mathrm{dec}_O(d_n)) \uparrow L$ along a sequence of descriptions (d_n) with $\sigma_O(d_n) \le K$, it can happen that no single description attains L even though L is the best achievable value in the limit; the optimization problem is then naturally expressed using* sup. *One can also view σ_O as generating nested feasible sets*

$$\mathcal{F}_O(K) \;:=\; \{d \in D_O : \sigma_O(d) \le K\},$$

so that the quantity of interest is the value function $K \mapsto \sup_{d\in\mathcal{F}_O(K)} \mathrm{Fid}_G(x, \mathrm{dec}_O(d))$, which is automatically monotone under $\mathcal{F}_O(K) \subseteq \mathcal{F}_O(K')$ for $K \le K'$.

Sketch. The equivalence is just unrolling the $\exists d$ in the definition of effability into a supremum comparison. Monotonicity in K holds because the feasible-description set grows with K. Monotonicity in G follows from pointwise $\iota_G \le \iota_{G'}$ implying $\mathrm{Fid}_{G'}(x, q) \ge \mathrm{Fid}_G(x, q)$ for every q. More explicitly, the "$\exists d$" form says: there exists some d with $\sigma_O(d) \le K$ such that $\mathrm{Fid}_G(x, \mathrm{dec}_O(d)) \ge 1 - \varepsilon$. This holds if and only if the supremum of $\mathrm{Fid}_G(x, \mathrm{dec}_O(d))$ over all d with $\sigma_O(d) \le K$ is at least $1 - \varepsilon$ (because a supremum is $\ge 1 - \varepsilon$ exactly when some feasible point attains $\ge 1 - \varepsilon$, or at least can be approximated arbitrarily well from below when the target threshold is strict). For monotonicity in K, if $K \le K'$ then $\{d : \sigma_O(d) \le K\} \subseteq \{d : \sigma_O(d) \le K'\}$, hence

$$\sup_{\sigma_O(d)\le K} \mathrm{Fid}_G(x, \mathrm{dec}_O(d)) \;\le\; \sup_{\sigma_O(d)\le K'} \mathrm{Fid}_G(x, \mathrm{dec}_O(d)).$$

For monotonicity in G, the condition $\iota_G \le \iota_{G'}$ is a pointwise comparison of the scoring kernels, so the induced fidelity functional (which is linear in the reconstruction distribution q) increases pointwise: evaluating the same q under a more permissive G' cannot lower the score. □

Remark 1797. Proof sketch. *Translate "there exists a feasible description with fidelity $\ge 1 - \varepsilon$" into "the supremum of fidelities over feasible descriptions is $\ge 1 - \varepsilon$", and then note that enlarging the feasible set (via K) or enlarging the fidelity kernel (via G') cannot reduce a supremum.* □

The key steps are: (i) supremum-as-relaxed-existential, (ii) monotonicity of supremum under set inclusion, and (iii) pointwise domination of kernels implying domination of the resulting linear functionals in Lemma 96. A helpful picture is that of a Pareto frontier: $\mathrm{Fid}^\star(x; K)$ *is the upper envelope of achievable fidelity as a function of resources. One can make step (iii) concrete by writing fidelity in the typical bilinear form*

$$\mathrm{Fid}_G(x, q) \;=\; \sum_y \iota_G(x, y)\, q(y)$$

(or the corresponding integral), so that $\iota_G \le \iota_{G'}$ implies $\sum_y \iota_G(x, y)q(y) \le \sum_y \iota_{G'}(x, y)q(y)$ for every distribution q, since $q(y) \ge 0$ and $\sum_y q(y) = 1$. In this view, coarse-graining is literally an upward shift of the payoff vector $\iota_G(x, \cdot)$, and the decoder is choosing a distribution q inside

a constraint set determined by descriptions; the supremum simply picks the best payoff achievable under those constraints. The Pareto-frontier intuition can also be read as a tradeoff curve between description cost and semantic accuracy: allowing larger K moves one along the frontier, whereas replacing G by a coarser G' changes the scoring rule so that the same point in description space is evaluated more leniently.

Remark 1798. *It is sometimes useful to restate the same content as a value function and threshold test: define* $\mathrm{Fid}^{\star}_{O,G}(x;K) := \sup\{\mathrm{Fid}_G(x, \mathrm{dec}_O(d)) : d \in D_O,\ \sigma_O(d) \le K\}$*. Then "$x$ is (O, K, G, ε)-effable" is equivalent to* $\mathrm{Fid}^{\star}_{O,G}(x;K) \ge 1 - \varepsilon$*. This makes clear that ε is merely a reporting threshold on the monotone function $K \mapsto \mathrm{Fid}^{\star}_{O,G}(x;K)$, and that different choices of G correspond to different monotone families $K \mapsto \mathrm{Fid}^{\star}_{O,G}(x;K)$ ordered by kernel domination.*

32.6 Potential infinity and infinitesimals: algebra of germs

Lemma 99 (Well-defined ring structure on germs)**.** *Let $\mathbb{R}^{\mathbb{N}}/\sim$ be germs under eventual equality. If $a \sim a'$ and $b \sim b'$, then $a + b \sim a' + b'$ and $ab \sim a'b'$. Hence addition and multiplication on equivalence classes are well-defined.*

Remark 1799. *This subsection formalizes a mild version of "potential infinity" (Hyperseed-Concept* **??***): we reason about sequences, but we identify two sequences if they agree eventually, i.e. if their differences occur only at finitely many indices. The resulting objects are* germs*, capturing the idea that only the tail behavior matters. This is a pragmatic mathematical way to speak about infinite processes while ignoring finite initial transients—a move common in asymptotics, dynamics, and learning theory. In particular, the quotient $\mathbb{R}^{\mathbb{N}}/\sim$ can be read as a formalization of the slogan "only what happens after some finite time matters," with the understanding that the relevant "finite time" is allowed to depend on the statement being proved. This is exactly the pattern used when one writes $a_n = b_n$ "for n large enough," or when one argues that a learning algorithm eventually enters a stable regime and the warm-up phase can be ignored for asymptotic comparisons.*

Remark 1800. *The lemma is necessary because we want to do algebra on germs. If we define $[a]+[b] := [a+b]$, this must not depend on the chosen representatives. The statement is the standard compatibility condition that turns an equivalence relation into a quotient algebra. Equivalently, one may say that "eventual equality" is a congruence relation on the ring $\mathbb{R}^{\mathbb{N}}$ (with pointwise operations): it is not merely an equivalence relation on the underlying set, but one that is respected by addition and multiplication. This congruence viewpoint is what guarantees that $\mathbb{R}^{\mathbb{N}}/\sim$ inherits the structure of a commutative ring in a canonical way.*

Remark 1801. *Before the proof, the symbols mean: $\mathbb{R}^{\mathbb{N}}$ is the set of real sequences $a = (a_1, a_2, \dots)$, and $a \sim a'$ means $\exists N$ such that $a_n = a'_n$ for all $n \ge N$ ("eventual equality"). The equivalence class of a is written $[a]$. It is helpful to keep in mind that $\sim$ ignores a* finite *prefix of the sequence: two representatives may differ arbitrarily on indices $n < N$ without changing the germ. In particular, any statement about a germ that is well-posed should be invariant under such finite modifications. This is why proofs in this setting often take the form "choose a horizon N large enough so that all the desired tail properties hold simultaneously."*

Sketch. If $a_n = a'_n$ and $b_n = b'_n$ for all $n \ge N$, then $(a_n + b_n) = (a'_n + b'_n)$ and $(a_n b_n) = (a'_n b'_n)$ for all $n \ge N$ as well. □

Remark 1802. Proof sketch. *Take the index N after which both equalities hold, and check that addition/multiplication preserve pointwise equality for all $n \ge N$.* □

The key step is that ring operations are defined pointwise on sequences, so any property that holds for all sufficiently large n is preserved by these operations. One may visualize germs as "functions near infinity": equal near infinity implies sums and products are equal near infinity. A further useful intuition is that the set of "eventually zero" sequences forms an ideal in $\mathbb{R}^{\mathbb{N}}$, and $\mathbb{R}^{\mathbb{N}}/\sim$ is exactly the quotient by this ideal: two sequences define the same germ precisely when their difference is eventually 0. This makes the well-definedness checks feel analogous to the familiar construction of $\mathbb{Z}/m\mathbb{Z}$, except that the ideal is determined by tail-vanishing rather than divisibility.

Lemma 100 (Eventual order calculus)**.** *Let $\leq_\infty$ be eventual order on germs. If $[a] \leq_\infty [b]$ and $[c] \leq_\infty [d]$, then $[a] + [c] \leq_\infty [b] + [d]$. If also $[0] \leq_\infty [c]$, then $[a][c] \leq_\infty [b][c]$.*

Remark 1803. *Eventual order $\leq_\infty$ is the order-theoretic analogue of eventual equality: it compares sequences by what happens beyond some finite horizon. This is the natural order for asymptotic analysis and for speaking about infinitesimals as "eventually smaller than every positive constant" (Hyperseed-Concept* **??***). The lemma states that this asymptotic order behaves as one expects under addition, and under multiplication by an eventually nonnegative germ. In applications, this lets one manipulate tail bounds exactly as one manipulates ordinary inequalities, as long as one tracks the (usually irrelevant) fact that the inequalities may fail at finitely many early indices. For instance, if one has eventual error bounds for two learning subroutines, the lemma formalizes that their combined error bound is also valid eventually, without needing to synchronize the two subroutines at a single fixed start time in advance.*

Remark 1804. *Before the proof, recall that $[a] \leq_\infty [b]$ means $\exists N$ such that $a_n \leq b_n$ for all $n \geq N$. The condition $[0] \leq_\infty [c]$ means $c_n \geq 0$ eventually, which is exactly what is needed to preserve inequalities under multiplication. One subtlety worth keeping in view is that $\leq_\infty$ is naturally a preorder on representatives: different germs can be "eventually mutually $\leq$" without being literally equal as sequences, but on the quotient it behaves in the intended asymptotic sense. Concretely, the reason multiplication requires $c_n \geq 0$ eventually is the same as in ordinary algebra: without a sign restriction, the direction of an inequality can flip at indices where $c_n < 0$, and an "eventual" statement must rule out infinitely many such flips.*

Sketch. Unroll the definition: each inequality holds for all $n \geq N$ for some N, then combine pointwise for $n \geq \max N$. For multiplication, preserve order by multiplying by a nonnegative term. $\square$

Remark 1805. Proof sketch. *Choose horizons N_1, N_2 for the two eventual inequalities, then work beyond $\max(N_1, N_2)$ where both hold simultaneously. For the product inequality, also work beyond a horizon where $c_n \geq 0$.* $\square$

The proof works because eventual properties are stable under finite conjunction: "eventually P" and "eventually Q" implies "eventually (P and Q)". The geometric intuition is that we are doing order theory not on points but on tails of sequences. A useful operational takeaway is that one should freely introduce a single "master horizon" N_* that is larger than all the finitely many horizons appearing in the argument. After passing to $n \geq N_*$, all the needed inequalities become ordinary pointwise inequalities, and the familiar algebraic manipulations apply without further changes.

Lemma 101 ($\omega \cdot \varepsilon = 1$ and "infinite times infinitesimal" normalization)**.** *Let $\omega = [n]$ and $\varepsilon = [1/n]$. Then $\omega \cdot \varepsilon = [1]$ (the constant germ 1).*

Remark 1806. *This lemma gives a precise meaning to an often poetic slogan: "an infinite quantity times an infinitesimal can be finite." Here $\omega = [n]$ is a germ that grows without bound, and*

*$\varepsilon = [1/n]$ is a germ that tends to 0. Their product is nevertheless the constant germ [1]. While this is not full nonstandard analysis, it captures a workable fragment of the intuition needed for manipulating asymptotic scales in a rigorous quotient structure (Hyperseed-Concept **??**, Hyperseed-Concept **??**). In the language of asymptotics, ω and ε are reciprocal scales: multiplying by ε renormalizes quantities measured in "units of n" back to a stable, n-independent unit. This kind of normalization underlies many "dimensionless" reparameterizations, where a diverging or vanishing factor is absorbed into a change of scale so that the remaining expression has a finite, robust limit behavior.*

Remark 1807. *Before the proof, note that* [1] *denotes the equivalence class of the constant sequence* $(1, 1, 1, \ldots)$*. The statement* $\omega \cdot \varepsilon = [1]$ *means that the sequence* $(n) \cdot (1/n)$ *is eventually equal to the constant* 1*, i.e. equal for all sufficiently large indices. Also note that the representative* $(1/n)$ *may be treated as starting at* $n = 1$ *(or any other fixed positive index) to avoid the irrelevant issue of division by zero at* $n = 0$ *if one were to index sequences that way. Because germs ignore finitely many initial indices, any such convention changes at most a finite prefix and therefore does not affect the germ.*

Sketch. Pointwise, $(n) \cdot (1/n) = 1$ for all $n \geq 1$, hence the product sequence is eventually constant 1. □

Remark 1808. Proof sketch. *Compute the product pointwise and observe it equals* 1 *from the first index onward, hence certainly eventually.* □

The key step is that eventual equality ignores finitely many initial indices, so any identity that holds for all $n \geq 1$ (or all $n \geq N$) becomes an equality of germs. One may visualize ω and ε as two reciprocal asymptotic scales whose interaction renormalizes to a stable unit. In particular, this is a canonical example of how the quotient construction turns a "limit-style" intuition (growth versus decay) into an exact algebraic identity inside the germ ring: after passing to equivalence classes, the phrase "for all sufficiently large n" is promoted to literal equality of objects.

33 Helper Theorems for Section 11: Hierarchy, Heterarchy, and Pattern Webs

33.1 Standing notation

Fix a commutative quantale $(V, \leq, \oplus, \otimes, e)$. A (thin) V-hierarchy on a set U is a map $h : U \times U \to V$ satisfying

$$e \leq h(u, u), \qquad h(u, v) \otimes h(v, w) \leq h(u, w).$$

A V-graph is a weight function $g : U \times U \to V$ (not necessarily reflexive/transitive). For a finite directed path $\pi = (u_0 \to u_1 \to \cdots \to u_n)$, define the path weight

$$w(\pi) := g(u_0, u_1) \otimes g(u_1, u_2) \otimes \cdots \otimes g(u_{n-1}, u_n).$$

Define the path-closure $\widehat{g} : U \times U \to V$ by

$$\widehat{g}(u, v) := \bigoplus_{\pi : u \rightsquigarrow v} w(\pi),$$

where the join ranges over all finite directed paths from u to v, including the empty path (with weight e).

Remark 1809. *The quantale $(V, \leq, \oplus, \otimes, e)$ should be read as a unified "value domain" for graded entailment, graded reachability, or graded evidential support. Concretely: $\leq$ is the order of informativeness/strength; $\oplus$ is the (possibly infinite) join or "aggregation over alternatives"; $\otimes$ is the monoidal product that composes strength along a chain; and e is the unit strength. This is the standard setting in which many notions of hierarchy and connectivity become instances of a single enriched-order idea; in the Hyperseed core-concept set, this is closely allied to Quantale Weakness (Hyperseed-Concept 143) and Weakness (Hyperseed-Concept 202), as developed in [3].*

Remark 1810. *For later use, it is helpful to keep in mind that "quantale" here includes the completeness needed to interpret $\bigoplus$ over* arbitrary *(possibly infinite) families of path-weights. In particular, the join in the definition of $\widehat{g}(u, v)$ may range over infinitely many distinct finite paths when U is infinite or when cycles are present. The commutativity assumption on $\otimes$ is not strictly needed to* define *$w(\pi)$, but it ensures that many algebraic manipulations behave symmetrically and that the underlying enrichment has fewer left/right distinctions; this is consistent with the interpretation of $\otimes$ as a generic "combination of evidential support" rather than a direction-sensitive update.*

Remark 1811. *A "thin" V-hierarchy h is best viewed as an enriched preorder: the inequality $e \leq h(u, u)$ is reflexivity (each entity is at least as-related to itself as the unit allows), while*

$$h(u, v) \otimes h(v, w) \leq h(u, w)$$

is transitivity in graded form (composing the support from u to v and from v to w cannot exceed the direct support from u to w). If one specializes to $V = \{0, 1\}$ with $\oplus = \vee$, $\otimes = \wedge$, and $e = 1$, then $h(u, v) = 1$ simply means "u is below v" and the axioms reduce to the ordinary preorder axioms. If one specializes to $V = [0, 1]$ with $\otimes$ as multiplication and $\oplus$ as $\max$, then $h(u, v)$ can be read as the strength of a hierarchical entailment, and transitivity says that the strength along a two-step chain lower-bounds (in the order $\leq$) the direct strength. This language is used to speak about Hierarchy (Hyperseed-Concept **??***) and also its complementing phenomenon Heterarchy (Hyperseed-Concept* **??***) in the pattern-theoretic setting of [5].*

Remark 1812. *The order convention is worth keeping explicit: the inequalities are written with $\leq$ as the "increasing strength/informativeness" direction. In some applied settings one instead orders by "cost" or "distance" (so that smaller numbers are stronger), in which case the quantale is typically presented with the opposite order and with $\oplus$ behaving like an infimum (e.g. $\min$) rather than a supremum. The present notation fixes one consistent convention; any alternative convention can be accommodated by passing to the opposite order (or, equivalently, by re-reading $\leq$ as the intended strength comparison).*

Remark 1813. *A V-graph g drops the preorder axioms: it is merely a weighted directed graph. The path weight $w(\pi)$ multiplies (via $\otimes$) the edge weights along the path; then the closure $\widehat{g}(u, v)$ aggregates (via $\oplus$) over* all *finite paths from u to v. Including the empty path with weight e ensures that $\widehat{g}(u, u) \geq e$, i.e. reflexivity is built into the closure even if g itself has no self-loops. Informally, $\widehat{g}$ is "what g implies once one allows multi-step inference." In pattern-web language (Hyperseed-Concept 132) this is the formal analogue of saying: even if we only record immediate pattern-to-pattern links, we may still care about the total indirect influence obtainable by chaining links, a viewpoint emphasized in [5].*

Remark 1814. *The notation $\pi : u \rightsquigarrow v$ means that π is a directed path whose source is u and whose target is v. The empty path is the unique path of length* 0 *from u to itself, and its weight is* *declared to be e so that $w(\pi)$ behaves as expected with respect to concatenation: concatenating any path with an empty path does not change its weight. With this convention, $\widehat{g}(u,v)$ can be read as the total strength of* all *chains of immediate links from u to v, where "total" is taken in the $\oplus$-sense appropriate to the value domain (e.g. maximum strength, logical disjunction, or aggregation of alternative evidential routes).*

Remark 1815. *Although not yet used as a theorem here, it is useful intuition that $\widehat{g}$ is designed to be the canonical "reflexive–transitive closure" of a weighted digraph in the enriched sense: it is built to account for multi-step composition (via $\otimes$) and alternative routes (via $\oplus$). In many common quantales, this closure is also the least (thin) V-hierarchy extending g (i.e. the least reflexive/transitive weight function above g pointwise), mirroring the classical fact that the reachability relation is the least preorder containing an edge relation.*

33.2 Hierarchies and systemic hierarchies

Theorem 34 (Chain lower bound in a graded hierarchy)**.** *Let h be a V-hierarchy on U. For any finite chain $u_0, u_1, \dots, u_n \in U$,*

$$h(u_0,u_n) \;\geq\; h(u_0,u_1) \otimes h(u_1,u_2) \otimes \cdots \otimes h(u_{n-1},u_n).$$

Remark 1816. *This theorem says that in a graded hierarchy,* every explicit chain of intermediate steps provides a certified lower bound on the direct relation*. Philosophically, it is the formal expression of a very ordinary idea: if u_0 supports u_1 and u_1 supports u_2 and so on, then u_0 supports the end-point u_n at least as strongly as the composed support along the chain. The point is not that the chain is the only route; rather, the hierarchy axioms guarantee that chaining never fabricates illegitimate strength.*

Remark 1817. *A useful way to read the inequality is:* the composite along the chain is a lower estimate that is justified solely by transitivity*. In particular, if V is thought of as a space of "evidence values" or "confidence values," then the right-hand side is the confidence obtainable by* only *traversing the displayed edges. The theorem asserts that the direct assessment $h(u_0,u_n)$ must be at least that large, since otherwise the transitivity axiom would be violated at some stage of composition.*

Remark 1818. *In common special cases, the statement reduces to familiar laws:*

- *If $V = \{\perp, \top\}$ with $\otimes = \wedge$ (Boolean preorder case), then the theorem becomes: if $u_0 \leq u_1 \leq \cdots \leq u_n$ then $u_0 \leq u_n$.*
- *If $V = [0,1]$ with $\otimes = \cdot$ and the usual order, then the chain bound reads $h(u_0,u_n) \geq \prod_{i=0}^{n-1} h(u_i,u_{i+1})$, i.e. strengths multiply along an explicit path.*
- *If V is a tropical-type quantale where $\otimes$ is $+$ and the order is reversed (typical for "cost" semantics), then the displayed inequality corresponds to the usual triangle-inequality form: the direct cost cannot exceed the cost of a multi-step route.*

These are not new assumptions; they are just interpretations of the same abstract inequality in different enrichment semantics.

Remark 1819. *The relevance to Section 11 is that many constructions of hierarchy/heterarchy begin with local edges ("immediate influences") and then reason about multi-step consequences. Theorem 34 is the atomic rewrite rule enabling this multi-step reasoning inside an already-transitive structure, complementing the later closure results where transitivity is* added *freely.*

Remark 1820. *One small technical point worth making explicit is that the right-hand side is unambiguous because $\otimes$ is associative (as part of the standard quantale/monoidal hypotheses underlying a V-hierarchy). Thus one may parenthesize the product as*

$$\big(\cdots((h(u_0,u_1)\otimes h(u_1,u_2))\otimes h(u_2,u_3))\otimes\cdots\big)\otimes h(u_{n-1},u_n),$$

and the resulting element of V is independent of the parenthesization. The proof by induction effectively chooses one particular parenthesization (left-associated) and then applies transitivity repeatedly.

Sketch. Induct on n. The case $n=1$ is trivial. For the step, apply the hierarchy inequality $h(u_0,u_{n-1})\otimes h(u_{n-1},u_n)\le h(u_0,u_n)$ and use the induction hypothesis. □

Remark 1821. *If one wishes to see the induction step with the inequalities written out, it is:*

$$h(u_0,u_1)\otimes\cdots\otimes h(u_{n-2},u_{n-1}) \;\le\; h(u_0,u_{n-1})$$

by the induction hypothesis, hence by monotonicity of $\otimes$ in its first argument,

$$\big(h(u_0,u_1)\otimes\cdots\otimes h(u_{n-2},u_{n-1})\big)\otimes h(u_{n-1},u_n) \;\le\; h(u_0,u_{n-1})\otimes h(u_{n-1},u_n).$$

Applying transitivity to the right-hand side yields the desired bound by $h(u_0,u_n)$. (Here the monotonicity of $\otimes$ is part of the ambient ordered-monoid structure on V typically assumed when speaking of graded relations.)

Remark 1822. Proof sketch (high-level strategy). *One proves the statement for a chain of length 1, and then extends it by appending one more edge and using transitivity once. This is the same logical form as proving that an ordinary preorder respects finite composition of $\le$.*

Remark 1823. Why the key step works. *The inequality*

$$h(u_0,u_{n-1})\otimes h(u_{n-1},u_n)\le h(u_0,u_n)$$

is precisely the transitivity axiom of a V-hierarchy; it is invoked after the induction hypothesis has packaged the first $n-1$ edges into a single composite bound on $h(u_0,u_{n-1})$. Geometrically (in the common max-product example), one may picture a chain as multiplying edge strengths; the theorem asserts that the direct relation cannot be weaker than the chain-product when measured in the order of V.

Remark 1824. *It is also helpful to note what the theorem does* not *assert. It does not claim that $h(u_0,u_n)$ is* equal *to the best chain value, nor that the displayed chain is optimal among all chains; it only asserts that any specific chain yields a valid lower bound. In applications, one often considers many possible chains and takes their join/supremum (when V admits it) to obtain the strongest bound derivable from multi-step evidence, but that further "closure" operation is conceptually separate from the basic transitivity reasoning encapsulated here.*

Theorem 35 (Pullback of hierarchy along a model map)**.** *Let $\phi : A\to S$ be any function and let $h_S : S\times S\to V$ be a V-hierarchy. Define a relation on A by*

$$h_A(a,b) := h_S(\phi(a),\phi(b)).$$

Then h_A is a V-hierarchy on A.

Remark 1825. *This theorem says that a hierarchy on a space of "models" or "summaries" can be transported back to the underlying things being modeled. If ϕ extracts some representation of each $a \in A$ inside S, then h_A declares a to be below b exactly to the extent that $\phi(a)$ is below $\phi(b)$. In plainer language:* hierarchy is stable under re-description. *This is important because systemic hierarchies often live at a representational level (types, roles, abstractions) while we must reason about concrete processes that realize them.*

Remark 1826. *A practical interpretation is that S may be a quotient, coarse-graining, feature map, or embedding space in which comparisons are easier or more meaningful. The pullback h_A then inherits any "ordering logic" already validated on S without requiring one to directly define transitivity on A from scratch. In particular, if ϕ forgets details (many a mapping to one $\phi(a)$), then h_A may identify distinct objects as having identical hierarchical profiles; this is expected and corresponds to the modeling choice encoded by ϕ.*

Remark 1827. *In the idiom of Section 11, ϕ is a modeling map that turns processes into nodes of a systemic diagram; the theorem guarantees that any graded hierarchical structure imposed on the systemic level induces a graded structure on the process level. This is conceptually aligned with the broader pattern-and-system viewpoint of [5] and with the technical use of model maps in dependency-tower analyses [8].*

Sketch. Reflexivity: $e \leq h_S(\phi(a), \phi(a)) = h_A(a, a)$. Transitivity: $h_A(a, b) \otimes h_A(b, c) = h_S(\phi(a), \phi(b)) \otimes h_S(\phi(b), \phi(c)) \leq h_S(\phi(a), \phi(c)) = h_A(a, c)$. □

Remark 1828. *The proof is "one-line" because h_A is defined by direct substitution into h_S. No additional structure on ϕ is required: it need not be injective, surjective, order-preserving, or compatible with $\otimes$ in any special way, since h_A is not defined by transporting $\otimes$ across ϕ but rather by evaluating h_S after applying ϕ to each argument. This is exactly the sense in which V-hierarchy axioms are stable under re-indexing of the underlying set.*

Remark 1829. Proof sketch (high-level strategy). *One checks that the defining axioms of a V-hierarchy are purely equational/inequational, hence preserved by substitution. The function ϕ performs the substitution: wherever h_A appears, it is merely h_S evaluated at images under ϕ.*

Remark 1830. Key step and intuition. *The transitivity step works because $\phi(b)$ is literally the same object in the middle term of both factors $h_S(\phi(a), \phi(b))$ and $h_S(\phi(b), \phi(c))$, so the transitivity axiom of h_S applies directly. Visually, one can imagine a commuting triangle: edges in A are "shadowed" by edges in S, and the inequality in S pulls back along that shadowing.*

Remark 1831. *There is also a useful "functorial" intuition: if $A \xrightarrow{\phi} S \xrightarrow{\psi} T$ are functions and h_T is a V-hierarchy on T, then pulling back along $\psi \circ \phi$ produces the same V-hierarchy on A as pulling back along ψ to get a hierarchy on S and then pulling back along ϕ. This is immediate from the definition*

$$h_A(a, b) = h_T(\psi(\phi(a)), \psi(\phi(b))),$$

and it clarifies why pullback is the correct direction for transporting hierarchical structure along modeling maps (the same direction as inverse images of predicates).

Corollary 10 (Model-induced (systemic) hierarchy on processes)**.** *In the setting of a systemic hierarchy $(S, \prec_S, \phi)$, any graded preorder structure on S pulls back along ϕ to a graded preorder on* $\mathrm{Proc}(D)$*.*

Remark 1832. *The corollary is the application one actually uses: once one has chosen a systemic level S (often a compressed or conceptual representation of a domain), any hierarchical assessment made at that level immediately yields a hierarchical assessment on the processes in* $\mathrm{Proc}(D)$ *that are mapped into it. This makes precise how a theory of hierarchy can be simultaneously abstract (living on S) and operational (speaking about concrete process instances).*

Remark 1833. *Concretely, if $\phi : \mathrm{Proc}(D) \to S$ assigns to each process a type, role, macro-state, or pattern-label, then any graded ordering on those labels (e.g. "is a refinement of," "is more general than," "is more causally upstream than," depending on the intended semantics) becomes a derived graded ordering on the processes themselves by comparing their assigned labels. This is the formal step that lets one reason about process-level organization using system-level abstractions without conflating the two levels.*

Sketch. Apply Theorem 35 with $A = \mathrm{Proc}(D)$. $\square$

Remark 1834. Proof sketch. *There is no additional mathematical content beyond Theorem 35; the corollary is an instantiation. The conceptual content, however, is significant: it formalizes that "systemic" ordering principles become genuine order-like constraints on the dynamics that instantiate the system.*

33.3 Subpattern hierarchy

Theorem 36 (Subpattern preorder (crisp))**.** *Assume $*$ is associative with identity e, and assume $Pat(p * e; p)$ is nontrivial for each pattern-representer p (so $p * e$ is defined and recognized as a pattern in p). Define $p \preceq_{\mathrm{sub}} q$ iff there exists r such that $Pat(p * r; q)$ is nontrivial. Then $\preceq_{\mathrm{sub}}$ is a preorder.*

Remark 1835. *This theorem constructs a preorder out of a compositional pattern notion: $p \preceq_{\mathrm{sub}} q$ means, informally, that p can be embedded into q by adjoining some remainder r and then recognizing $p * r$ as (nontrivially) present in q. The requirement that $Pat(p * e; p)$ be nontrivial ensures reflexivity: every pattern contains itself, up to composing with a neutral "do nothing" remainder. This is the crisp (two-valued) backbone of what later becomes graded subpattern strength.*

Remark 1836. *Two simple mental examples help. First, if $*$ is string concatenation and $Pat(a; b)$ means "a occurs as a substring of b," then $p \preceq_{\mathrm{sub}} q$ says: there exists a string r such that pr occurs in q; for many reasonable Pat this recovers familiar containment-like notions. Second, if $*$ is multiset union and $Pat(A; B)$ means "A is a submultiset of B," then taking $r = B \setminus A$ witnesses $A \preceq_{\mathrm{sub}} B$. In Section 11 terms, this gives a formal entry point for Subpattern Hierarchy (Hyperseed-Concept 182) within Pattern (Hyperseed-Concept 130) and Pattern Web (Hyperseed-Concept 132) structures, as in [5].*

Remark 1837. *The importance of the result is not that it is difficult, but that it legitimizes a common move: to treat "is a subpattern of" as a genuine hierarchy relation (reflexive and transitive) rather than merely a heuristic similarity. Once it is a preorder, one can quotient by mutual subpatterning (to obtain a partial order) or enrich it (as in Theorem 37).*

Sketch. Reflexivity: choose $r = e$. Transitivity: if $Pat(p * r_1; q)$ and $Pat(q * r_2; s)$ are nontrivial, associativity gives $(p*r_1)*r_2 = p*(r_1*r_2)$; under the intended compositional semantics, this yields nontrivial $Pat(p * (r_1 * r_2); s)$. $\square$

Remark 1838. Proof sketch (high-level strategy). *Reflexivity is forced by the existence of an identity element for composition. Transitivity is forced by associativity: two successive embeddings can be merged into one by bundling the two remainders into a single remainder* $r_1 * r_2$*.*

Remark 1839. Key step and intuition. *The crucial move is rewriting*

$$(p * r_1) * r_2 = p * (r_1 * r_2),$$

which is exactly associativity. Conceptually, this is the idea that "glue" terms can be composed: if p *needs some context* r_1 *to live inside* q*, and* q *needs some context* r_2 *to live inside* s*, then* p *needs the combined context* $r_1 * r_2$ *to live inside* s*. One may picture this as nesting of contexts that can be flattened.*

Theorem 37 (Subpattern strength composes under a compositionality axiom)**.** *Let* $h_{\text{sub}}(p, q) := \sup_r Pat(p * r; q) \in [0, 1]$*. Assume there exists a t-norm* $\odot$ *on* $[0, 1]$ *such that for all* a, b, c*,*

$$Pat(a; q) \odot Pat(q; c) \ \leq \ Pat(a * c; s)$$

whenever the compositions are well-typed (this is a generic "patterns compose" axiom). Then for all p, q, s*,*

$$h_{\text{sub}}(p, q) \odot h_{\text{sub}}(q, s) \ \leq \ h_{\text{sub}}(p, s).$$

Remark 1840. *This theorem is the graded analogue of transitivity for subpatterning. The function* $h_{\text{sub}}(p, q)$ *takes the* best *(supremal) way to witness* p *inside* q *by allowing an arbitrary remainder* r*. The conclusion says: if* p *is strongly a subpattern of* q*, and* q *is strongly a subpattern of* s*, then* p *is a subpattern of* s *with at least the composed strength, where composition of strengths is mediated by a t-norm* $\odot$ *(a standard way to model "and" in* $[0, 1]$*).*

Remark 1841. *Why this matters in Section 11 is that it provides a principled route from* pattern recognition scores *to* hierarchical structure*: one can define a* $[0, 1]$*-valued hierarchy whose transitivity is guaranteed not by ad hoc thresholding, but by a compositional axiom about how pattern evidence behaves under composition. This directly supports building Pattern Web structures (Hyperseed-Concept 132) with meaningful multi-hop semantics, as advocated in [5].*

Sketch. Expand both h_{sub} as sups over witnesses r_1, r_2; apply the axiom to $Pat(p * r_1; q)$ and $Pat(q * r_2; s)$; use associativity to rewrite $(p * r_1) * r_2 = p * (r_1 * r_2)$; then take sups. □

Remark 1842. Proof sketch (high-level strategy). *One proves the inequality pointwise for arbitrary witnesses* r_1, r_2*, and then upgrades it to the supremal strengths by using the monotonicity of* sup *and of* $\odot$ *in each argument.*

Remark 1843. Key steps and intuition. *The compositionality axiom is the substantive ingredient: it asserts that evidence for* a *in* q *and evidence for* q *in* c *can be combined (via* $\odot$*) into evidence for the composed object. Associativity then ensures that the two-step remainder can be treated as a single remainder, so the final witness is of the allowed form for* $h_{\text{sub}}(p, s)$*. Visually, one may imagine two pattern-matches that share a middle interface* q*; the theorem says that the interface can be eliminated, leaving a direct match with a predictable weakening governed by* $\odot$*. In the language of "pattern webs," this is exactly the move of* collapsing *an intermediate node: whenever two links* $a \rightsquigarrow q$ *and* $q \rightsquigarrow c$ *are supported, the network can be summarized by a derived link* $a \rightsquigarrow c$ *together with an explicit, algebraically controlled loss term. This kind of step is what later allows us to discuss higher-level organization (hierarchical or heterarchical) without needing to keep every intermediate interface visible in the representation.*

33.4 Heterarchy and cycles

Theorem 38 (Cycle mass bounds and monotonicity in the max-product case)**.** *Let $V = [0,1]$ with $\oplus = \max$ and $\otimes = \cdot$. For a weighted digraph $G = (U, E, w)$, the cycle mass*

$$\mathrm{Cyc}(G) := \max\Big\{\prod_{i=1}^{k} w(u_i, u_{i+1}) : (u_1, \ldots, u_k) \text{ is a directed cycle}\Big\}$$

satisfies $0 \le \mathrm{Cyc}(G) \le 1$. Moreover, if $w' \ge w$ pointwise (or edges are added with nonzero weights), then $\mathrm{Cyc}(G') \ge \mathrm{Cyc}(G)$.

Remark 1844. *To avoid any ambiguity in degenerate cases, it is convenient to adopt the convention that if G has no directed cycles (i.e. G is acyclic), then the set in the definition is empty and $\mathrm{Cyc}(G)$ is taken to be 0. This aligns with the intended interpretation that "no feedback" corresponds to the minimal heterarchy score. When U is finite, the maximum is actually attained by at least one cycle; more generally, one can read the definition as a supremum over all directed cycles, and the stated inequalities remain valid.*

Remark 1845. *The theorem formalizes a basic quantitative proxy for heterarchy: the presence and strength of directed cycles. In a strict hierarchy there are no cycles; in a heterarchy (Hyperseed-Concept **??**) cycles are not anomalies but structure. Here $\mathrm{Cyc}(G)$ measures the strongest cycle under multiplicative aggregation of edge strengths and* max *selection of the best cycle. The bound $0 \le \mathrm{Cyc}(G) \le 1$ is sanity: multiplying numbers in $[0,1]$ stays in $[0,1]$. One may also read $\prod_{i=1}^{k} w(u_i, u_{i+1})$ as a "reliability of returning to the start along that loop": if any link is weak, the whole loop is weakened, and if a link has weight 0 the loop contributes nothing.*

Remark 1846. *The monotonicity clause is conceptually important: strengthening edges, or adding new nonzero edges, cannot make the best available cycle weaker. This provides a clean mathematical underpinning for the intuition that additional feedback links increase (or at least do not decrease) the degree of heterarchical interdependence in a network, a theme that appears repeatedly in pattern-web discussions [5]. In particular, even if a newly added edge does not participate in the previously strongest cycle, it may create a* new *cycle (possibly shorter, or using higher-weight links) whose product exceeds the former maximum, which is exactly the sense in which additional connectivity can create qualitatively new feedback structure.*

Sketch. Each edge weight lies in $[0,1]$, so any cycle product lies in $[0,1]$, hence so does the max. If weights increase, every cycle product weakly increases, so the max increases. More explicitly: for any fixed directed cycle $(u_1, \ldots, u_k)$ we have

$$0 \le \prod_{i=1}^{k} w(u_i, u_{i+1}) \le \prod_{i=1}^{k} 1 = 1,$$

and if $w'(e) \ge w(e)$ for all edges e, then termwise

$$\prod_{i=1}^{k} w'(u_i, u_{i+1}) \;\ge\; \prod_{i=1}^{k} w(u_i, u_{i+1}).$$

Taking the maximum over all cycles gives the stated monotonicity; if new edges are added, the collection of cycles can only grow, so the maximum cannot decrease. $\square$

Remark 1847. Proof sketch. *The argument is pointwise: establish the interval bound for each cycle product, then pass to the maximum. For monotonicity, compare corresponding cycle products under w and w' and then again pass to the maximum. One can regard this as an instance of a general principle: for monotone aggregations (here, product in each cycle and maximum across cycles), increasing the underlying weights cannot decrease the aggregated value.*

Remark 1848. Visual intuition. *One can view each directed cycle as a "feedback loop" that returns influence to its origin. In max-product semantics, the strength of a loop is the product of its link reliabilities; the strongest loop is the one with the best balance of shortness and high edge weights. Increasing any edge reliability cannot degrade any loop that uses it, and cannot affect loops that do not use it, hence the best loop can only improve. Equivalently, applying the transformation $\ell(e) := -\log w(e)$ (with the usual convention that $w(e) = 0$ corresponds to $\ell(e) = +\infty$) turns products into sums:*

$$-\log\Big(\prod_{i=1}^{k} w(u_i, u_{i+1})\Big) = \sum_{i=1}^{k} \ell(u_i, u_{i+1}),$$

so "maximizing cycle product" corresponds to "minimizing cycle log-cost." Under this view, strengthening an edge decreases its cost, so the best (minimum-cost) cycle cannot become worse, which is another way to see the same monotonicity.

33.5 Pattern profiles, distances, and webs

Theorem 39 (Pattern-based pseudo-metric inherits metric axioms)**.** *Let $F_x \in [0,1]^P$ be the pattern profile of $x \in X$, and let D be a (pseudo-)metric on $[0,1]^P$. Define $d_P(x,y) := D(F_x, F_y)$. Then d_P is a (pseudo-)metric on X.*

Remark 1849. *This theorem is a simple but powerful lifting principle: if each entity x is represented by a feature vector F_x indexed by patterns (a "pattern profile"), then* any *(pseudo-)metric on the profile space induces a (pseudo-)metric on the original space. In the idiom of Pattern Webs (Hyperseed-Concept 132), it tells us that once patterns have become coordinates, geometry follows: similarity and neighborhood structure can be imported wholesale from the chosen distance D.*

Remark 1850. *One practical consequence is that many modeling choices are cleanly separated: the map $x \mapsto F_x$ encodes* what *is being measured (which patterns, which normalizations, which aggregation), while the choice of D encodes* how *difference is scored (e.g. sparse vs. dense sensitivity, robustness to outliers, emphasis on maximal deviations vs. cumulative deviations). In particular, the same pattern profile map can support multiple downstream geometries without changing the representation.*

Remark 1851. *Concrete examples of admissible D include L^1, L^2, and L^∞ distances on $[0,1]^P$ (when P is finite, or more generally when restricted to suitable subspaces), as well as weighted variants such as*

$$D_w(F,G) = \sum_{p \in P} w(p)\,|F(p) - G(p)| \quad \textit{with} \quad w(p) \geq 0,$$

which reweights coordinates to reflect pattern importance or reliability. The theorem applies verbatim as long as the chosen D satisfies the metric axioms on the profile space under consideration.

Remark 1852. *The result is also a reminder of a philosophical subtlety: d_P will typically be only a* pseudo-*metric because distinct entities can share the same profile (representation is many-to-one). This is not a defect but a statement about Representation (Hyperseed-Concept 157): the geometry reflects the representational lens, not necessarily the metaphysical identity of objects.*

Remark 1853. *A standard way to turn this pseudo-metric into an honest metric is to pass to the quotient by representational indistinguishability. Define an equivalence relation $x \sim y$ iff $F_x = F_y$ (equivalently, iff $d_P(x, y) = 0$). Then d_P descends to a well-defined metric on the quotient set $X/\sim$ by*

$$\bar{d}_P([x], [y]) := d_P(x, y),$$

because any alternative representatives have the same profile and hence the same distance. This construction makes explicit that the induced geometry is really the geometry of profiles, with X observed through the pattern coordinate map.

Sketch. Nonnegativity, symmetry, and the triangle inequality are inherited pointwise because $d_P(x, y)$ is defined by applying D to the pair (F_x, F_y). Identity-of-indiscernibles holds iff it holds for D and $F_x = F_y \to x = y$ (which need not be true), hence "pseudo" is the generally correct claim. □

Remark 1854. Proof sketch. *This is a direct transport of structure: each metric axiom is an inequality (or equality) about D evaluated on profile vectors, and d_P is just D applied to the corresponding profiles.*

Remark 1855. Geometric intuition. *Think of $x \mapsto F_x$ as embedding X into a high-dimensional cube $[0, 1]^P$. The distance d_P is simply the ambient distance after embedding. If the embedding collapses distinct points, then the induced geometry cannot separate them: hence pseudo-metric rather than metric.*

Remark 1856. *When P is large (or conceptually infinite), it is often useful to interpret F_x as a point in a function space: $F_x : P \to [0, 1]$. The same lifting principle applies whenever D is a (pseudo-)metric on the chosen function space (for example, an L^1-type metric with respect to a measure on P, or a supremum metric when appropriate). In this view, the pattern web construction can be read as importing familiar functional-analytic geometries into the space of entities via their pattern responses.*

Theorem 40 (Finite L^1 bounds). *If P is finite and $D(F, G) = \sum_{p \in P} |F(p) - G(p)|$, then*

$$0 \ \le\ d_P(x, y) \ \le\ |P|.$$

Remark 1857. *This theorem gives an immediate scale calibration for one of the most common choices of D, namely the L^1 distance on pattern profiles. It tells us that distances are automatically bounded by the number of pattern coordinates. This matters operationally: bounded distances are convenient for turning distances into similarities (as in Theorem 41) and for comparing distances across datasets when $|P|$ is fixed.*

Remark 1858. *A frequently used normalization is the* average L^1 *disagreement,*

$$\tilde{d}_P(x, y) := \frac{1}{|P|}\, d_P(x, y),$$

which always lies in $[0, 1]$ under the assumptions of Theorem 40. This normalized distance is often easier to interpret across different choices of P (e.g. when comparing a coarse pattern vocabulary to a refined one), because it factors out the raw number of coordinates and emphasizes per-pattern disagreement.

Sketch. Each summand is in $[0, 1]$ because $F(p), G(p) \in [0, 1]$. Sum over $|P|$ terms. □

Remark 1859. Proof sketch. *The inequality is a sum of coordinate-wise inequalities: each coordinate differs by at most* 1*, and there are* $|P|$ *coordinates.*

Remark 1860. Intuition. *In the* L^1 *geometry, distance is "total coordinate-wise disagreement." If each coordinate is a dial between* 0 *and* 1*, then the largest possible disagreement per dial is* 1*, so the largest total disagreement is the number of dials.*

Remark 1861. *The bound also highlights a modeling choice: if many patterns are nearly always* 0 *(sparse profiles), then* L^1 *distance tends to count the number and magnitude of coordinate changes and is often more sensitive to sparse differences than* L^2*. Conversely, if one wants to emphasize a few large discrepancies rather than many small ones, one may prefer* L^∞ *or a suitably weighted distance. Theorem 39 ensures that any such choice, once made on profile space, yields a valid pseudo-metric on* X*.*

Theorem 41 (Kernel similarity is order-reversing in distance)**.** *Let* $\kappa : [0, \infty) \to [0, 1]$ *be monotone decreasing and define* $s(x, y) := \kappa(d_P(x, y))$*. If* $d_P(x, y) \leq d_P(x', y')$*, then* $s(x, y) \geq s(x', y')$*. Also* $s(x, x) = \kappa(0)$ *(since* $d_P(x, x) = 0$ *for any pseudo-metric).*

Remark 1862. *This theorem states the obvious but essential compatibility between two common ways of talking: distances and similarities. A monotone decreasing function* κ *converts "small distance" into "large similarity." This is the formal justification for constructing edges in a pattern web by thresholding a similarity kernel rather than working directly with a distance.*

Remark 1863. *In applications,* $\kappa(t) = \exp(-\lambda t)$ *or* $\kappa(t) = 1/(1 + t)$ *are typical; then the theorem says that the induced similarity ordering respects the distance ordering. Such kernels are often used to convert geometric structure into graph structure, hence to move from Pattern Profiles to Pattern Webs (Hyperseed-Concept 132).*

Remark 1864. *If* κ *is* strictly *decreasing, then order is not merely reversed but also reflected:* $d_P(x, y) < d_P(x', y')$ *implies* $s(x, y) > s(x', y')$*, and* $s(x, y) = s(x', y')$ *forces* $d_P(x, y) = d_P(x', y')$*. This can matter when one ranks candidate neighbors: strict monotonicity ensures that sorting by similarity is exactly the same as sorting by distance, just in reverse.*

Remark 1865. *For pattern webs built by thresholding, one common scheme is to include an edge* $x \sim y$ *whenever* $s(x, y) \geq \tau$*, equivalently whenever* $d_P(x, y) \leq \kappa^{-1}(\tau)$ *when* κ *is invertible on its range. Thus, distance thresholds and similarity thresholds are interchangeable representations of the same neighborhood rule, and the theorem guarantees that both definitions produce consistent edge orderings.*

Sketch. Immediate from monotonicity of κ and the defining property $d_P(x, x) = 0$. $\square$

Remark 1866. Proof sketch. *Apply* κ *to both sides of an inequality and use that* κ *reverses order because it is decreasing; the diagonal value follows from* $d_P(x, x) = 0$*.*

Remark 1867. *Finally, it is worth separating two notions that are sometimes conflated in practice: (i) a* similarity score s *that is merely order-reversing in a distance (as here), and (ii) a* positive definite kernel *in the sense of kernel methods. Theorem 41 only uses monotonicity and therefore applies broadly; additional conditions are required if one wants* s *to define an inner-product feature map or to guarantee that kernel matrices are positive semidefinite.*

33.6 Free V-category closure and practical corollaries

Theorem 42 (Edge domination and monotonicity of path-closure)**.** *For any V-graph g on U and its closure $\widehat{g}$:*

1. *(Edge domination) $g(u,v) \leq \widehat{g}(u,v)$ for all u,v.*
2. *(Monotonicity) If $g \leq g'$ pointwise then $\widehat{g} \leq \widehat{g'}$ pointwise.*
3. *(Idempotence) $\widehat{(\widehat{g})} = \widehat{g}$.*

Remark 1868. *This theorem collects three structural facts about the closure $g \mapsto \widehat{g}$ that one expects of any sensible "add all indirect consequences" operator. (1) says no direct edge is forgotten. (2) says strengthening the base graph cannot weaken its closure. (3) says closing twice does nothing new: once all indirect paths have been accounted for, repeating the operation is redundant. These properties make $\widehat{g}$ a canonical bridge from local relations to global, multi-step relations.*

Remark 1869. *In the language of Section 11, one can begin with a heterarchical or partially hierarchical pattern web (a V-graph) and then pass to a derived structure in which every multi-hop inference is represented explicitly (a V-hierarchy/V-category). This is one clean mathematical way to relate local Pattern Web edges to emergent global Hierarchy and Heterarchy phenomena [5].*

Sketch. (1) The length-1 path $u \to v$ is included in the join defining $\widehat{g}(u,v)$. (2) Every path weight is monotone in each edge weight, and joins preserve order. (3) Once all path information is already included in $\widehat{g}$, re-closing under paths adds nothing. Formally, paths in $\widehat{g}$ correspond to concatenations of paths in g, which are already represented in the original closure. □

Remark 1870. Proof sketch (high-level strategy). *For (1) exhibit a specific path (the single edge). For (2) compare corresponding path weights under g and g' and then take joins. For (3) show that any path in $\widehat{g}$ is built from pieces that were already joins of g-paths, so nothing strictly new can appear.*

Remark 1871. Intuition. *The closure is like taking a graph and adding an edge for every path, with the edge weight computed as the aggregated strength of that path. Doing this twice is like re-adding edges that already exist. In max-product semantics, for instance, $\widehat{g}(u,v)$ is the strength of the best path from u to v; taking "best paths of best paths" cannot improve on already having taken best paths once.*

Theorem 43 (Minimality (universal property) of the free V-category)**.** *Let $h : U \times U \to V$ be any V-category (reflexive/transitive in the enriched sense) such that $g(u,v) \leq h(u,v)$ for all u,v. Then $\widehat{g}(u,v) \leq h(u,v)$ for all u,v. Equivalently, $\widehat{g}$ is the least V-category majorizing g.*

Remark 1872. *This theorem is the universal property that justifies calling $\widehat{g}$ the "free" V-category generated by the V-graph g. It says: among all enriched-preorder structures h that dominate the given edges, $\widehat{g}$ is the smallest one. In plain terms, $\widehat{g}$ adds exactly the transitive consequences forced by g, and nothing extra. This is the precise sense in which $\widehat{g}$ is a principled completion of a mere web into a hierarchy-like structure.*

Remark 1873. *Within Section 11, this minimality is what allows one to move between heterarchical webs and hierarchical summaries without smuggling in unintended assumptions: any additional strength beyond $\widehat{g}$ must come from extra axioms or extra data, not from the closure construction itself.*

Sketch. Fix a path $\pi = (u = u_0 \to \cdots \to u_n = v)$. Since $g(u_i, u_{i+1}) \le h(u_i, u_{i+1})$ and h is a V-category, repeated use of transitivity yields

$$w(\pi) = \bigotimes_i g(u_i, u_{i+1}) \;\le\; \bigotimes_i h(u_i, u_{i+1}) \;\le\; h(u, v).$$

Taking the join over all paths π gives $\widehat{g}(u, v) \le h(u, v)$. $\square$

Remark 1874. Proof sketch. *Prove the claim first for a single path: h dominates each edge, hence dominates the $\otimes$-product along the path by monotonicity and transitivity. Then take the join over all paths; since $h(u, v)$ is an upper bound for each path weight, it is also an upper bound for their join.*

Remark 1875. Why the steps work. *The inequality $g \le h$ is used locally on edges; the V-category transitivity of h is used globally to compress an n-step chain into a single comparison with $h(u, v)$. The structure mirrors the classical fact that the reflexive-transitive closure of a relation is the smallest preorder containing it; here everything is graded and the operations are $\otimes$ and $\oplus$ rather than $\wedge$ and $\vee$.*

Theorem 44 (Max-product closure equals shortest paths in log-space)**.** *Let $V = [0, 1]$ with $\oplus = \max$ and $\otimes = \cdot$, and let $g : U \times U \to [0, 1]$. Define edge costs $c(u, v) \in [0, \infty]$ by*

$$c(u, v) := \begin{cases} -\log g(u, v) & \text{if } g(u, v) > 0, \\ +\infty & \text{if } g(u, v) = 0. \end{cases}$$

Let $d^*(u, v)$ be the shortest-path cost from u to v under additive costs c (min over all paths of sum of edge costs), with the convention that the empty path has cost 0. Then

$$\widehat{g}(u, v) \;=\; \exp(-d^*(u, v)).$$

Remark 1876. *This theorem provides a computational and conceptual translation: max-product path aggregation is equivalent to min-sum shortest paths after a logarithmic change of variables. Intuitively, multiplying probabilities along a path and then taking the best path (maximum product) is the same as adding "surprisal costs" $-\log g$ along a path and then choosing the cheapest path (minimum sum). Thus a seemingly specialized enriched-closure operation reduces to a classical shortest-path problem. In particular, the logarithmic transform is not merely a heuristic: it is an isomorphism between two standard algebraic "path aggregation" calculi, namely the multiplicative–max calculus on $(0, 1]$ and the additive–min (tropical) calculus on $[0, \infty)$. Any choice of logarithm base yields the same minimizing path, since changing bases scales all costs by a positive constant factor, leaving argmin structure invariant.*

Remark 1877. *In the setting of pattern webs, this equivalence allows one to interpret strong indirect pattern connections as "geodesics" in a cost geometry induced by $-\log$ weights. It also makes available the entire toolbox of shortest-path algorithms for computing $\widehat{g}$. When quantales are used to reason about least-effort trajectories more broadly, one meets similar log/energy dualities; see [21] for a thematically related quantale-based least-effort perspective. Concretely, if the underlying directed graph is finite and the costs $c(e) = -\log g(e)$ are nonnegative (as they are when $g(e) \in (0, 1]$), then standard algorithms such as Dijkstra's algorithm apply directly to compute $d^*(u, v)$, and then $\widehat{g}(u, v)$ is obtained by a single exponentiation. From a modeling perspective, this means one can reason about indirect pattern reinforcement either multiplicatively (via reliability/affinity propagation) or additively (via effort/energy accumulation), switching viewpoints depending on which is more interpretable or computationally convenient.*

Sketch. For any path π, $w(\pi) = \prod_i g(e_i)$ so $-\log w(\pi) = \sum_i(-\log g(e_i)) = \sum_i c(e_i)$. Taking max over $w(\pi)$ is equivalent to taking min over $-\log w(\pi)$, hence $-\log \widehat{g}(u,v) = d^*(u,v)$ and exponentiating gives the claim. Here one uses that $-\log$ is strictly decreasing on $(0,1]$, so for any two candidate path weights $w_1, w_2 \in (0,1]$ we have $w_1 \geq w_2 \iff -\log w_1 \leq -\log w_2$. In the common extension where some edges may have $g(e) = 0$, one may set $c(e) = +\infty$ so that any path containing such an edge has infinite cost and therefore cannot be minimizing, matching the fact that such a path has product weight 0 and therefore cannot be maximizing unless all paths have weight 0. □

Remark 1878. Proof sketch. *The proof is a change of coordinates:* $-\log$ *turns products into sums and* max *into* min *because* $-\log$ *reverses order on* $(0,1]$*. After this change,* $\widehat{g}$ *becomes the exponential of minus the shortest-path distance. Equivalently, one may view the construction as transporting the closure operation along the monotone anti-isomorphism* $(0,1], \leq \to [0,\infty), \geq$ *given by* $x \mapsto -\log x$*. This makes explicit why the closure respects composition: multiplicative composition of affinities corresponds exactly to additive composition of efforts, and the "best" composite (maximal affinity) corresponds to the "cheapest" composite (minimal effort).*

Remark 1879. Intuition. *One may think of* $g(u,v)$ *as a "reliability" or "affinity" and of* $c(u,v) = -\log g(u,v)$ *as the corresponding "effort." A path with high product reliability is exactly a path with low total effort. The closure* $\widehat{g}(u,v)$ *therefore reports the reliability of the least-effort route from* u *to* v*. This perspective also clarifies limiting cases: edges with* g *close to* 1 *correspond to very small effort (nearly "free" transitions), while edges with* g *close to* 0 *correspond to very large effort (nearly "forbidden" transitions). Moreover, since* $-\log$ *is additive, repeated moderate reliabilities compound into a linear accumulation of effort, which is often easier to compare across paths than products of many terms; the closure* $\widehat{g}$ *can therefore be read as a global measure of indirect support that is sensitive to both path length and edge strength in a principled way.*

33.7 Multi-resolution transforms and weakness

Theorem 45 (Sup-pushforward dominates original intensities)**.** *Let* $\alpha : X \to X'$ *be surjective,* $\beta : P \to P'$ *any map, and define the pushed-forward intensity*

$$I'(p', x') := \sup\{I(p,x) : \beta(p) = p',\ \alpha(x) = x'\}.$$

Then for all $p \in P$ *and* $x \in X$*,*

$$I'(\beta(p), \alpha(x)) \ \geq\ I(p,x).$$

Remark 1880. *This theorem addresses what happens to pattern intensities under coarse-graining (Hyperseed-Concept 86) or resolution change: multiple fine patterns* p *may map to one coarse pattern* p'*, and multiple fine entities* x *may map to one coarse entity* x'*. The sup-pushforward defines the coarse intensity as the best intensity among all fine representatives consistent with* (p', x')*. The claim is a monotonicity guarantee:* coarse-graining via supremum cannot lose intensity for any specific fine instance*, because that fine instance remains among the candidates.*

Remark 1881. *This "sup semantics" is a natural choice in transfer and abstraction pipelines (Transfer Learning: Hyperseed-Concept 192), where coarse concepts are intended to summarize whatever fine evidence is most salient. It is also aligned with the Transweave idea of transporting learned structure across representational changes [7] (Transweave: Hyperseed-Concept 193).*

Sketch. The set inside the supremum defining $I'(\beta(p), \alpha(x))$ includes the particular witness (p,x), so the supremum is at least $I(p,x)$. □

Remark 1882. Proof sketch. *This is the defining property of* sup*: it is an upper bound for every element of the set being aggregated. Since (p, x) is in that set after mapping, its intensity is bounded above by the supremum, yielding the inequality.*

Theorem 46 (Compositionality of sup-pushforward under successive coarse-graining)**.** *Suppose $X \xrightarrow{\alpha_1} X' \xrightarrow{\alpha_2} X''$ with both maps surjective, and $P \xrightarrow{\beta_1} P' \xrightarrow{\beta_2} P''$. Let I_1 be the sup-pushforward of I along (α_1, β_1), and I_2 the sup-pushforward of I_1 along (α_2, β_2). Let I_{12} be the sup-pushforward of I along $(\alpha_2 \circ \alpha_1,\ \beta_2 \circ \beta_1)$. Then $I_2 = I_{12}$ pointwise.*

Remark 1883. *This theorem says that sup-based coarse-graining is* associative*: performing abstraction in two stages yields exactly the same result as abstracting in one stage. This is crucial if one wants a consistent multi-resolution theory rather than a collection of ad hoc summaries. In epistemic terms, it means the order in which one forgets detail (first from X to X', then to X'') does not affect what intensities remain at the coarsest level, provided one uses the supremum aggregator.*

Remark 1884. *The result connects directly to Section 11's interest in multi-level pattern webs and hierarchical representations: it ensures that when one constructs pattern-web summaries at different levels of granularity, the induced intensities behave coherently across levels. This kind of consistency condition is central in transfer-learning formalisms [7].*

Sketch. Both sides evaluate to the supremum of $I(p, x)$ over the same constraint set: $(\beta_2 \circ \beta_1)(p) = p''$ and $(\alpha_2 \circ \alpha_1)(x) = x''$. The intermediate sup does not change the overall sup because $\sup_{x'} \sup_{x \in \alpha_1^{-1}(x')}$ equals $\sup_{x \in (\alpha_2 \circ \alpha_1)^{-1}(x'')}$, and similarly for patterns. $\square$

Remark 1885. Proof sketch. *Unfold both definitions until each side is written as a supremum over the original fine pairs (p, x) subject to the same composite constraints. Then observe that nested suprema over fibers of α_1 inside fibers of α_2 collapse to a single supremum over the composite fiber.*

Remark 1886. Intuition. *The supremum operator is indifferent to how you partition the candidate set before taking the maximum: taking the best element in each bin and then the best across bins yields the same as taking the best element overall. That invariance is exactly what fails for many other aggregators, hence the special utility of* sup *in a multi-resolution setting.*

Theorem 47 (Iterated coarse-graining monotonically increases weakness)**.** *Let $H \subseteq X \times X$ be an indistinction relation and let $\alpha : X \to X'$ be a coarse-graining map. Let H' be the pushed-forward indistinction relation defined by $(\alpha(x), \alpha(y)) \in H'$ whenever $(x, y) \in H$. For any weakness functional $w(\cdot)$ monotone under adding undistinguished pairs,*

$$w(H) \ \leq \ w(H').$$

Moreover, for a chain of coarse-grainings $X \to X' \to X'' \to \cdots$, the resulting weaknesses form a nondecreasing sequence.

Remark 1887. *This theorem expresses a fundamental directionality: coarser resolution produces more indistinction, hence (for any reasonable monotone measure) greater weakness. Here H encodes which pairs are treated as "not distinguished" (Indistinction is the flip-side of Distinction: Hyperseed-Concept 98). Pushing H forward along α can only identify more pairs, because multiple fine points may collapse to one coarse point, and any prior indistinction survives the collapse.*

Remark 1888. *The formal statement is intentionally generic about $w(\cdot)$: it may be any weakness functional in the sense of [3], or the more general cognitive-architectural notion of weakness discussed in [2]. The moral is that weakness is not merely an accident of a particular observer; it* *is structurally induced by coarse-graining operations. This provides a clean mathematical backbone for Weakness (Hyperseed-Concept 202) as a monotone companion to abstraction. In particular, by leaving w abstract one can accommodate both "relational" weakness (where w is defined directly from an indistinguishability relation H) and "informational" weakness (where H is first converted into an information-loss proxy such as a quotient structure, a partition, or an entropy-like statistic). The point of the lemma is then not the detailed formula for w, but the order property it respects: whenever a process enlarges the set of indistinguishable pairs (or, equivalently, reduces the set of discriminations), any such w must move monotonically in the direction of greater weakness. This makes explicit the sense in which abstraction is not neutral: even with an idealized observer, the coarse-graining map α can force formerly separable states to become inseparable, thereby raising weakness in a way that is induced by the representation change itself.*

Remark 1889. *The "moreover" clause states that repeated coarse-graining yields a monotone time-series of weakness values. In a multi-level pattern-web construction, this can be read as saying that as one moves upward through levels of abstraction, the space becomes progressively less discriminating, and any monotone measure of that loss of discrimination accumulates rather than oscillates. Equivalently, if one indexes abstraction levels by $t = 0, 1, 2, \dots$ and writes H_t for the induced indistinguishability relation at level t, then $H_t \subseteq H_{t+1}$ (in the natural inclusion order on relations), so the trajectory $w(H_t)$ is a nondecreasing sequence. This rules out "free" recovery of discriminative power under further coarse-graining: any later increase in discrimination would require an operation other than coarse-graining (e.g. refinement, additional sensors/features, or an explicit memory of distinctions lost at earlier levels). In pattern-web language, the higher-level nodes may still support useful inference, but the granularity of admissible distinctions is constrained monotonically by the abstraction pipeline.*

Sketch. The pushed-forward relation H' contains (at least) the image of H under $\alpha \times \alpha$, so it collapses at least as many distinctions. Apply monotonicity of $w(\cdot)$ once, and iterate for a chain. More concretely, if $H \subseteq X \times X$ encodes indistinguishability on the fine space X and $\alpha : X \to X'$ is the coarse-graining map, one standard pushed-forward choice is the least relation $H' \subseteq X' \times X'$ such that $(x, y) \in H \Rightarrow (\alpha(x), \alpha(y)) \in H'$. For indistinguishability, H' typically also contains all pairs that are forced to coincide by the map itself, i.e. whenever $\alpha(x) = \alpha(y)$ one has $(\alpha(x), \alpha(y)) \in H'$ even if $(x, y) \notin H$; thus H' is at least as large as the direct image $(\alpha \times \alpha)[H]$ and may be strictly larger due to many-to-one identification. If the weakness axiom is phrased as monotonicity under relation inclusion (or under any equivalent preorder capturing "having fewer distinctions"), then $H \preceq H'$ implies $w(H) \leq w(H')$, and repeating the same comparison along $\alpha_0, \alpha_1, \dots$ yields the monotone chain inequality. ☐

Remark 1890. Proof sketch. *The proof is order-theoretic: show that H' is "larger" than H in the sense relevant to the monotonicity axiom of w, and then conclude $w(H) \leq w(H')$. Iterating the one-step argument gives a nondecreasing sequence along a chain. Here "larger" can be read literally as set inclusion $H \subseteq H'$ when H and H' live on a common carrier, or more generally as the existence of a comparison map that embeds the fine indistinguishability information into the coarse one. In many presentations, indistinguishability relations (or partitions/equivalence relations derived from them) form a lattice ordered by refinement, and coarse-graining moves upward in that lattice (toward coarser partitions with bigger equivalence classes). Any weakness functional that is monotone with respect to that order—whether defined via counting indistinguishable pairs, measuring the size distribution of equivalence classes, or evaluating a cost of identification—inherits the same one-step monotonicity, and therefore the same monotone behavior under iteration.*

Remark 1891. Intuition. *Think of H as the set of pairs your observer cannot tell apart. Coarse-graining merges states, so if two fine states were already indistinct, their coarse images are certainly indistinct; and in addition, distinct fine states may map to the same coarse state and thus become indistinct* even if they were formerly distinguished. *Any weakness measure that increases when you add indistinct pairs must therefore increase (or stay constant) under coarse-graining. A useful mental model is to imagine X as high-resolution sensory microstates and X' as the corresponding macro-descriptions (features, categories, buckets). The map α forgets some coordinates; forgetting cannot create new evidence that separates two cases, but it can destroy separating evidence that used to exist. Thus the induced indistinguishability relation on X' necessarily contains at least the transported old indistinguishabilities and often strictly more, because collisions $\alpha(x) = \alpha(y)$ force a new indistinguishability regardless of what held at the fine level. This is exactly the sense in which weakness is structurally induced: once you decide to work at the coarse level, the loss of discriminations is not a contingent failure of attention but a consequence of the representational collapse encoded by α.*

34 Helper theorems for habits, self-weaving webs, and morphic resonance (Section 12)

Standing assumptions and notation. Fix a commutative quantale $(V, \leq, \oplus, \otimes, e)$ and a (finite, when needed) pattern class P. A pattern-support state is a function $s : P \to V$ (Section 12 preamble). Given a V-relation (kernel) $A : P \times P \to V$, define the relational image (Def. 145):

$$(A?s)(q) := \bigoplus_{p \in P} A(p, q) \otimes s(p).$$

Given $d \in V$, define scaling (Def. 146):

$$(d \odot s)(p) := d \otimes s(p).$$

Given an external input $u_t : P \to V$, define the habit update operator (Def. 147):

$$\mathrm{Upd}_{A,d,u_t}(s) := u_t \oplus (d \odot s) \oplus (A?s),$$

where $\oplus$ on the right is pointwise in V^P.

For scalar habit statistics (Defs. 141–143), fix a scalarization $\pi : V \to [0, 1]$ and define $p_t(p) := \pi(s_t(p))$.

Remark 1892. *The quantale $(V, \leq, \oplus, \otimes, e)$ plays two roles at once: it is an algebra of "intensities" (how much support a pattern has), and it is an algebra of "composition" (how supports propagate and combine). The order $\leq$ is the notion of "no more than" or "no stronger than." The operation $\oplus$ is a join-like combination (often interpreted as taking the stronger of two independent supports, or the least upper bound), while $\otimes$ is a multiplicative-like combination (often interpreted as chaining supports along a path, or conjoining evidence). The unit e is the neutral element for chaining, so that $e \otimes v = v$; this matches the intuition that an "empty chain" should not change a support value. Quantales (and in particular their use as graded logics/evidence algebras) connect to the general notion of* Quantale Weakness *in the Hyperseed core-concept set (Hyperseed-Concept 143) and to broader discussions of weakness-as-structure in adaptive systems [3, 2].*

Remark 1893. *The notation* $(A?s)$ *is the standard "relational image" (a.k.a. matrix-vector product, but in the quantale rather than over* $\mathbb{R}$*): for each target pattern* $q \in P$*, we look at all sources* $p \in P$*, combine the strength of the edge* $A(p,q)$ *with the current support* $s(p)$ *using* $\otimes$*, and then aggregate over all sources using* $\oplus$*. Concretely, if* $V = [0,1]$ *with* $\oplus = \max$ *and* $\otimes = \cdot$*, then* $(A?s)(q) = \max_p A(p,q)\, s(p)$*, i.e. the strongest incoming reinforcement chain into* q*. If instead* $V = \{0,1\}$ *with* $\oplus = \vee$ *and* $\otimes = \wedge$*, then* $(A?s)(q) = 1$ *iff there exists some* p *with both* $A(p,q) = 1$ *and* $s(p) = 1$*, i.e. ordinary reachability of active patterns. This relational viewpoint is the algebraic spine behind many "pattern web" and reinforcement intuitions in [5], and it links naturally to the Hyperseed notion of* Pattern *(Hyperseed-Concept 130).*

Remark 1894. *The update operator* Upd_{A,d,u_t} *says: next support is the pointwise join of (i) the exogenous drive* u_t*, (ii) the decayed previous support* $d \odot s$*, and (iii) the internally propagated support* $A?s$*. Philosophically, this is a minimal dynamical synthesis of three sources of "becoming": the outside world, the persistence of what already is, and the internal causal/associative web. One may hear here a faint echo of Peirce's triadic categories [14] (the immediate given, the brute secondness of constraint, and the mediating thirdness of habit), and of Whitehead's insistence that process must be understood through how it inherits and transmutes prior activity [15].*

Remark 1895. *The scalarization* $\pi : V \to [0,1]$ *is what allows one to compute scalar habit statistics from structured/graded evidence values. In the simplest case* $V = [0,1]$ *one may take* $\pi = \mathrm{id}$*; in the p-bit case* $V = [0,1]^2$ *later in this section,* π *may pick out a "positive" component or a "net" bias. This scalarization is a modeling choice: it specifies what an observer is willing to count as "more of the habit," and thus belongs as much to observer-indexed semantics as to pure algebra.*

Remark 1896. *It is often helpful to make explicit the ambient order on the function space* V^P*: we use the pointwise order (also written* $\leq$ *by abuse of notation), namely* $s \leq s'$ *iff* $s(p) \leq s'(p)$ *for all* $p \in P$*. With this convention, pointwise* $\oplus$ *is exactly the join operation in* V^P*, and the update* Upd_{A,d,u_t} *is naturally read as an order-theoretic combination of three monotone influences. In particular, whenever* $\otimes$ *is monotone in each argument (as it is in any quantale), both* $s \mapsto d \odot s$ *and* $s \mapsto A?s$ *are monotone maps* $V^P \to V^P$*, and hence* Upd_{A,d,u_t} *is monotone as well. This monotonicity is one of the basic "helper" properties used repeatedly when discussing convergence, fixed points, and the accumulation of habit under repeated updates.*

Remark 1897. *The clause "finite, when needed" for the pattern class* P *is mainly about how one wants to interpret the* $\bigoplus_{p\in P}$ *in the relational image. In a general quantale,* $\oplus$ *is defined for arbitrary joins, so* $\bigoplus_{p\in P}$ *is meaningful even for infinite* P *as the join of the set* $\{A(p,q) \otimes s(p) \mid p \in P\}$*. However, in applications one may restrict to finite* P *(or effectively finite support) to ensure that relational images can be computed concretely and to avoid measure-theoretic issues when* P *carries additional structure. Thus "finite when needed" is not a conceptual limitation of the formalism so much as a pragmatic stipulation about which helper theorems are intended to be computationally actionable.*

Remark 1898. *The kernel* $A : P \times P \to V$ *can be read as a weighted directed adjacency relation on the pattern class:* $A(p,q)$ *expresses "how much" activation of* p *can (directly) reinforce* q *in one step. Under iteration, the quantale product* $\otimes$ *governs how multi-step paths compose (chains of reinforcement), while* $\oplus$ *governs how alternative paths compete or accumulate. This is the sense in which the algebra is a "self-weaving web": even if* u_t *is sparse or intermittent, the term* $A?s$ *can sustain and spread support across the web in a way that depends only on the internal connectivity structure encoded by* A*.*

Remark 1899. *The decay/scaling element $d \in V$ is best thought of as a persistence parameter that regulates how much of the prior state is carried forward independently of web propagation. In many concrete instances one assumes $d \leq e$ (so that $d \otimes v \leq e \otimes v = v$), which makes $d \odot s$ a literal "decay" or "forgetting" term. Nonetheless, the formal definition allows more general choices (including context-dependent or pattern-dependent decay, by replacing d with a function $d : P \to V$), and later helper lemmas typically isolate exactly which inequalities on d are required for boundedness, stability, or contraction-like behavior under iteration.*

Remark 1900. *The time index in u_t and s_t is intentionally minimal: the operator Upd_{A,d,u_t} defines a one-step transition, and one may study either non-autonomous dynamics (time-varying input u_t) or autonomous dynamics (constant u). In the autonomous case, fixed points of $s \mapsto \mathrm{Upd}_{A,d,u}(s)$ provide a natural notion of "habit attractor" or "stable support profile" compatible with a steady environment; in the non-autonomous case, helper estimates typically compare trajectories $t \mapsto s_t$ against such fixed points or against each other to quantify the degree of resonance, drift, or entrainment caused by the changing u_t.*

Remark 1901. *Although this section foregrounds algebraic definitions, the motivating interpretations (habits, morphic resonance, and self-weaving webs) depend on iterating the update and examining how repeated exposure and internal propagation reshape the support landscape. Concretely, when u_t intermittently excites a small subset of patterns, the term $A?s$ can amplify recurrent subgraphs of A (feedback motifs), and the term $d \odot s$ can preserve partial activation between exposures. The helper theorems that follow are meant to make these informal statements precise in order-theoretic language (e.g. monotone iteration, inflationary behavior under suitable assumptions, and comparisons between kernels), while remaining agnostic about which particular quantale V is chosen in a given modeling instance.*

34.1 Habit-taking / habit-reversal as monotone time-series properties

Lemma 102 (Strict version of Lemma 3)**.** *Assume for every $p \in P$ the scalar propensity $p_t(p)$ is nondecreasing in t. Then for every p, T for which the conditional expectations exist, $\mathrm{Post}_T(p) \geq \mathrm{Pre}_T(p)$ (Lemma 3 in the main text).*

Moreover, if there is a set of pairs (p, T) of positive $(\nu \times \tau)$-measure such that $\mathrm{Post}_T(p) > \mathrm{Pre}_T(p)$, then the habit-taking statistic

$$\mathbb{E}_{p\sim\nu, T\sim\tau}\big[\mathrm{Post}_T(p) - \mathrm{Pre}_T(p)\big]$$

is strictly > 0 (hence the context manifests tendency-to-take-habits in Def. 143).

Remark 1902. *Intuitively, this lemma formalizes the idea that if each individual propensity time-series is monotone upward, then "after" averages must dominate "before" averages. The second clause adds a modest but important strengthening: if* some *non-negligible fraction of (p, T) pairs show a strict improvement, then the* average *improvement is strictly positive. This is exactly what one wants if one is trying to detect an intrinsic tendency-to-take-habits (Hyperseed-Concept 189) from data: a merely nonnegative statistic is consistent with stasis, but a strictly positive statistic witnesses genuine directional drift.*

Remark 1903. *The phrase "for which the conditional expectations exist" is doing real work: it rules out pathologies where the time-window averages defining $\mathrm{Pre}_T(p)$ and $\mathrm{Post}_T(p)$ are undefined (e.g. because of non-integrability). In the typical empirical setting one assumes bounded propensities $p_t(p) \in [0, 1]$, in which case these conditional expectations exist automatically. Under such boundedness, the lemma can be read as a statement purely about order: monotone sample paths force monotone conditional means.*

Remark 1904. *The result is not surprising once stated, but it is structurally important: it lets us replace a potentially messy definition involving conditional expectations with a simple sufficient condition (monotonicity). In later subsections, we will prove monotonicity of the underlying state dynamics under natural assumptions; this lemma is the bridge that transports those order-theoretic facts into the probabilistic/empirical habit statistics of Section 12.*

Sketch. The weak inequality is exactly Lemma 3: averages of a nondecreasing sequence after T dominate averages before T. For strictness, the expectation of a random variable is strictly positive if it is positive on a set of positive measure and never negative. □

Remark 1905. *One way to make the strictness clause completely explicit is to consider the random variable*

$$X(p,T) \;:=\; \mathrm{Post}_T(p) - \mathrm{Pre}_T(p).$$

By the first part of the lemma (or Lemma 3), $X(p,T) \geq 0$ for all (p,T) for which the conditional expectations exist. If, in addition, $X(p,T) > 0$ on a set of positive $(\nu \times \tau)$-measure, then the integral of X against $(\nu \times \tau)$ must be strictly positive. This is the standard "nonnegative and not almost everywhere zero" criterion for strict positivity of an expectation, and it shows that strict habit-taking is an identifiable *phenomenon at the level of averaged statistics (as opposed to being an artifact of a few measure-zero exceptional points).*

Remark 1906. *The same logic also isolates the only way strictness can fail: even if each trajectory $t \mapsto p_t(p)$ is nondecreasing, it may be* flat *on almost all relevant windows, so that $\mathrm{Post}_T(p) = \mathrm{Pre}_T(p)$ except on a negligible set. In that case the statistic is 0, correctly reflecting that (in the sense of the chosen sampling measures ν, τ) there is no detectable directional drift. Thus the strictness clause should be read as a joint condition: it requires not merely monotonicity but also that strict increases occur with non-negligible frequency under the sampling scheme.*

Remark 1907. Proof sketch. *The strategy is purely order-theoretic: if a sequence never goes down, then any average taken over later indices cannot be smaller than an average taken over earlier indices. The strictness part is a basic measure-theoretic observation: a nonnegative random variable with positive probability of being strictly positive has strictly positive expectation.* □

What makes the lemma useful is that it isolates the only place where time enters: once monotonicity in t is established, the before/after statistic becomes almost tautological. One can picture the graph of $t \mapsto p_t(p)$ as a nondecreasing curve; the "Post" average samples the curve to the right of T and the "Pre" average samples to the left, so the inequality is the statement that the center-of-mass of the right-hand sample cannot lie below the left-hand sample.

Remark 1908. *Because this subsection also targets habit-*reversal *(Hyperseed-Concept 188), it is worth spelling out the symmetric interpretation: if each $t \mapsto p_t(p)$ is nonincreasing, then the same averaging argument yields $\mathrm{Post}_T(p) \leq \mathrm{Pre}_T(p)$, and strict decrease on a set of positive measure yields a strictly negative mean $\mathbb{E}[\mathrm{Post} - \mathrm{Pre}] < 0$. In other words, the sign of the same statistic distinguishes "habit-taking" (upward drift) from "habit-reversal" (downward drift) once the appropriate monotonicity direction is established.*

Lemma 103 (Monotone scalarizations transport order to propensities)**.** *Assume $\pi : V \to [0,1]$ is monotone (order-preserving). If $s \leq s'$ in V^P (pointwise), then for all $p \in P$,*

$$\pi(s(p)) \leq \pi(s'(p)).$$

Remark 1909. *This lemma says that an order-preserving "readout" π cannot invert comparisons: if a state s' has at least as much support as s for every pattern, then the scalarized propensities must also be at least as large. It is a small fact, but it is the essential hinge between the abstract quantale-valued dynamics and any concrete scalar statistic we might compute. Without it, one could have a paradoxical situation where increasing evidence yields decreasing measured propensity merely because the observer chose a perverse scalarization.*

Remark 1910. *The pointwise order on V^P is crucial here: $s \leq s'$ means* every *pattern-coordinate has weakly increased. This is exactly the setting in which a monotone π can be applied coordinatewise without losing the comparison. In applications, π is often chosen to be a "forgetful" or "compression" map (e.g. projecting a multidimensional evidence record to a single confidence score); the lemma guarantees that such compression does not introduce spurious inversions when the underlying evidence order is respected.*

Remark 1911. *A simple example: if $V = [0,1]^2$ is a p-bit evidence domain, then $\pi_{\text{pos}}(v^+, v^-) = v^+$ is monotone, whereas $\pi(v^+, v^-) = v^- - v^+$ is* anti-monotone *in the first coordinate and so would not satisfy the lemma's assumption. The point is not that anti-monotone maps are illegitimate, but that they measure a different attitude: they interpret "more positive evidence" as "less" in the output scale.*

Remark 1912. *More generally, any map of the form $\pi(v) = \sum_i w_i v_i$ on $V = [0,1]^n$ with weights $w_i \geq 0$ is monotone in the product order, and so it respects increases in any coordinate. This kind of example is typical when V packages multiple "facets" of support (frequency, recency, coherence, etc.) and the observer reports a single propensity by an order-respecting aggregation.*

Sketch. Immediate from pointwise order and monotonicity of π. $\square$

Remark 1913. Proof sketch. *Unpack the definitions: $s \leq s'$ means $s(p) \leq s'(p)$ for each p, and monotonicity of π means $v \leq w \Rightarrow \pi(v) \leq \pi(w)$. Compose these two implications.* $\square$

The lemma is the precise way to say that π is an "observer-compatible" projection from structured support to a single dial reading: it respects the direction of increase encoded in $\leq$.

Corollary 11 (Inflationary dynamics imply habit-taking under monotone scalarization)**.** *Assume π is monotone and the state sequence satisfies $s_{t+1} \geq s_t$ pointwise for all t. Then each $p_t(p) = \pi(s_t(p))$ is nondecreasing in t, hence the habit-taking statistic in Def. 143 is ≥ 0 (and > 0 under the strictness condition of Lemma 102).*

Remark 1914. *This is the promised bridge: if the* state *evolves inflationarily (never losing support), and if the observer's measurement map π is monotone, then the measured propensities are monotone in time, so the tendency-to-take-habits statistic (Hyperseed-Concept 189) is nonnegative. In other words, an order-theoretic property of the underlying dynamics implies an empirically testable statistical signature.*

Remark 1915. *For strict positivity in the corollary, it is enough (though not necessary) that there exist a set of times t and patterns p of positive sampling measure for which $s_{t+1}(p) > s_t(p)$ in V and for which π is strictly order-reflecting at those points in the weak sense that $v < w$ implies $\pi(v) < \pi(w)$ along the realized comparisons. The lemma itself only assumes monotonicity, so strictness must ultimately come from the empirical fact that the dynamics sometimes make genuine progress (not merely weak progress) in directions that the scalarization can detect.*

Remark 1916. *This corollary is also a methodological statement: it tells us that in order to establish habit-taking it may suffice to prove inflationarity of* Upd *(or of a simplified update such as* Cl_A*) rather than to analyze the full before/after expectations directly.*

Sketch. Apply Lemma 103 to $s_t \leq s_{t+1}$ for each t, then invoke Lemma 3. □

Remark 1917. Proof sketch. *First transport monotonicity from* s_t *to* p_t *using the monotone scalarization lemma; then apply the already-established "monotone time-series implies Post* $\geq$ *Pre" fact.* □

Conceptually, the proof composes two monotonicities: (i) dynamical monotonicity in the state space V^P*, and (ii) observational monotonicity in passing from* V*-values to scalars. This composition is one of the recurring themes of the section: order structure is preserved through the whole pipeline.*

34.2 Update operator monotonicity and comparative statics

Lemma 104 (Monotonicity in all arguments)**.** *The operator* Upd_{A,d,u_t} *is monotone in each of* s*,* u_t*,* A*, and* d*: if* $s \leq s'$*,* $u_t \leq u'_t$*,* $A \leq A'$*, and* $d \leq d'$ *(pointwise order for relations), then*

$$\mathrm{Upd}_{A,d,u_t}(s) \leq \mathrm{Upd}_{A',d',u'_t}(s').$$

Remark 1918. *The lemma asserts a strong form of* comparative statics*: if you increase any of the ingredients of the update—start from a larger state, feed in a larger input, strengthen the internal kernel, or reduce decay by taking a larger* d *in the quantale order—then the resulting next state cannot decrease. For dynamical systems meant to model reinforcement and habit formation, this is the algebraic analogue of the intuition that "more cause cannot yield less effect," provided our algebra* $(V, \leq, \oplus, \otimes)$ *is chosen so that* $\leq$ *truly means "no stronger than."*

Remark 1919. *This monotonicity is a central reason for working in a quantale rather than in an arbitrary semiring: completeness and residuation-like order behavior make it possible to reason about dynamics with lattice-theoretic tools. In the background lies the same philosophy that makes fixed-point theorems practical for self-modifying systems and goal dynamics [10]: if the update is monotone on a complete lattice, then least/greatest fixed points and convergence-by-iteration become accessible.*

Sketch. Prop. 14 in the main text gives monotonicity in s, u_t, and A. Monotonicity in d follows similarly because $(d \odot s)(p) = d \otimes s(p)$ and $\otimes$ is monotone in each argument in a quantale. Join $\oplus$ is monotone as it is the least upper bound. □

Remark 1920. Proof sketch. *Prove each argument is monotone separately, then combine them:* Upd *is built by composing and joining monotone maps, and such constructions preserve monotonicity.* □

The key step is recognizing that the only "nontrivial" operations are $\otimes$ *and* $\oplus$*, and both are monotone in a quantale. Visually, one can think of* Upd *as three pipes (input, persistence, propagation) feeding into a single "max/join" combiner; increasing any pipe cannot make the combined output smaller.*

Corollary 12 (Trajectory dominance)**.** *Fix sequences* (A, d, u_t) *and* (A', d', u'_t) *with* $A \leq A'$*,* $d \leq d'$*, and* $u_t \leq u'_t$ *for all* t*. If* $s_0 \leq s'_0$*, and* $s_{t+1} = \mathrm{Upd}_{A,d,u_t}(s_t)$ *while* $s'_{t+1} = \mathrm{Upd}_{A',d',u'_t}(s'_t)$*, then* $s_t \leq s'_t$ *for all* t*.*

Remark 1921. *This corollary is the dynamical version of the monotonicity lemma: if one system is "everywhere stronger" in parameters and initialization than another, then it stays stronger at all future times. In practice, it lets us bound complicated trajectories by simpler ones (e.g. with larger kernels or inputs), and it guarantees that improving a learning environment cannot perversely reduce learned support, as long as the improvements correspond to increases in the quantale order.*

Sketch. Induction on t using Lemma 104. □

Remark 1922. Proof sketch. *Assume $s_t \leq s'_t$; apply the monotonicity lemma at time t to obtain $s_{t+1} \leq s'_{t+1}$; conclude by induction from the base case $s_0 \leq s'_0$.* □

The proof works because the inequality is preserved by one update step, and time is nothing but iteration of that step. Geometrically (in the poset V^P), the update map carries order intervals to order intervals.

Lemma 105 (Inflationarity in the no-decay case)**.** *Assume $d = e$ (no decay). Then for all s and t,*

$$s \leq \mathrm{Upd}_{A,e,u_t}(s).$$

In particular, if $u_t \equiv u$ is constant, the trajectory is pointwise ascending: $s_0 \leq s_1 \leq s_2 \leq \cdots$.

Remark 1923. *This lemma isolates a particularly transparent regime: when there is no decay, the system never forgets. Then the update always includes the previous state as a join-summand, so it must be inflationary. This is the simplest abstract situation in which "habit-taking" is almost built into the algebra: the dynamics is literally cumulative. One may see this as the most extreme formalization of a system with perfect retention.*

Sketch. If $d = e$ then $(d \odot s)(p) = e \otimes s(p) = s(p)$, hence $\mathrm{Upd}_{A,e,u_t}(s) = u_t \oplus s \oplus (A?s) \geq s$. □

Remark 1924. Proof sketch. *Substitute $d = e$ so that the decay term becomes exactly s, and then note that joining with s cannot yield something below s.* □

The proof is a one-line algebraic expression of an intuitive picture: the next state is the old state plus possible additions; if nothing is ever subtracted, monotone accumulation follows automatically.

34.3 Closure, Kleene star, and downstream support

Recall (Defs. 148–149). Define the one-step closure operator

$$\mathrm{Cl}_A(s) := s \oplus (A?s),$$

and define iterates $\mathrm{Cl}_A^{(0)}(s) := s$, $\mathrm{Cl}_A^{(n+1)}(s) := \mathrm{Cl}_A(\mathrm{Cl}_A^{(n)}(s))$. When V^P is a complete lattice (e.g. P finite, V complete), define the limit

$$\mathrm{Cl}_A^{(\omega)}(s) := \bigoplus_{n \geq 0} \mathrm{Cl}_A^{(n)}(s).$$

Also define $A^0 := I$, $A^{n+1} := A^n \circ A$ and $A^* := \bigoplus_{n \geq 0} A^n$ (Def. 149).

Remark 1925. *The operator Cl_A is the "pure reinforcement" update: keep whatever support you already have, and add what can be transmitted to you in one step through A. Iterating Cl_A therefore accumulates reinforcement through chains of length $0, 1, 2, \ldots$. The ω-iterate $\mathrm{Cl}_A^{(\omega)}(s)$ is the result of allowing* all finite *reinforcement chains to contribute. The definition uses $\bigoplus_{n \geq 0}$, so completeness of V^P ensures that this infinite join exists; in the finite P case this is automatic because joins reduce to finite ones after stabilization in many concrete quantales.*

Remark 1926. *For readers tracking the mechanics: the symbol "?" denotes the (left) action of a V-kernel $A : P \times P \to V$ on a state $s \in V^P$. Concretely, one typically has a formula of the form*

$$(A?s)(q) = \bigoplus_{p \in P} A(p,q) \otimes s(p),$$

so $A?s$ is an "incoming aggregation" into q from all sources p, weighted by $A(p,q)$ and gated by the current support $s(p)$. Under this reading, $\mathrm{Cl}_A(s) = s \oplus (A?s)$ literally means: preserve the current support at each node, and also add in any support that can flow to the node in one A-step. The quantale axioms (associativity of $\otimes$ and distributivity over $\oplus$) are exactly what make iterative propagation agree with path-composition via A^n later on.

Remark 1927. *The Kleene star A^* is the familiar transitive-closure construction, generalized from boolean adjacency matrices to V-weighted kernels: A^n aggregates all paths of length n, and A^* aggregates all finite lengths. In max-product semantics, $A^*(p,q)$ is the weight of the best (maximal) path from p to q; in boolean semantics it is reachability. This is why the next theorem can be read as saying that closure equals "propagate along all finite paths," an idea closely aligned with the "pattern web" viewpoint [5].*

Remark 1928. *It is also useful to keep in mind the familiar algebraic identities for the Kleene star (when the relevant joins exist): one has*

$$A^* = I \oplus (A \circ A^*) = I \oplus (A^* \circ A),$$

expressing the idea that a finite path is either empty (the I contribution) or a first step followed by a finite path (the $A \circ A^*$ contribution), equivalently a finite path followed by a last step (the $A^* \circ A$ contribution). These identities are a compact way to see why A^* behaves like a "saturation" or "closure" of A under finite chaining, and they parallel the idempotence phenomenon for $\mathrm{Cl}_A^{(\omega)}$ discussed below.

Theorem 48 ($\mathrm{Cl}^{(\omega)}$ is a closure operator)**.** *Assume P is finite and V is a commutative quantale. Then $\mathrm{Cl}_A^{(\omega)} : V^P \to V^P$ is:*

1. *inflationary: $s \le \mathrm{Cl}_A^{(\omega)}(s)$,*
2. *monotone: $s \le s' \to \mathrm{Cl}_A^{(\omega)}(s) \le \mathrm{Cl}_A^{(\omega)}(s')$,*
3. *idempotent: $\mathrm{Cl}_A^{(\omega)}(\mathrm{Cl}_A^{(\omega)}(s)) = \mathrm{Cl}_A^{(\omega)}(s)$,*
4. *a least-fixed-point operator: $\mathrm{Cl}_A^{(\omega)}(s)$ is the least fixed point of Cl_A above s (Thm. 12 in the main text).*

Remark 1929. *In plain language, the theorem says that if you repeatedly apply "add whatever A can transmit in one step" and then take the limit, you obtain a genuine closure operation: it only adds (inflationary), respects ordering (monotone), stabilizes after being applied once (idempotent), and in fact produces the* smallest *stable state that contains the original seed s. This is the formal underpinning of the intuition that a habit web has an "eventual downstream envelope" determined by reinforcement paths.*

Remark 1930. *One can also read these clauses operationally as guaranteeing a well-behaved notion of "downstream support." Inflationary says no support is ever lost by closure; monotonicity says that adding more initial support cannot reduce what is eventually supported downstream; idempotence says that once a state has been fully saturated with all its downstream consequences, re-saturating does not change it. In many applications, these are the exact properties needed for closure to serve as a semantic abstraction: it defines an equivalence relation* $s \sim s'$ *iff* $\mathrm{Cl}_A^{(\omega)}(s) = \mathrm{Cl}_A^{(\omega)}(s')$*, i.e. two seeds are behaviorally indistinguishable with respect to all downstream reinforcement consequences.*

Remark 1931. *The least-fixed-point characterization is the most conceptually potent clause: it says that* $\mathrm{Cl}_A^{(\omega)}(s)$ *is not merely some limit, but the* canonical *limit picked out by order theory (Kleene iteration / Knaster–Tarski). This connects the present dynamics to the same mathematical machinery used elsewhere in the document to discuss stability of self-referential systems [10].*

Remark 1932. *The condition "least fixed point above s" should be read with care: it is a* relative *least fixed point (a least post-fixed state containing s). Equivalently, among all states t such that* $s \leq t$ *and* $\mathrm{Cl}_A(t) = t$*, the element* $\mathrm{Cl}_A^{(\omega)}(s)$ *is the smallest. This is precisely the sense in which the closure is "minimal but sufficient": it includes everything forced by repeated reinforcement, and nothing beyond that forced content.*

Sketch. Inflationary and monotone follow because Cl_A is inflationary and monotone, so the iterates form an ascending chain; the join dominates all iterates. Idempotence and least-fixed-point characterization are exactly the Kleene/Knaster–Tarski content of Thm. 12. □

Remark 1933. Proof sketch. *The proof proceeds in two layers. First, show that one-step closure* Cl_A *is inflationary and monotone; therefore its iterates form an increasing chain. Second, take the join of this chain; completeness ensures it exists, and the Knaster–Tarski/Kleene theorem ensures this join is the least fixed point above the seed.* □

The reason idempotence holds is subtle but standard: once you have included the contribution of all *finite reinforcement chains, applying "one more step" cannot reveal anything genuinely new, because any would-be new contribution would already correspond to a finite chain (namely the previous chain plus one edge). A helpful picture is the reachability closure in a directed graph: once all reachable nodes are marked, repeating the marking rule does nothing.*

Remark 1934. *If one wants to see the monotonicity/inflationary claims at the level of a single line, they are inherited from the lattice and action structure:* $s \leq s \oplus x$ *always, hence* $s \leq \mathrm{Cl}_A(s)$*; and if* $s \leq s'$ *then typically* $A?s \leq A?s'$ *(monotonicity of the action), hence* $s \oplus (A?s) \leq s' \oplus (A?s')$*. This is the basic reason the Kleene iteration* $\mathrm{Cl}_A^{(0)}(s) \leq \mathrm{Cl}_A^{(1)}(s) \leq \cdots$ *forms an ascending chain whose join can be taken.*

Theorem 49 (Explicit path-sum form (Thm. 12 restated))**.** *Under the assumptions above,*

$$\mathrm{Cl}_A^{(\omega)}(s) = A^*?s.$$

Equivalently, for each $q \in P$*,*

$$\mathrm{Cl}_A^{(\omega)}(s)(q) = \bigoplus_{n \geq 0} (A^n?s)(q),$$

so closure aggregates support transmitted along all finite reinforcement chains.

Remark 1935. *A convenient intermediate identity (often proved by a short induction) is that finite iteration of* Cl_A *corresponds to truncating the star at finite depth:*

$$\mathrm{Cl}_A^{(n)}(s) = \bigoplus_{k=0}^{n}(A^k?s).$$

The base case $n = 0$ *reads* $\mathrm{Cl}_A^{(0)}(s) = A^0?s = s$*, while the inductive step uses distributivity of the action over joins together with the associativity implicit in* $A^{k+1} = A^k \circ A$*. Taking* $\bigoplus_{n\geq 0}$ *of both sides then yields exactly the stated formula* $\mathrm{Cl}_A^{(\omega)}(s) = \bigoplus_{k\geq 0}(A^k?s) = A^*?s$*, making explicit how "closure as a limit of iterates" coincides with "closure as a path-sum."*

Remark 1936. *This theorem gives the computational/semantic reading of* $\mathrm{Cl}_A^{(\omega)}$*: it is exactly "apply A along any finite number of steps, and aggregate." The expression* $A^*?s$ *is thus a compact way to say "everything that can be downstream of the seed, with weights given by chaining through A." When* V *is max-product, one can read* $A^n?s$ *as "best path of length* n *from any seeded pattern into* q*," and then the outer join as "best over all lengths."*

Remark 1937. *In particular, the formula* $\mathrm{Cl}_A^{(\omega)}(s)(q) = \bigoplus_{n\geq 0}(A^n?s)(q)$ *makes clear what "downstream" means: node* q *receives support not only from immediate predecessors (the* $n = 1$ *term), but also via predecessors-of-predecessors, and so on. The join over* n *expresses that a node can be supported in multiple ways (different path lengths and different intermediate nodes), and the quantale structure specifies how such alternatives are aggregated (e.g. maximum, sum, logical disjunction). Thus, while the notation resembles classical transitive closure, it simultaneously encodes both* reachability *and* strength of support *in a single object.*

Remark 1938. *The result connects the fixed-point view (closure as least stable state) with the path-combinatorics view (closure as sum over chains). This duality is one reason the Kleene star is so persistent in computer science and logic: it lets one translate between recursion and enumeration without changing meaning.*

Sketch. This is item (3) of Thm. 12: unfold the recurrence, observe $\mathrm{Cl}_A^{(n)}(s) = \bigoplus_{k=0}^{n} A^k?s$, then take $n \to \omega$ and use distributivity. More explicitly, the iteration defining $\mathrm{Cl}_A^{(n)}(s)$ can be read as a repeated "one-step propagate and then join" process: starting from the seed s, at each stage you add all contributions that can be obtained by applying A one more time and then joining with what has already been accumulated. This is precisely why the nth iterate collects all path contributions of length at most n, and why the closed form $\bigoplus_{k=0}^{n} A^k?s$ matches the operational unfolding. In the limit step $n \to \omega$, one uses that the ambient join-semilattice (or quantale/module structure, depending on the setup of Thm. 12) admits countable joins and that the action $A \mapsto (A?s)$ and the finite compositions A^k interact well with joins. The distributivity invoked here is the algebraic property that allows one to commute the join over iteration depth with the joins implicit in composition/action, so that the ω-iterate agrees with the Kleene-star form. □

Remark 1939. Proof sketch. *Inductively expand* Cl_A *to see that after* n *iterations you have accumulated contributions from paths of length up to* n*. Then take the join over all* n *and recognize the Kleene star.* □

The key step is the algebraic distributivity that permits rearranging "join over times" with "join over paths." Intuitively, each iteration adds one more hop of propagation, so the bookkeeping by iteration count coincides with bookkeeping by path length. In slightly more detail: the "time" index n *counts how many rounds of applying the propagation kernel* A *you have performed, while a "path"* *of length k corresponds to k consecutive uses of A, i.e. to the composite A^k. Thus, iterating Cl_A is equivalent to accumulating, stage by stage, the images $A^k?s$ for increasing k. Recognizing the Kleene star is then exactly recognizing that $\bigoplus_{k\geq 0} A^k$ is A^*, and hence that the eventual closure is the star-action $A^*?s$. This is also the point where it matters that joins are taken in the correct order: one wants to be allowed to first join over all ways of taking k steps (which is already encoded in A^k as a join over intermediate states), and then join over k, without changing the outcome. Distributivity guarantees that this "flattening" of a two-level join is legitimate.*

Lemma 106 (Monotonicity of A^* and of downstream closure)**.** *If $A \leq B$ (pointwise as V-relations), then $A^* \leq B^*$, and hence for all states s,*

$$A^*?s \leq B^*?s.$$

Also, if $s \leq s'$, then $A^*?s \leq A^*?s'$.

Remark 1940. *This lemma states that strengthening the kernel can only strengthen its long-run transitive closure, and strengthening the seed can only strengthen the propagated result. It formalizes an intuitive monotonicity of "downstream influence." In applied terms: if you make some reinforcement links stronger (or add new ones), you cannot end up with* less *eventual downstream habit support. Equivalently, the assignment $A \mapsto A^*$ is an order-preserving endomorphism on the poset of V-relations, and the downstream-closure operator $s \mapsto A^*?s$ is order-preserving both in the kernel and in the initial condition. This matters when comparing interventions or learning updates: any update that is monotone at the level of local edges (relations) remains monotone after taking "all finite chains" of influence. One can also read the second monotonicity statement as a form of positive homogeneity of propagation with respect to evidence/activation: starting from a larger seed s' (in the order of the underlying module of states) cannot lead to a smaller propagated state after allowing arbitrary finite downstream traversals.*

Sketch. $A \leq B$ implies $A^n \leq B^n$ for all n by induction using monotonicity of relational composition; joining over n yields $A^* \leq B^*$. Monotonicity of $(\cdot?\cdot)$ in each argument gives the image inequalities. To spell out the induction: for $n = 0$ one typically has $A^0 = I \leq I = B^0$ (identity relation), and for the step $n \mapsto n+1$ one uses that composition is monotone in both arguments, so $A^{n+1} = A^n \circ A \leq B^n \circ B = B^{n+1}$ whenever $A^n \leq B^n$ and $A \leq B$. Taking $\bigoplus_{n\geq 0}$ on both sides (the join defining the Kleene star) preserves the inequality because joins are least upper bounds. Finally, since $A^* \leq B^*$ and the action/image operator ? is assumed monotone in its relation argument, it follows that $A^*?s \leq B^*?s$ for each s; similarly, $s \leq s'$ and monotonicity in the state argument gives $A^*?s \leq A^*?s'$. ☐

Remark 1941. Proof sketch. *Use induction on n to transport $A \leq B$ through repeated composition, then take joins to get $A^* \leq B^*$, and finally apply monotonicity of the image operator in each argument.* ☐

A visual intuition: A^* is built from all finite concatenations of edges from A. If every edge in A is no stronger than the corresponding edge in B, then every path in A is no stronger than the corresponding path in B, and taking the best/combined over paths preserves this ordering. In more operational terms, A^* aggregates the effect of zero steps (the identity), one step (A), two steps (A^2), and so on. The inequality $A \leq B$ ensures that at each fixed path length n, the n-step influence computed using A is bounded above by the n-step influence computed using B. The Kleene star then simply collects these bounds uniformly over all finite lengths, so the global "allow any finite number of hops" influence remains monotone. This is the same kind of reasoning used in reachability and dynamic programming: if you increase the weight/availability of every edge, then every finite walk *can only become at least as good, and optimizing/aggregating over all walks respects that ordering. The lemma packages this intuition into a clean algebraic statement that can be reused whenever downstream support is compared across kernels or across initial activations.*

34.4 Self-weaving webs and autocatalytic support

Recall (Def. 150). Fix a threshold $\theta \in V$. A nonempty $S \subseteq P$ is θ-autocatalytic if there exists a state $s : P \to V$ such that: (i) $s(p) \geq \theta$ for all $p \in S$, and (ii) $(A?s)(p) \geq \theta$ for all $p \in S$.

Remark 1942. *It is useful to read the two conditions as a* static *and a* dynamic *requirement. Condition (i) says that every pattern in S is already "present" (or supported) at least at level θ in the seed state s. Condition (ii) says that if one applies a single round of propagation through the relational web A (via the image operator $A?$), the support fed back into each $p \in S$ is still at least θ. In particular, (ii) does not require that $A?s$ equals s on S, only that the propagated support does not drop below threshold on S; this is what makes the definition robust to the presence of additional incoming support from outside S or additional mass in s outside S.*

Remark 1943. *Autocatalysis is the idea that a set of patterns can collectively sustain itself: each member already has at least threshold support, and moreover the internal propagation $A?s$ reinforces each member back up to threshold. This matches the intuitive meaning of* Autocatalytic Sets *(Hyperseed-Concept 61): the set is not merely present, but self-producing via the web of relations A. The term "self-weaving web" (Hyperseed-Concept 168) suggests the same image: the fabric of patterns is woven by the very threads it contains, a theme emphasized in process-oriented accounts of organization [15] and in pattern-web treatments [5]. In graph language (when P is viewed as nodes and A as weighted edges), a θ-autocatalytic set can be thought of as a subgraph whose internal connectivity is strong enough that one step of message-passing keeps every node in the subgraph above the activation level θ.*

Remark 1944. *A simple example in the boolean quantale: let $P = \{a, b\}$ and $A(a, b) = A(b, a) = 1$, with $s(a) = s(b) = 1$. Then $A?s = s$ and $S = \{a, b\}$ is autocatalytic for $\theta = 1$. In max-product $[0, 1]$, take $A(a, b) = A(b, a) = 0.9$ and $s(a) = s(b) = 1$; then $(A?s)(a) = (A?s)(b) = 0.9$, so S is autocatalytic at any threshold $\theta \leq 0.9$. Note that in the $[0, 1]$ case the set is* not *autocatalytic at $\theta = 1$, even though the seed state itself places both elements at value 1; what fails is that propagation through A attenuates support. This highlights that autocatalysis depends on the interaction between the seed s and the coupling strengths encoded by A, not merely on the raw initial levels.*

Lemma 107 (Autocatalysis persists under closure)**.** *Assume S is θ-autocatalytic with witness state s. Let $s^\infty := \mathrm{Cl}_A^{(\omega)}(s)$. Then for all $p \in S$:*

$$s^\infty(p) \geq \theta \quad \textit{and} \quad (A?s^\infty)(p) \geq \theta.$$

Remark 1945. *The lemma says that once a set is autocatalytic at threshold θ, taking the full downstream closure cannot destroy that property. Closure can only add support, never remove it, so the autocatalytic set remains above threshold, and its internally propagated reinforcement remains above threshold as well. This is the formal reason self-weaving is stable under "letting the reinforcement dynamics run." In particular, even if the closure process introduces new patterns outside S (possibly strongly connected to S), the original members of S do not lose their guaranteed lower bound θ because all operators involved are order-preserving.*

Sketch. By inflationarity, $s \leq s^\infty$, hence $s^\infty(p) \geq s(p) \geq \theta$ on S. Monotonicity of the image operator gives $A?s^\infty \geq A?s$, hence $(A?s^\infty)(p) \geq \theta$ on S. $\square$

Remark 1946. *One can also view the argument as a two-step domination chain on S:*

$$s^\infty \;\geq\; s \;\geq\; \theta \quad\Rightarrow\quad A?s^\infty \;\geq\; A?s \;\geq\; \theta,$$

where the first implication uses inflationarity of $\mathrm{Cl}_A^{(\omega)}$ and the second uses monotonicity of $A?$. Nothing in the proof requires special algebraic properties beyond these order-theoretic ones, which is why the result transfers cleanly across different choices of quantale-like value domains V.

Remark 1947. Proof sketch. *Use two monotonicities: s^∞ dominates s because closure is inflationary, and $A?$ is monotone so applying it to a larger state yields a larger image. Combine these with the witness inequalities for s.* □

Geometrically, closure moves you upward in the lattice V^P, and the operator $A?$ is an order-preserving transformation; therefore once a coordinate is above threshold, it stays above threshold under these upward moves. If one imagines each coordinate $p \in P$ as a "height" of support, then Cl_A is an update rule that can only raise heights (never lower them), so any already-high region (the autocatalytic subset) remains high throughout the closure ascent.

Theorem 50 (Self-weaving implies a nontrivial stable attractor in pure reinforcement)**.** *Assume P is finite and V complete. If (P, A) is self-weaving at threshold θ (i.e. it contains a θ-autocatalytic subset), then there exists a non-bottom fixed point s^* of Cl_A with $s^*(p) \geq \theta$ on that subset. Moreover, in pure reinforcement dynamics $s_{t+1} = \mathrm{Cl}_A(s_t)$ started from the witness seed s, the trajectory converges (as a join) to $s^* = \mathrm{Cl}_A^{(\omega)}(s)$.*

Remark 1948. *This theorem asserts the existence of an "attractor" purely from the presence of an autocatalytic seed: if some subset can reinforce itself above threshold, then iterating pure closure produces a stable fixed point that is nontrivial (not bottom) and that maintains at least threshold support on that subset. The second sentence explains the dynamics: starting from the witness state, repeatedly applying Cl_A accumulates all downstream consequences and converges (in the order-theoretic sense of taking a join) to the fixed point. The "non-bottom" conclusion can be read concretely as: there is at least one pattern (indeed, every pattern in the autocatalytic subset) whose eventual stabilized support is not the minimal value of V, so the attractor represents a genuinely present structure rather than the null state.*

Remark 1949. *The finiteness of P helps connect the order-theoretic ω-iteration to an intuitive finite-time stabilization: ascending chains in V^P often stabilize after finitely many steps when the underlying combinatorics is finite and the closure operator is Scott-continuous (or otherwise well-behaved). Even when one does not assume a specific continuity condition, the ω-join formulation still provides a canonical "limit" object s^* that captures everything that can be generated by repeated reinforcement from the seed.*

Remark 1950. *The importance is that we get stability without metric arguments, Lyapunov functions, or contraction estimates: it is a* poset-based *stability result, hinging on monotonicity and completeness. This is one of the deep reasons monotone dynamical systems are so tractable: the "shape" of the order replaces much of the analytic complexity. In particular, rather than proving that trajectories get closer in some distance, one proves that trajectories are* nested *(ascending) and therefore have a least upper bound that is automatically forward-invariant under the closure operator.*

Sketch. Take $s^* := \mathrm{Cl}_A^{(\omega)}(s)$. Thm. 12 gives that s^* is a fixed point of Cl_A, and Lemma 107 gives $s^* \geq \theta$ on the autocatalytic subset, hence nontrivial. The convergence statement is the definition of $\mathrm{Cl}^{(\omega)}$ as the join of iterates. □

Remark 1951. *The proof can be mentally decomposed into three conceptual steps: (1) define the candidate limit state by iterating reinforcement transfinitely up to ω (i.e. taking the join of all finite iterations), (2) invoke the fixed-point characterization that ω-closure yields a Cl_A-stable state, and (3) use the persistence lemma to transfer the original threshold guarantee from the seed to the limit. In this way the existence of an attractor is not an additional assumption but a consequence of the internal self-support conditions already present in the autocatalytic seed.*

Remark 1952. Proof sketch. *Define the candidate attractor as the ω-closure of the witness seed. Fixed-point theorems (as packaged in Thm. 12) guarantee it is stable under Cl_A, and the persistence lemma guarantees it retains threshold support on the autocatalytic subset.* ☐

The "convergence" here is not convergence in a metric but in the lattice sense: the sequence $s, \mathrm{Cl}_A(s), \mathrm{Cl}_A^2(s), \ldots$ is ascending, so its least upper bound is a natural limit. Visually, one can picture repeatedly flooding a directed weighted graph with support starting from s; each iteration allows support to travel one more step, and the flooded region (with weights) stabilizes at s^*. In this picture, the fixed-point condition $\mathrm{Cl}_A(s^*) = s^*$ says that once the flooding has reached s^*, another round of propagation does not expand or intensify anything further: the web has finished weaving itself.

34.5 Morphic resonance and anti-resonance as cross-context coupling

Recall (Defs. 151–153). Let L index contexts. Each $\ell \in L$ has pattern class P_ℓ, internal kernel A_ℓ, decay d_ℓ, and external input $u_{\ell,t}$. For $\ell_0 \neq \ell$, a coupling kernel is a V-relation $K_{\ell_0 \to \ell} : P_{\ell_0} \times P_\ell \to V$, with induced input $(K_{\ell_0 \to \ell} ? s_{\ell_0,t})(q)$ defined by the same image formula. The coupled update is

$$s_{\ell,t+1} = u_{\ell,t} \oplus (d_\ell \odot s_{\ell,t}) \oplus (A_\ell ? s_{\ell,t}) \oplus \bigoplus_{\ell_0 \neq \ell} (K_{\ell_0 \to \ell} ? s_{\ell_0,t}).$$

Remark 1953. *This is the formal mechanism for* morphic resonance *(Hyperseed-Concept 115) in the present algebraic setting: each context ℓ has its own internal reinforcement dynamics, but it also receives inputs induced from other contexts via coupling kernels $K_{\ell_0 \to \ell}$. The term "morphic resonance" evokes the hypothesis that patterns formed in one domain can bias pattern-formation in another [13]; here it is treated operationally as cross-context propagation of support values through a kernel, without committing to any particular physical substrate.*

Remark 1954. *Notation check: $s_{\ell,t} \in V^{P_\ell}$ is the state in context ℓ at time t; $A_\ell : P_\ell \times P_\ell \to V$ is the within-context kernel; $K_{\ell_0 \to \ell} : P_{\ell_0} \times P_\ell \to V$ is the between-context kernel, and $(K_{\ell_0 \to \ell} ? s_{\ell_0,t}) \in V^{P_\ell}$ is an induced input into the target context. The outer $\bigoplus_{\ell_0 \neq \ell}$ is a join in the state space V^{P_ℓ}, i.e. taken pointwise over patterns in P_ℓ.*

Lemma 108 (Coupling images are monotone)**.** *Fix $\ell_0 \neq \ell$. If $s \leq s'$ in $V^{P_{\ell_0}}$ and $K \leq K'$ pointwise, then*

$$K ? s \leq K' ? s' \quad \text{in } V^{P_\ell}.$$

Remark 1955. *This lemma is the cross-context analogue of monotonicity for internal propagation: if the source context has more support and/or the coupling kernel is stronger, then the induced drive into the target cannot be weaker. It is the minimal algebraic sanity condition needed for interpreting $K_{\ell_0 \to \ell}$ as a "channel" of resonance rather than as an adversarial transformer.*

Sketch. Immediate from monotonicity of $\otimes$ and of joins in the definition $(K?s)(q) = \bigoplus_p K(p,q) \otimes s(p)$. ☐

Remark 1956. Proof sketch. *For each q, compare each summand $K(p, q) \otimes s(p)$ to $K'(p, q) \otimes s'(p)$ using monotonicity of $\otimes$, then compare the joins using monotonicity of $\oplus$.* □

The proof works coordinatewise: the state space order is pointwise, so one checks the inequality separately for each target pattern $q \in P_\ell$.

Theorem 51 (Global monotonicity of morphic resonance dynamics)**.** *Define the global state space $S := \prod_{\ell \in L} V^{P_\ell}$ with pointwise order. For each t, the global update map $F_t : S \to S$ induced by Def. 153 is monotone in the global state and monotone in each parameter family $(u_{\ell,t})$, (A_ℓ), (d_ℓ), and $(K_{\ell_0 \to \ell})$.*

Remark 1957. *The theorem says that the entire coupled multi-context system preserves order: if you start from a globally larger configuration (every context has at least as much support for every pattern), then after one update step you remain globally larger. Likewise, strengthening any of the parameters (inputs, internal kernels, decays, couplings) cannot decrease the next global state. This is crucial because it lets one reason about morphic resonance by bounding and comparison, rather than by solving coupled nonlinear recurrences directly.*

Remark 1958. *It also shows that "morphic resonance" in this formal sense is compatible with the same lattice-theoretic stability toolkit used for single-context habit dynamics: the price of coupling is not the loss of monotonic structure. This is one reason quantale-based models scale naturally from individual habit loops to networks-of-contexts.*

Sketch. Each component update is a pointwise join of monotone terms: $u_{\ell,t}$, $(d_\ell \odot s_{\ell,t})$, $(A_\ell ? s_{\ell,t})$, and the coupling images. Apply Lemma 104 plus Lemma 108 and closure of monotonicity under finite products. □

Remark 1959. Proof sketch. *Prove monotonicity for each context component separately by expressing it as a join of monotone maps; then assemble these componentwise monotone maps into a product map on S, which is again monotone.* □

The key observation is compositionality: monotonicity is stable under (i) forming joins, (ii) composing monotone functions, and (iii) taking product maps. This mirrors the architectural idea that complex cognitive/behavioral dynamics can be built from individually sensible modules without forfeiting global order properties [19].

Corollary 13 (Cross-context habit-taking under monotone scalarization)**.** *Assume a monotone scalarization π and suppose a source context ℓ_0 has $s_{\ell_0,t}$ pointwise nondecreasing in t. Then for any target ℓ, each induced coupling drive $t \mapsto \pi((K_{\ell_0 \to \ell} ? s_{\ell_0,t})(q))$ is nondecreasing. Thus coupling can create the same "before/after" bias of Def. 143 across contexts, provided the target dynamics is not strongly contractive.*

Remark 1960. *This corollary says: monotone growth in a source context propagates as monotone growth of the* input signal *into other contexts, after applying a monotone scalarization. In conceptual terms, once one domain starts "taking a habit," other domains coupled to it can inherit a habit-taking bias through resonance (Hyperseed-Concept 192 is a nearby conceptual cousin, though the present coupling is algebraic rather than task-reduction based). One way to read the statement is that it is purely a claim about the* ordering *of drives: if, over time, the source state $s_{\ell_0,t}$ becomes "no smaller" in the relevant partial order, then every downstream context sees a drive that is likewise "no smaller" once we (i) push the source state through the coupling operator and (ii) read it out through a monotone π. In particular, nothing in the claim depends on a specific parametric form of the dynamics internal to the target context; it is a structural property of the cross-context* *map. Equivalently, if one thinks of $K_{\ell_0 \to \ell}?(\cdot)$ as a kind of cross-context feature transport (kernel smoothing, message passing, or aggregation), the corollary isolates the simple but practically important fact that* monotone in $\Rightarrow$ monotone out *survives both the aggregation and the final scalar readout, provided both are order-preserving.*

Sketch. Monotonicity of $s_{\ell_0,t}$ implies monotonicity of $K_{\ell_0 \to \ell}?s_{\ell_0,t}$ by Lemma 108, then apply Lemma 103. Intuitively, the first step is the order-preservation of the image operator: if $s_{\ell_0,t} \leq s_{\ell_0,t'}$ (pointwise, or in the ambient lattice order) for $t \leq t'$, then applying the same kernel cannot reverse that inequality. The second step is that a monotone scalarization π cannot reverse inequalities either, so composing the two maps preserves the time-order of the resulting scalar signal. $\square$

Remark 1961. Proof sketch. *Monotone source state $\Rightarrow$ monotone induced image (by monotonicity of the image operator) $\Rightarrow$ monotone scalar readout (by monotonicity of π).* $\square$

The final sentence of the corollary flags the obvious caveat: even if an input signal increases, a sufficiently contractive target dynamics could still damp it. The corollary isolates what is guaranteed at the level of the induced drive itself. In more operational terms, the corollary is best viewed as separating signal formation *from* signal response*. The induced drive (produced by resonance and read out by π) is guaranteed to be monotone under the stated hypotheses, but the subsequent state trajectory in context ℓ depends on the update rule in ℓ (e.g., whether it saturates, forgets quickly, thresholds sharply, or exhibits strong negative feedback). Thus the result is a clean input-side monotonicity statement, not a stability or convergence theorem for the coupled system. A useful mental model is: resonance controls what gets "broadcast" across contexts, while the internal dynamics controls what gets "stored" or "amplified." The corollary formalizes that the broadcast itself respects growth, even when storage does not.*

Anti-resonance (Def. 154, p-bit case). Assume $V = [0,1]^2$ and p-bit negation is $\neg(v^+, v^-) = (v^-, v^+)$. Define $\mathrm{AntiRes}_{\ell_0 \to \ell}(s) := K^-_{\ell_0 \to \ell}?(\neg \circ s)$. Here $(\neg \circ s)$ is the pointwise (or componentwise) negation of the source state, so that any site (or feature coordinate) carrying evidence-for/evidence-against information has those roles swapped before being transported. The notation $K^-_{\ell_0 \to \ell}$ emphasizes that the anti-resonant channel can be parametrically distinct from the resonant one, allowing, for example, different receptive fields, different strengths, or different sparsity patterns for inhibitory versus excitatory transfer. In applications, it is often helpful to regard Res and AntiRes as two separately tunable conduits: one that imports support and one that imports counter-support. This makes it possible to model cross-context influence that is not merely "the negative" of resonance, but an independently shaped form of coupling that can preferentially transmit contradiction, skepticism, or inhibitory evidence.

Remark 1962. *Anti-resonance is the formal dual of resonance: instead of importing the "positive" support of patterns from a source context, one imports a negated version (swapping evidence-for and evidence-against) and then transmits it through a (typically different) kernel K^-. This aligns with the Hyperseed notion of* Morphic Anti-Resonance *(Hyperseed-Concept 114). The choice $V = [0,1]^2$ makes explicit a paraconsistent/evidence-pair semantics, where support and counter-support can coexist rather than annihilate each other, echoing themes in paraconsistent logics [23, 24]. The evidence-pair view is especially relevant for cross-context coupling because different contexts may legitimately disagree: a pattern might be strongly supported by one context while also strongly opposed by another. Encoding both coordinates allows the model to represent such tension explicitly rather than forcing an early collapse to a single signed scalar. Anti-resonance then becomes a principled way to import "the other side" of a pattern: what was treated as supporting evidence* *upstream becomes opposing evidence downstream (and vice versa), which can be used to model inhibitory transfer, adversarial correlation, or deliberate counter-conditioning between contexts. Note also that the duality here is algebraic rather than logical negation in the classical sense: $\neg$ is an involution on $[0,1]^2$ (applying it twice returns the original pair), and it preserves the total mass $v^+ + v^-$ while swapping the allocation between pro and con. This makes it well-suited for settings where one wants to conserve "amount of evidence" but reverse its polarity.*

Lemma 109 (Negation effects on common scalarizations)**.** *For $v = (v^+, v^-) \in [0,1]^2$:*

$$\pi_{\text{pos}}(\neg v) = v^-, \qquad \pi_{\text{net}}(\neg v) = \max(0,\, v^- - v^+).$$

Hence if $v^+ > v^-$ then $\pi_{\text{net}}(\neg v) = 0$ (net suppression).

Remark 1963. *This lemma simply computes what happens to two natural scalar readouts under evidence-pair negation. The first readout π_{pos} treats "positive evidence" as the scalar propensity, so negation swaps it to the negative coordinate. The second readout π_{net} treats only net-positive bias as salient; after negation, a pattern that was net-supported becomes net-suppressed (clipped to* 0*), capturing the idea that anti-resonance can selectively cancel rather than merely invert. It is worth emphasizing the behavioral difference between these two choices. Under π_{pos}, anti-resonance does not necessarily* decrease *the scalar signal; it reinterprets which coordinate is considered "positive" and therefore may yield a large scalar output whenever the source carried large counter-support. Under π_{net}, by contrast, the scalarization is explicitly one-sided: only* net *support survives, so swapping coordinates tends to turn net support into net opposition, which is then clipped away. Concretely, if $v = (0.9, 0.2)$ (strongly supported, weakly opposed), then $\neg v = (0.2, 0.9)$ and $\pi_{\text{net}}(\neg v) = \max(0, 0.9 - 0.2) = 0.7$ while $\pi_{\text{net}}(v) = \max(0, 0.9 - 0.2) = 0.7$ would not be correct since $\pi_{\text{net}}(v) = \max(0, 0.9 - 0.2) = 0.7$ and after negation becomes* $\max(0, 0.2 - 0.9) = 0$ *if the coordinates are interpreted as (v^+, v^-); this illustrates exactly why the swap matters: anti-resonance can extinguish what resonance would amplify, depending on which coordinate is treated as "for" versus "against" at readout time. From a modeling standpoint, this offers two distinct inhibitory mechanisms: (i) re-routing activation into a channel that the downstream system treats as negative evidence (via π_{pos}), or (ii) enforcing a strict "no drive unless net-positive" policy (via π_{net}), which yields genuine suppression in the presence of dominant counter-evidence.*

Sketch. Immediate from Def. 141 and the definition of p-bit negation (swap components). More explicitly: $\neg(v^+, v^-) = (v^-, v^+)$, so $\pi_{\text{pos}}(\neg v)$ returns the first coordinate of (v^-, v^+), namely v^-. Likewise, $\pi_{\text{net}}(\neg v) = \max(0, (v^-) - (v^+))$ by direct substitution into the net readout. The "net suppression" condition is then the observation that if $v^+ > v^-$, the quantity $(v^- - v^+)$ is negative and is clipped to 0 by the outer max. □

Remark 1964. Proof sketch. *Compute $\pi_{\text{pos}}(v^-, v^+) = v^-$ and $\pi_{\text{net}}(v^-, v^+) = \max(0, v^- - v^+)$ directly.* □

The "net suppression" clause is a useful interpretive guide: if a pattern is more supported than opposed, then anti-resonance followed by π_{net} yields no positive drive at all. In applications, this corresponds to a channel that can inhibit without generating spurious positive activation. A further way to see the same point is that π_{net} is intentionally asymmetric: it treats opposition as something that can only remove *drive, not create negative drive. Thus, after anti-resonance, any configuration in which the original v^+ dominated v^- becomes one in which the swapped pair has dominant second coordinate, producing a negative net that is discarded. This implements an "inhibit-only" effect at the scalar level, which is often desirable when downstream modules interpret scalar drives as nonnegative activation intensities rather than signed quantities. This also clarifies* *why anti-resonance need not be viewed as merely producing an "opposite habit." With π_{net}, anti-resonance can act as a* gate *that blocks transfer of strongly supported patterns while still allowing transfer of patterns that were originally contested (e.g., with $v^- \geq v^+$, where anti-resonance yields a nonzero net-positive signal). In that sense, the anti-resonant channel can be tuned to preferentially propagate cautionary or adversarial evidence across contexts.*

34.6 Stability, amplification, and decay in the p-bit toy quantale

Recall (Def. 155, Thm. 13). Assume $V = [0,1]^2$ with $\oplus = \max$ and $\otimes = \cdot$ componentwise. Define $|v|_\infty := \max(v^+, v^-)$ and extend to states/relations by maxima over entries. For homogeneous, no-input single-context updates $s_{t+1} = (d \odot s_t) \oplus (A?s_t)$, let $\rho := \max(|d|_\infty, |A|_\infty)$.

Remark 1965. *This "toy quantale" is deliberately concrete: $\oplus = \max$ means supports accumulate by taking the strongest available contributor, while $\otimes = \cdot$ means chaining along a link multiplies strengths. The ∞-norm $|v|_\infty$ measures the largest component of the evidence pair; extending it by maxima over entries yields a coarse but convenient global magnitude measure for the entire state or kernel. The parameter ρ is thus a crude upper bound on the strongest single-step amplification available either from persistence (d) or from propagation (A).*

Corollary 14 (Exponential decay bound (unrolling Thm. 13))**.** *Under the assumptions of Thm. 13, for all $t \geq 0$,*

$$|s_t|_\infty \leq \rho^t \, |s_0|_\infty.$$

In particular, if $\rho < 1$ then $|s_t|_\infty \to 0$ exponentially fast.

Remark 1966. *This corollary says that when the system has no external input, and the strongest possible single-step amplification is strictly less than 1, then all support must eventually vanish: forgetting dominates reinforcement. The result is the discrete-time analogue of linear stability under a spectral radius bound, but it is proved here purely with max-product inequalities rather than linear algebra. Its role in the overall narrative is to show that habit formation requires either sufficiently strong internal loops ($\rho \geq 1$) or sustained external/coupled inputs; otherwise decay wins.*

Sketch. Thm. 13 gives $|s_{t+1}|_\infty \leq \rho \, |s_t|_\infty$. Iterate the inequality. □

Remark 1967. Proof sketch. *Apply the one-step contraction estimate repeatedly: each step multiplies the bound by at most ρ, so after t steps the bound is ρ^t times the initial magnitude.* □

The geometric picture is a shrinking envelope: $|s_t|_\infty$ lies inside a ball whose radius decays like ρ^t. Even though the underlying dynamics uses max *and products rather than sums, the inequality behaves like the familiar "multiply by ρ each step" recurrence.*

Lemma 110 (Input-bounded contraction estimate)**.** *In the same p-bit setting, for the inhomogeneous update $s_{t+1} = u_t \oplus (d \odot s_t) \oplus (A?s_t)$, one has*

$$|s_{t+1}|_\infty \leq \max\big(|u_t|_\infty,\ \rho \, |s_t|_\infty\big).$$

If $\rho < 1$ and $|u_t|_\infty \leq U$ for all t, then

$$|s_t|_\infty \leq \max\big(\rho^t |s_0|_\infty,\ U\big),$$

so the long-run magnitude is controlled by the sustained input scale.

Remark 1968. *This lemma makes explicit the tradeoff between contraction and drive. If the internal dynamics is contractive ($\rho < 1$), then past support fades unless new support is injected via u_t. The inequality says precisely that the system's magnitude is bounded by whichever is larger: the current input magnitude or the contracted previous magnitude. Thus, even a forgetful system can maintain nontrivial long-run support if it is continually stimulated.*

Sketch. Use the same bounding steps as in the proof of Thm. 13 on the two terms $(d \odot s_t)$ and $(A?s_t)$, and note that $\oplus$ is componentwise max so the ∞-norm of a join is the max of the norms. Then unroll the recurrence by induction. □

Remark 1969. Proof sketch. *Bound the contribution of each join-summand to $|s_{t+1}|_\infty$, observe that max-join turns into an outer max on norms, and then iterate the resulting scalar recurrence.* □

The essential step is that in the max-product setting, norms behave well with respect to both $\oplus$ and $\otimes$: max does not create larger magnitudes than its largest input, and componentwise multiplication scales magnitudes multiplicatively. This makes the inequality almost inevitable once the norm is chosen.

Theorem 52 (Driven closure attractor as a Kleene-star closure)**.** *Assume $d = e$ and $u_t \equiv u$ is constant (Prop. 15 main text), and assume P finite and V complete. Let $s_{t+1} = u \oplus s_t \oplus (A?s_t)$ and define $s_\infty := \bigoplus_{t \geq 0} s_t$. Then*

$$s_\infty = A^*?(s_0 \oplus u) = \mathrm{Cl}_A^{(\omega)}(s_0 \oplus u).$$

In particular, if $s_0 \leq u$ then $s_\infty = A^*?u$.

Remark 1970. *This theorem identifies the long-run accumulated state under constant driving and no decay: it is exactly the closure of the combined seed $(s_0 \oplus u)$ under the reinforcement kernel A, equivalently the Kleene-star propagation $A^*?(s_0 \oplus u)$. The conceptual message is that constant input u behaves like an ever-present set of "roots" from which reinforcement chains can grow. In the long run, everything reachable (in the graded sense determined by V) from these roots will be activated to the extent permitted by A^*.*

Remark 1971. *The special case $s_0 \leq u$ is philosophically neat: if the system's initial support is already contained in what the environment continuously supplies, then the eventual attractor depends only on u and the internal kernel A. In that regime, "who the system was" matters less than "what it is being fed" plus "how it internally propagates." This resonates with the broader theme that sustained conditions can sculpt stable habit structure.*

Sketch. Since $d = e$, the update is inflationary (Lemma 105), so the join s_∞ exists. In particular, for the recurrence $s_{t+1} = F(s_t)$ given in this toy quantale update, inflationarity means $s_t \leq F(s_t) = s_{t+1}$ for every t, i.e. $(s_t)_{t \geq 0}$ is an ascending chain. Because we are working in a join-semilattice (indeed, the ambient setting provides the relevant completeness for the construction), the supremum of this chain exists, and we may write

$$s_\infty = \bigvee_{t \geq 0} s_t,$$

which is the least upper bound of all iterates.

After one step, $s_t \geq u$ for all $t \geq 1$, so the dynamics is pure closure starting from $s_0 \oplus u$: indeed $s_1 = F(s_0)$ contains the joined-in input u, and since the update always joins u again, once $u \leq s_1$

we have $u \leq s_t$ for all $t \geq 1$ by monotonicity and the ascending-chain property. Consequently, for $t \geq 1$ we may simplify the driven update by absorbing the constant drive into the state:

$$s_t \oplus u = s_t \quad (\text{because } u \leq s_t),$$

so the recurrence reduces to iterating the internal closure operator alone, with the input acting only through the choice of initial seed.

iterating yields $s_\infty = \mathrm{Cl}_A^{(\omega)}(s_0 \oplus u)$. Here $\mathrm{Cl}_A^{(\omega)}$ denotes the ω-iteration (countable iteration) of the one-step closure induced by A, i.e. the least fixed point above the seed $s_0 \oplus u$ obtained by repeatedly applying Cl_A and taking the join of all finite stages. Equivalently, s_∞ is characterized as the least element s such that $s_0 \oplus u \leq s$ and $\mathrm{Cl}_A(s) \leq s$, which matches the usual closure-as-least-fixed-point intuition in this quantale setting.

Apply Thm. 49. Concretely, this theorem supplies the explicit "Kleene star" description of the ω-closure in terms of the star A^* (built from the joins of finite powers of A), so that the limiting state can be written in the closed form provided there, with the dependence on the initial condition appearing only through the seed $s_0 \oplus u$. □

Remark 1972. Proof sketch. *Show the sequence is ascending (no decay, join with s_t), so the join limit exists. Observe that constant input can be absorbed into the initial seed after one step, reducing the driven recurrence to repeated closure. Then use the explicit A^* representation of* $\mathrm{Cl}_A^{(\omega)}$*.*
□

Show the sequence is ascending (no decay, join with s_t), so the join limit exists. Observe that constant input can be absorbed into the initial seed after one step, reducing the driven recurrence to repeated closure. Then use the explicit A^* representation of $\mathrm{Cl}_A^{(\omega)}$*. In slightly more detail: inflationarity gives $s_0 \leq s_1 \leq s_2 \leq \cdots$, hence the limit is computed by a join over all finite times. The absorption step is the observation that the "drive" u is not merely added once, but re-added at every step; after the first update it is therefore redundant to keep writing it explicitly, since joining it again does not change the state once u is already below the current iterate. This is what turns a driven system into an autonomous closure iteration without changing the eventual supremum.*

The key step is the absorption of u: because u is joined in at every step, once it has appeared it never disappears, and thus it may be treated as part of the seed for the closure dynamics. A graph picture helps: imagine adding a permanent set of "source nodes" that are always active at level u; the eventual activation pattern is exactly what you get by taking the transitive closure of influence from those sources through the internal edges A. Equivalently, one can regard A as encoding one-step propagation rules, so that applying Cl_A *once adds all consequences reachable in one propagation layer, applying it twice adds all consequences reachable in two layers, and so on; the ω-iteration collects all finite propagation depths. The A^* formula packages this iterative expansion into a single expression (a join of A^n over all $n \geq 0$ acting on the seed), making the roles of "amplification" (new reachability through repeated application of A) and "stability" (eventual fixed-point behavior under closure) manifest.*

35 Helper theorems for mind, representation, and perception (Section 13)

Standing notation. Let U be the ambient universe of entities. Let $(\mathrm{Ctx}, \preceq)$ be the poset of contexts (Def. 159), with $C \preceq D$ meaning "D refines C". For each $C \in \mathrm{Ctx}$, let $\mathrm{asp}_C : U \to U_C$ be the aspect extraction map, and for $C \preceq D$ let $\pi_{D \to C} : U_D \to U_C$ satisfy

$$\mathrm{asp}_C = \pi_{D \to C} \circ \mathrm{asp}_D.$$

Write $x|_C := \mathrm{asp}_C(x)$. Let V be the quantale/evidence domain used for intensities (Section 3), hence $(V, \leq)$ is a complete lattice.

Fix a context C and a finite pattern basis $B_C \subseteq P_C$. The pattern signature of an entity X in aspect C is

$$\mathrm{Sig}_C(X) : B_C \to V, \quad \mathrm{Sig}_C(X)(P) := \mathrm{Int}_X(P)$$

(Def. 164), and strong inheritance in aspect C is $\mathrm{Sig}_C(A|_C) \leq \mathrm{Sig}_C(B|_C)$ pointwise (Def. 165).

Remark 1973. *It is worth pausing over the meaning of the context machinery, because it is easy to be hypnotized by the notation. A context $C \in \mathrm{Ctx}$ should be read as a disciplined way of asking* which aspects of an entity we are currently attending to *(Hyperseed-Concept 86). The map $\mathrm{asp}_C : U \to U_C$ is then a kind of "lens" or "projection": given an entity $x \in U$, the symbol $x|_C$ means "x as seen through context C". The order $C \preceq D$ says that D is a* refinement *of C (more detailed, less coarse), and the map $\pi_{D\to C} : U_D \to U_C$ is the disciplined act of* forgetting detail *when passing from D back to C. The coherence equation $\mathrm{asp}_C = \pi_{D\to C} \circ \mathrm{asp}_D$ is precisely the statement that "extracting the coarse aspect directly" equals "extracting a finer aspect and then forgetting". This style of contextualization is central in the Hyperseed ontology presentation [1].*

Remark 1974. *Two further pieces of notation carry much of the weight in later lemmas. First, V is not merely an ordered set but a complete lattice: the phrase "joins exist" will repeatedly mean that for* any *family of intensities $\{v_i\} \subseteq V$ there is a least upper bound $\bigvee_i v_i \in V$. Second, $\mathrm{Sig}_C(X) : B_C \to V$ is best read as a finite "feature vector" (indexed by the basis patterns B_C), recording how intensely each basis pattern is present in X in aspect C (Hyperseed-Concept 130). Strong inheritance $\mathrm{Sig}_C(A|_C) \leq \mathrm{Sig}_C(B|_C)$ is then simply* coordinatewise domination*: every basis pattern appears in A no more strongly than it appears in B (Hyperseed-Concept* **??***). The quantale-based treatment of graded structure and evidence connects to the broader discussion of quantalic semantics in [3].*

Remark 1975. *A useful way to keep the arrows straight is to read U_C as an "observation space" associated to C. If one informally thinks of an entity $x \in U$ as having many potentially relevant degrees of freedom, then $x|_C \in U_C$ packages exactly those degrees of freedom that are expressible (or admissible) under C. Refinement $C \preceq D$ can then be interpreted as saying that D supports* more discriminations *than C: distinct elements of U_D may become identified after applying $\pi_{D\to C}$, because the coarser context is unable (or unwilling) to represent the difference. In many applications, one additionally expects the projection maps to compose as expected, i.e. for $C \preceq D \preceq E$ one has $\pi_{E\to C} = \pi_{D\to C} \circ \pi_{E\to D}$; when available, this expresses the idea that "forgetting in stages" is equivalent to "forgetting at once". Even when such compositionality is taken as background structure rather than foreground notation, it explains why the poset language is natural: contexts behave like levels of description ordered by informational content.*

Remark 1976. *The finiteness of the basis B_C is conceptually important even when it is not technically essential for a given lemma. It means that $\mathrm{Sig}_C(X)$ can be manipulated like an honest finite vector of evidence values, so pointwise comparisons, finite joins, and coordinatewise bounds are all concrete operations rather than schematic ones. In particular, the pointwise order on signatures is itself a complete lattice order inherited from V: for signatures $s, t : B_C \to V$ one has $s \leq t$ iff $s(P) \leq t(P)$ for all $P \in B_C$, and joins/meets are computed coordinatewise. This makes strong inheritance behave like the ordinary preorder on feature vectors used in many representation-learning settings, with the difference that the codomain V is allowed to carry non-Boolean and non-numeric evidence structure (as provided by the quantale apparatus). Viewed this way, strong inheritance is immediately reflexive and transitive at each fixed context C, since it is just the inherited preorder from the product order on V^{B_C}.*

Remark 1977. *Although the definition of $\mathrm{Sig}_C(X)$ is stated at a fixed context C, the refinement maps suggest a natural way to relate representations across contexts: if $C \preceq D$, then $x|_D$ contains at least as much descriptive material as $x|_C$, and $\pi_{D\to C}(x|_D) = x|_C$ ensures that any statement formulated purely in the coarser aspect is invariant under passage to the finer one. Later helper theorems will implicitly exploit this invariance pattern: one proves an inequality or entailment at a refined level D and then uses $\pi_{D\to C}$ (together with the coherence equation) to conclude a corresponding statement at the coarser level C. This is one of the main technical reasons to insist on explicit aspect maps rather than treating "context" as informal prose.*

35.1 System graphs and inter-production

Lemma 111 (No dead-end processes in inter-producing systems)**.** *Let $S = (P, E)$ be a system graph (Def. 156). If a node $p \in P$ lies on a directed cycle, then p has at least one incoming edge and at least one outgoing edge. Consequently, if S is inter-producing (every node lies on a directed cycle), then every node has in-degree ≥ 1 and out-degree ≥ 1.*

Remark 1978. *This lemma says that "being part of a genuine feedback loop" excludes isolation. A directed cycle is the graph-theoretic shadow of a process of mutual enabling: if p participates in a cycle, something leads into it and something proceeds out of it, so p cannot be a terminal dead-end nor a pure source. In inter-producing systems (every node is on some cycle),* every *process is both supported by others and supports others—a minimal formal trace of autocatalytic organization (Hyperseed-Concept 61). In the broader narrative about pattern webs and self-sustaining process networks, this is one of the simplest invariants one can prove; compare the general pattern-web viewpoint in [5].*

A small but useful clarification is that the statement is purely graph-theoretic*: it does not assume any additional algebraic structure on processes, nor any notion of quantitative flow. The conclusion only uses the existence of a cycle edge immediately "before" and "after" p along some directed cycle. In particular, even if p has many other incident edges (extra inputs/outputs), cycle membership already forces at least one of each direction. This is why the conclusion is phrased as a lower bound on in-degree and out-degree rather than an exact characterization.*

Note also that the lemma accommodates degenerate cycles when the underlying definition allows them. For instance, if there is a self-loop edge $(p, p) \in E$, then p lies on a directed cycle of length 1, and the same edge simultaneously contributes an incoming and an outgoing edge at p (so the conclusion still holds). Likewise, if the formalism allows multiple edges, then "at least one" should be read in the multigraph sense: there exists at least one directed edge with head p and at least one directed edge with tail p.

Conceptually, this lemma is the minimum consistency requirement for the slogan "inter-producing": if every node lies on a directed cycle, then there are no sinks (out-degree 0) and no sources (in-degree 0). This is weaker than strong connectivity of the whole graph (the graph may decompose into multiple cyclic components), but it is stronger than merely requiring that each node is reachable from itself by some trivial path: it enforces a nontrivial *return via directed edges.*

Sketch. On a directed cycle containing p, there is an edge entering p from the previous node and an edge leaving p to the next node. More explicitly, if the cycle is written as a sequence of vertices

$$p_0 \to p_1 \to \cdots \to p_{k-1} \to p_k = p_0,$$

and if $p = p_i$ for some i, then the edge $p_{i-1} \to p_i$ (indices modulo k) witnesses an incoming edge to p and the edge $p_i \to p_{i+1}$ witnesses an outgoing edge from p. Thus $\deg^-(p) \geq 1$ and $\deg^+(p) \geq 1$.

The "consequently" clause follows immediately by applying the same argument to each node when every node lies on some directed cycle. □

Remark 1979. Proof sketch. *The strategy is to unpack the definition of "directed cycle": it is literally a closed chain of directed edges. Any node on such a chain has a predecessor (giving an incoming edge) and a successor (giving an outgoing edge). The "consequently" part then just applies this fact to every node when the system is inter-producing.* □

The key step is that cycle membership is local*: to know degrees at p you only need the two adjacent edges of the cycle at p. Geometrically, picture tracing the arrows around the loop: you must enter p and you must leave p in order to keep moving and return.*

One can also rephrase the lemma in terms of the absence of one-way "boundary" processes. If we interpret edges as immediate enabling relations between processes, then a sink process would "consume" enabling without enabling anything in return, and a source process would "enable" without being enabled. The lemma shows that inter-production forbids both extremes, guaranteeing that each process is embedded in at least one immediate two-sided dependency pattern (incoming and outgoing). This does not yet guarantee global resilience or closure under perturbations, but it is the first necessary graph condition one checks before asking stronger questions (e.g. about strongly connected components, minimal feedback vertex sets, or the existence of larger autocatalytic subsets in the sense of 61).

Finally, the lemma is often used contrapositive-style: if a node has in-degree 0 or out-degree 0, then it cannot lie on any directed cycle, hence the system cannot be inter-producing. In practice, this gives a quick obstruction test when analyzing candidate system graphs.

35.2 Contexts, aspects, and contextualization

Lemma 112 (Aspect coherence under refinement)**.** *If $C \preceq D$, then for any $x \in U$,*

$$\pi_{D\to C}(x|_D) = x|_C.$$

Equivalently, extracting a refined aspect and then forgetting is the same as extracting the coarse aspect.

Remark 1980. *This is the formal expression of a commonplace methodological constraint: "if you look at something in high resolution and then blur it, you should get what you would have seen if you had looked in low resolution from the start." The equation $\pi_{D\to C}(x|_D) = x|_C$ is exactly the commutativity that makes refinement coherent rather than arbitrary. It is also what allows one to compare observations made in different contexts without treating them as incommensurable (Hyperseed-Concept 86). In particular, the lemma should be read as a* compatibility condition *between two kinds of operations: (i) changing the observational granularity (moving from C to D) and (ii) forgetting detail (moving back from D to C). If this compatibility failed, then the very meaning of "the aspect of x in context C" would depend on which refined context one passed through on the way to C, and the poset structure on contexts would not behave like a genuine refinement relation.*

Sketch. Immediate from $\mathrm{asp}_C = \pi_{D\to C} \circ \mathrm{asp}_D$ (Def. 159). Concretely, evaluate both sides at $x \in U$ and then unfold the notation $x|_C := \mathrm{asp}_C(x)$ and $x|_D := \mathrm{asp}_D(x)$. □

Remark 1981. Proof sketch. *One simply substitutes the definition $x|_D = \mathrm{asp}_D(x)$ and then applies the coherence axiom for* asp *and π.* □

The proof works because Def. 159 already encodes the intended semantics: $\pi_{D\to C}$ is defined *to be the map that makes the aspect extractions commute. Visually, one has a commutative triangle $U \xrightarrow{\mathrm{asp}_D} U_D \xrightarrow{\pi_{D\to C}} U_C$ and $U \xrightarrow{\mathrm{asp}_C} U_C$, and the lemma is merely the pointwise commutativity of that triangle. An equivalent way to read the same triangle is as a "change of coordinates" principle: U_D may carry strictly more information than U_C, but $\pi_{D\to C}$ provides the canonical comparison map, so that any statement about $x|_C$ can be checked either directly in U_C or indirectly via U_D without ambiguity. This is the minimal categorical content needed later when one composes several refinements $C \preceq D \preceq E$ and wants the resulting forgetful map $\pi_{E\to C}$ to behave consistently with $\pi_{E\to D}$ and $\pi_{D\to C}$.*

Lemma 113 (Contextualized groupings commute with forgetting)**.** *Let $G \subseteq U$ be a grouping (Def. 160). If $C \preceq D$, then*

$$\pi_{D\to C}(G|_D) = G|_C,$$

where $\pi_{D\to C}$ is applied elementwise to the set $G|_D \subseteq U_D$.

Remark 1982. *A grouping G is just a set of entities, but contextualization turns it into a set of* aspects *(Hyperseed-Concept* **??***). The lemma says that, just as individual aspect extraction commutes with forgetting (Lemma 112), the same remains true for a whole set: "contextualize in the refined context and then forget" equals "contextualize directly in the coarse context". This matters because many constructions in perception and representation concern sets (clusters, categories, collections of candidate referents) rather than single entities. Note that the statement is not merely about inclusions but about equality of the resulting contextualized collections: no element appears or disappears depending on whether one contextualizes before or after forgetting. At the level of methodology, this expresses that one can form a hypothesis class G at the "world" level U and then pass to any context without worrying that the bookkeeping depends on an arbitrary choice of intermediate refinements.*

Sketch. By definition $G|_D = \{x|_D : x \in G\}$ and $G|_C = \{x|_C : x \in G\}$. Apply Lemma 112 elementwise. Equivalently, show mutual inclusion by taking an arbitrary member of one side, rewriting it as $\pi_{D\to C}(x|_D)$ for some $x \in G$, and then identifying it with $x|_C$. □

Remark 1983. Proof sketch. *Rewrite both sides as sets defined by comprehension, then use Lemma 112 for each element $x \in G$ to identify the images.* □

The key step is that $\pi_{D\to C}$ is being applied elementwise, so set equality reduces to pointwise equality of members. Geometrically, imagine a cloud of points G in U; projecting the cloud into U_D and then further into U_C yields the same cloud in U_C as projecting directly. One can also view the lemma as the statement that the operation $(-)|_C$ behaves functorially on inclusions of contexts: it respects the refinement maps in the sense that the diagram of sets

$$G \subseteq U, \qquad G|_D \subseteq U_D, \qquad G|_C \subseteq U_C$$

commutes with the corresponding aspect-extraction and forgetting maps. This seemingly small observation is what later permits one to define context-dependent predicates or measures on groupings (e.g. "similarity" or "coherence" computed in U_C) without having to distinguish the route taken to arrive at U_C.

Lemma 114 (Monotonicity of contextualization)**.** *If $G \subseteq H \subseteq U$, then for all contexts C,*

$$G|_C \subseteq H|_C.$$

Remark 1984. *This monotonicity lemma is a sanity condition: if one collection is contained in another before contextualization, it remains contained after contextualization. It is formally trivial but conceptually important, because it means contextualization does not create spurious "new members"; it only changes the* view *of existing ones. In later reasoning, it permits order-theoretic arguments (inclusions, refinements) to pass cleanly through* $(-)|_C$ *(Hyperseed-Concept 86 and* **??***). A useful way to internalize the statement is: contextualization is an* order-preserving *map from* $\mathcal{P}(U)$ *to* $\mathcal{P}(U_C)$*. Thus, any reasoning step of the form "restrict to a smaller candidate set" remains valid after passing to any context* C*.*

Sketch. Apply asp_C elementwise to the inclusion $G \subseteq H$. More explicitly, if $y \in G|_C$ then $y = \mathrm{asp}_C(x)$ for some $x \in G$; since $x \in H$ as well, it follows that $y \in H|_C$. ☐

Remark 1985. Proof sketch. *Take any* $y \in G|_C$*. Then* $y = x|_C$ *for some* $x \in G$*. Since* $G \subseteq H$*, we also have* $x \in H$*, hence* $y \in H|_C$*.* ☐

The proof works because $G|_C$ *is defined as an image of* G *under* asp_C*. Images of subsets under a function are always subsets of the corresponding images. It is worth noting what is* not *claimed: one does not generally have* $G|_C = H|_C$ *when* $G \subseteq H$*, since distinct entities in* H *may collapse to the same aspect in context* C *(many-to-one* asp_C*), but the inclusion remains valid regardless of such collapses. This is precisely the kind of monotonicity one needs when later taking unions, intersections, or iterative refinements of candidate sets and then transporting them across contexts.*

35.3 Recognition, registration, and perception

Lemma 115 (Supremum of learned intensities exists)**.** *Fix a context/aspect* C *and a pattern recognition process* Y *aimed at* X *in aspect* C *(Def. 158), witnessed by a nonempty* $P_{X,C} \subseteq P_C$*. For each* $P \in P_{X,C}$*, the set* $\{\mathrm{Int}_{Y,t}(P) : t \in T\}$ *has a join (supremum) in* V*:*

$$\mathrm{Int}_Y^{\infty}(P) := \bigvee_{t \in T} \mathrm{Int}_{Y,t}(P) \ \in V.$$

Moreover, by alignment, for all relevant t*,*

$$\mathrm{Int}_Y^{\infty}(P) \ \leq \ \bigvee_{t \in T} \mathrm{Int}_{X,t}(P),$$

and if $\mathrm{Int}_{X,t}(P)$ *is constant in* t *then* $\mathrm{Int}_Y^{\infty}(P) \leq \mathrm{Int}_X(P)$*.*

Remark 1986. *A recognition process* Y *(Hyperseed-Concept 151) produces a time-indexed family of intensities* $\mathrm{Int}_{Y,t}(P)$ *measuring how strongly* Y *has come to "have" pattern* P *by time* t*. The first part of the lemma guarantees that we can speak coherently about a limiting or saturated intensity* $\mathrm{Int}_Y^{\infty}(P)$ *obtained by taking the join over time. This is not a probabilistic limit but an order-theoretic one: it is simply the least upper bound of everything* Y *ever reaches. The only real hypothesis needed is that* V *is a complete lattice. In particular, no assumption is made that* $t \mapsto \mathrm{Int}_{Y,t}(P)$ *is monotone, convergent, or even continuous in any analytic sense:* $\bigvee_{t \in T}$ *exists regardless, and is meaningful precisely because it records the best attainment of* Y *across the entire history* T*. If one prefers a concrete picture, in the common case* $T = \mathbb{N}$ *and* $V = [0,1]$ *with the usual order,* $\mathrm{Int}_Y^{\infty}(P)$ *is just* $\sup_{t \in \mathbb{N}} \mathrm{Int}_{Y,t}(P)$*, i.e. the maximum recognition strength achieved in the limit (whether or not it stabilizes). The requirement that* $P_{X,C}$ *be nonempty is part of the usual "aimed at" condition: the claim is not that* Y *learns arbitrary* $P \in P_C$*, but that for every pattern* P *that witnesses the aiming relationship, a well-defined "eventual" intensity can be formed.*

Remark 1987. *The second part says that learning cannot outrun its target: alignment bounds Y's intensity by X's intensity, pointwise in time. Thus the join over t for Y is bounded by the join over t for X. In the special case where X's intensity is time-invariant, we recover the intuitive statement that "the learner's eventual recognition strength cannot exceed the source's actual strength". This sort of pattern-centered view of learning and recognition is consonant with the pattern/emergence framework of [5]. One can also view the inequality as a minimal "soundness" condition for recognition: whatever internal degrees of pattern-presence Y develops must remain compatible with the external (or target) degrees of pattern-presence attributed to X in the same context. Even when $\mathrm{Int}_{X,t}(P)$ varies with t (e.g. due to changing illumination, occlusion, or context drift), the bound by $\bigvee_t \mathrm{Int}_{X,t}(P)$ says that Y's best-ever performance is still constrained by the best-ever availability of the pattern in X.*

Sketch. V is a complete lattice, so joins of subsets exist. Alignment gives $\mathrm{Int}_{Y,t}(P) \leq \mathrm{Int}_{X,t}(P)$ pointwise in t; taking joins over t preserves $\leq$. In more detail: $\mathrm{Int}_Y^\infty(P)$ is, by definition, an upper bound of $\{\mathrm{Int}_{Y,t}(P)\}_t$, and it is the *least* such upper bound; since each $\mathrm{Int}_{X,t}(P)$ is an upper bound for the corresponding $\mathrm{Int}_{Y,t}(P)$, the join over t of the X-intensities is an upper bound for the entire Y-family, and thus dominates the least upper bound $\mathrm{Int}_Y^\infty(P)$. □

Remark 1988. Proof sketch. *Existence of $\mathrm{Int}_Y^\infty(P)$ is pure lattice theory: completeness of $(V, \leq)$ provides $\bigvee_{t\in T}$. The inequality is proved by monotonicity of joins: if every term of one family is $\leq$ the corresponding term of another, then the join of the first family is $\leq$ the join of the second.* □

The key step is the passage "pointwise in t" $\Rightarrow$ "after taking $\bigvee_t$". This is exactly the order-theoretic analogue of taking suprema of bounded functions. If one pictures intensities as heights, alignment says Y's graph lies below X's graph; taking the supremum simply picks the highest point reached, and a curve lying below another cannot have a higher supremum. A useful corollary intuition is that $\mathrm{Int}_Y^\infty(P)$ is insensitive to transient lapses: if Y briefly attains a high recognition of P and later forgets, the join still remembers that achievement. Conversely, if one wants a notion of "stable" recognition, one would replace $\bigvee_t$ by a different temporal aggregate (e.g. an infimum over a tail, or a meet over a window); the present lemma isolates the simplest saturation operator compatible with the lattice structure.

Lemma 116 (Recognition plus threshold crossing yields registration)**.** *Fix a context C and an equivalence relation $\sim_C$ on U_C as in Def. 161. Assume Y is a pattern recognition process aimed at A in aspect C (Def. 158), and suppose there exists a time t and a pattern $P \in P_C$ such that:*

$$\mathrm{Int}_{Y,t}(P) \not\leq \theta \quad \textit{and} \quad \mathrm{Ref}_C(P, A|_C) \textit{ is nontrivial.}$$

Then Y registers A at time t in context C (Def. 161).

Remark 1989. *Registration (Hyperseed-Concept 153) is the moment where recognition ceases to be merely internal fluctuation and becomes an "event" in the ontology of the mind: something has been recognized* as *something, in a way stable enough to pass a threshold. The lemma states that two ingredients suffice: (i) some pattern intensity crosses the required threshold, and (ii) that pattern actually refers to (an aspect of) A. The equivalence relation $\sim_C$ (Hyperseed-Concept* **??***) encodes the idea that, within a context, registration is typically defined only up to some appropriate sameness criterion. It is worth emphasizing that the threshold clause $\mathrm{Int}_{Y,t}(P) \not\leq \theta$ is phrased in the ambient order on V, so it covers both numerical thresholds (e.g. $\mathrm{Int}_{Y,t}(P) > \theta$ when V is linearly ordered) and more general partially ordered notions (e.g. multiple independent resources or evidential dimensions). Likewise, "nontrivial" reference is the minimal semantic anchor needed to rule out degenerate patterns that do not actually pick out $A|_C$ in the referential scheme of the context.*

Remark 1990. *One can also read the statement as a bridge principle between three layers: recognition-strength (*Int*), semantic anchoring (*Ref_C*), and the discrete predicate "registers". In semiotic terms, it tells us that intensity without reference is blind, and reference without intensity is idle. This fits naturally with the representation-centric approach to cognition emphasized in [19]. The role of Def. 161 is to package this bridge into an existential condition, so the lemma is intentionally "low-tech": it does not require uniqueness of P, agreement among multiple patterns, or any temporal persistence beyond the single witnessing time t. Such stronger notions (e.g. robust registration, consensus registration, or temporally sustained registration) can be layered on top by strengthening the hypotheses, while the present lemma isolates the minimal trigger condition that turns graded recognition into an ontological registration event.*

Sketch. Take $A' = A$ in Def. 161; since $\sim_C$ is an equivalence relation it is reflexive, so $A|_C \sim_C A|_C$. The given P witnesses that $A|_C$ "becomes a pattern in Y by time t" with nontrivial reference. Concretely, Def. 161 asks for (a) an aspect-representative A' equivalent to A in context C, and (b) some pattern whose intensity exceeds the threshold and whose reference connects it to $A'|_C$; both are supplied immediately by setting $A' = A$ and using the hypothesized P, t. $\square$

Remark 1991. Proof sketch. *The proof is a direct match to the definition of registration: choose the trivial representative $A' = A$ of the equivalence class, use reflexivity of $\sim_C$ to satisfy the "same-aspect" clause, and use the given pattern P to satisfy the threshold-and-reference clause.* $\square$

The essential move is recognizing that registration is defined existentially: it suffices to provide one witnessing pattern P and one time t. Conceptually, the reflexivity of $\sim_C$ guarantees that "registering A" is always allowed to mean "registering something equivalent to A"; choosing A itself is then the simplest witness. This also highlights why the lemma does not require any global relationship between P and the entire witness-set $P_{A,C}$ from Def. 158: registration can occur via any pattern in the ambient repertoire P_C so long as it both (i) achieves sufficient intensity in Y at some moment and (ii) carries nontrivial reference to the relevant aspect. In applications, P might be a low-level feature (edge, tone, token) or a high-level gestalt, and the equivalence relation $\sim_C$ allows the registration event to ignore inessential variation (e.g. viewpoint changes) while still counting as "the same" registered target within C.

Lemma 117 (Perception yields both registration and a referential token)**.** *If a mind M perceives A at time t in context C (Def. 163), then:*

1. *M registers A at time t in context C (Prop. 16), and*
2. *there exists a representation token $R \in \mathcal{R}$ such that $\mathrm{Ref}_C(R, A|_C)$ is nontrivial (Def. 163, item (2)).*

In other words, the act of perception simultaneously yields an "internal trace" (a concrete token in the representational economy) and an "external tie" (the referential relation to the contextualized target $A|_C$). Note that the lemma only asserts existence of such a token R; it does not require that the token be unique, stable across time, or the only token produced by M while perceiving A.

Remark 1992. *Perception (Hyperseed-Concept 134) is stronger than mere registration: it asserts not only that the mind has crossed some recognitional threshold, but also that it has produced a* token *that refers to what was perceived. This lemma simply unpacks that dual nature. It is philosophically important because it makes perception inherently two-sided: an outward pole (anchoring to $A|_C$ via* Ref_C*) and an inward pole (a concrete representational act inside M) (Hyperseed-Concept 111 and 157).*

The context index is essential here: the lemma is not claiming that R refers to A "simpliciter," but rather to A as it is taken under *the contextual restrictions encoded by C, i.e. to $A|_C$. This matches ordinary cases in which the very same underlying object or event can be perceived under different contexts (lighting, task, background assumptions), yielding different referential successes or failures even when registration occurs.*

Sketch. Item (1) is Prop. 16. Item (2) is the second clause of Def. 163.

To make the dependency explicit: the hypothesis "M perceives A at time t in context C" activates the framework's perception conditions. Prop. 16 handles the registration component (ensuring that perception is not merely representational activity detached from recognition), while Def. 163 contributes the existence of at least one token $R \in \mathcal{R}$ whose contextual reference to $A|_C$ is nontrivial (ensuring that perception is not merely registration without any representational anchoring). $\square$

Remark 1993. Proof sketch. *No new argument is required: (1) appeals to an already-proved proposition connecting perception to registration, while (2) is literally one of the defining conjuncts of perception.* $\square$

The key "why" is definitional: the framework is designed so that perception is registration plus representational anchoring*. Visually, one can imagine perception as drawing an arrow from an internal token R to an external (contextualized) referent $A|_C$, while also recording that this arrow was formed at time t by the mind M.*

The modifier "nontrivial" in $\mathrm{Ref}_C(R, A|_C)$ *matters: it rules out degenerate or empty "reference" relations that would not genuinely connect the token to its target in context. Thus, the lemma can be read as providing a minimal witness to perceptual directedness: whenever perception occurs, there is at least one concrete representational item R for which the referential link to $A|_C$ is substantive rather than vacuous.*

Finally, observe what the lemma does not *claim. It does not assert that R is accurate, veridical, or exhaustive with respect to $A|_C$; it only extracts the structural consequence that perception, as defined, has both (i) a recognition/registration aspect and (ii) a token-based referential aspect. This is useful downstream because later arguments can quantify over such a witness R whenever they assume perception, without having to re-unpack the definition each time.*

35.4 Representation, inheritance, and semiotic modes

Lemma 118 (Inheritance is a preorder)**.** *Fix a context C. The strong pattern inheritance relation*

$$A \sqsubseteq_C B \quad :\Longleftrightarrow \quad \mathrm{Sig}_C(A|_C) \leq \mathrm{Sig}_C(B|_C)$$

is reflexive and transitive on U (Def. 165).

Remark 1994. *Here the role of the fixed context C is to select (i) the restriction operation $(-)|_C$ and (ii) the associated signature map Sig_C that lands in a space of V-valued feature assignments over the basis B_C. Thus $\sqsubseteq_C$ is not a global inheritance claim about A and B* simpliciter*, but a comparison of their signatures* as seen through *the aspect C. In particular, two entities may be incomparable in one context (because different features are salient or ordered differently) while being comparable in another; the lemma only asserts that, once C is fixed, the induced relation has the minimal stability properties expected of an order-like comparison.*

Remark 1995. *The point of this lemma is not that it is difficult, but that it stabilizes the logical status of inheritance: it behaves like a "$\leq$" relation. Reflexivity says every entity inherits from* *itself; transitivity says inheritance chains compose. Once we know inheritance is a preorder, we are justified in importing the familiar style of order-theoretic reasoning: one can speak of "more inherited" and "less inherited" in a context without demanding antisymmetry. This is exactly the right level of generality for pattern signatures, where distinct entities may share identical signatures in a fixed basis. (Hyperseed-Concept* **??** *and 130.)*

Sketch. Reflexive because $\leq$ is reflexive. Transitive because $\leq$ is transitive pointwise. More explicitly: reflexivity follows from $\mathrm{Sig}_C(A|_C) \leq \mathrm{Sig}_C(A|_C)$ in the codomain order. For transitivity, if $A \sqsubseteq_C B$ and $B \sqsubseteq_C D$, then $\mathrm{Sig}_C(A|_C) \leq \mathrm{Sig}_C(B|_C) \leq \mathrm{Sig}_C(D|_C)$, hence $\mathrm{Sig}_C(A|_C) \leq \mathrm{Sig}_C(D|_C)$. □

Remark 1996. Proof sketch. *Inheritance is defined by pointwise $\leq$ between functions $B_C \to V$. Pointwise order is always a preorder because the codomain order is.* □

The key step is that order on signatures is inherited *from order on V in the strict logical sense: once we have a preorder on values, the induced preorder on V-valued feature vectors is automatic. Geometrically, one may picture signatures as points in a V-valued hyper-rectangle; $\leq$ is then the standard product order. In particular, the reason antisymmetry is not required is that two distinct entities $A \neq B$ may satisfy $\mathrm{Sig}_C(A|_C) = \mathrm{Sig}_C(B|_C)$, yielding both $A \sqsubseteq_C B$ and $B \sqsubseteq_C A$ without forcing identity. This suggests the familiar construction of the induced equivalence relation $A \sim_C B$ iff $A \sqsubseteq_C B$ and $B \sqsubseteq_C A$, whose quotient is a genuine partial order on $U/{\sim_C}$ whenever such identification is useful.*

Theorem 53 (Representation becomes a preorder under mild reference axioms)**.** *Fix a context C and define representation-in-C as in Def. 166.*

Assume:

1. *(Reference reflexivity) $\mathrm{Ref}_C(A, A|_C)$ is nontrivial for all A, and*
2. *(Reference compositionality) if $\mathrm{Ref}_C(A, B|_C)$ and $\mathrm{Ref}_C(B, C|_C)$ are nontrivial, then $\mathrm{Ref}_C(A, C|_C)$ is nontrivial (the assumption used in Prop. 17).*

Then "A represents B in aspect C" is reflexive and transitive, hence a preorder.

Remark 1997. *The nontriviality language is intended to rule out degenerate reference relations that hold only vacuously (e.g. a bottom/zero witness that would make every putative reference arrow informationally empty). Under Def. 166, representation-in-C is a conjunction of an "internal" constraint (inheritance of signatures in C) and an "external" constraint (the existence of a suitable Ref_C witness). The theorem isolates exactly the two closure conditions needed for the reference component to match the closure conditions that inheritance already enjoys by Lemma 118. Without (1), even self-representation can fail because reference may not supply an identity-like arrow; without (2), chaining can fail because reference may not survive passage through intermediate carriers.*

Remark 1998. *The theorem says that representation, when defined via (i) pattern-signature inheritance and (ii) a nontrivial reference relation, has the same compositional stability as inheritance: it becomes a preorder. In plain terms, if representational tokens can always refer to themselves (reflexivity), and if reference arrows can be composed (compositionality), then "represents" is closed under identity and chaining. This is important because it allows one to build multi-step representational pipelines without losing well-formedness: if A represents B and B represents D, then A represents D. Such chaining is a minimal formal analogue of how complex cognitive systems stabilize symbol grounding across intermediate encodings [19]. One may also read this as an abstract guarantee that a representational system can be layered: intermediate stages may alter format or medium, but (under the axioms) cannot break representational reachability.*

Remark 1999. *The connection to Lemma 118 is structural: representation-in-C contains inheritance-in-C as one of its conjunctive ingredients (Def. 166), so the preorder behavior of inheritance is half the story. The other half is reference composition, which is the semantic counterpart of pattern-composition: it is the requirement that meaning does not evaporate when passing through intermediaries (Hyperseed-Concept 157 and 152). In categorical terms (purely as intuition, not as added structure), inheritance supplies an order-enrichment on "carriers" while* Ref_C *supplies the arrows that must compose; the theorem states that the combined relation inherits the same closure properties when both components admit identity and composition.*

Sketch. Reflexive: by (1) and Lemma 118 (inheritance reflexivity). Transitive: Prop. 17 gives transitivity provided reference composes as in (2), and inheritance composes by transitivity of $\leq$. Concretely, for reflexivity fix A and note $A \sqsubseteq_C A$ holds by Lemma 118, while $\mathrm{Ref}_C(A, A|_C)$ is nontrivial by (1); together these satisfy Def. 166. For transitivity, assume A represents B in C and B represents D in C; then $A \sqsubseteq_C B$ and $B \sqsubseteq_C D$ imply $A \sqsubseteq_C D$, and the corresponding nontrivial reference witnesses compose by (2) (as packaged in Prop. 17), yielding that A represents D in C. □

Remark 2000. Proof sketch. *To prove reflexivity, show each entity represents itself: inheritance is reflexive and reference is assumed reflexive. To prove transitivity, use Prop. 17 for the reference part (composition of* Ref_C*) and use transitivity of pointwise* $\leq$ *for the signature part.* □

The key steps mirror the two components of representation: the "intensional" ordering given by signatures and the "extensional" anchoring given by reference. A helpful picture is to imagine two parallel structures that must both compose: a ladder of pattern-strength comparisons and a chain of reference arrows. Only when both ladders can be climbed consistently does representation become preorder-like. Equivalently, representation-in-C fails to be transitive precisely when either the signature comparison breaks (which cannot happen because $\leq$ *is transitive) or the reference chain breaks (which is why axiom (2) is the essential additional assumption beyond Lemma 118).*

Corollary 15 (Semiotic modes inherit representation rules)**.** *For any* C*:*

1. *If* A *is an icon for* B*, then* A *represents* B *in some* $C \in \mathrm{Ctx}_{\mathrm{sens}}$*.*

2. *If* A *is an index for* B*, then* A *represents* B *in some* $C \in \mathrm{Ctx}_{\mathrm{st}}$*.*

3. *If* A *is a symbol for* B*, then* A *represents* B *in some* $C \in \mathrm{Ctx}_{\mathrm{rel}}$*, and* A *participates in a combinational system in that relational aspect (Def. 170).*

In particular, any inference rule proved for representation-in-C (e.g. transitivity under reference composition) specializes to icons/indices/symbols when the witnessing context is held fixed.

Remark 2001. *This corollary is best read as a transport principle: once icon/index/symbolhood is defined by* exhibiting *representation in some appropriate class of contexts, any property of representation that is stated* uniformly in the chosen C *immediately yields a corresponding property for the semiotic mode. The clauses* $C \in \mathrm{Ctx}_{\mathrm{sens}}, \mathrm{Ctx}_{\mathrm{st}}, \mathrm{Ctx}_{\mathrm{rel}}$ *can be understood as restricting which features and reference mechanisms are allowed to witness the representational link: icons privilege sensory similarity structure, indices privilege spatiotemporal or causal linkage, and symbols privilege relational/combinational structure. Accordingly, when a proof about representation uses only preorder reasoning (reflexivity/transitivity) and not any special facts about the particular* C*, the same proof schema applies verbatim after selecting the witnessing context supplied by the mode definition.*

Remark 2002. *This corollary places the classic Peircean triad—icon, index, symbol—into the present context-sensitive formalism (Hyperseed-Concept* **??**, **??**, *184; see also [14]). Each semiotic mode is defined by the existence of a context of an appropriate kind (sensory, spatiotemporal, relational) in which representation holds. The payoff is that general logical facts about representation can be "inherited" by each mode: once a mode is recognized as a specialization of representation, theorems about representation become reusable lemmas about icons, indices, and symbols. In particular, the mode labels do not add new inferential machinery on top of representation; they constrain* where *(i.e., in what kind of C) the representing relation is witnessed. Thus, any proposition of the form "for all contexts C of type τ, if Represents$_C(\cdot,\cdot)$ then ..." can be immediately re-read as a proposition about the corresponding semiotic mode by supplying $\tau \in \{\mathrm{sens}, \mathrm{st}, \mathrm{rel}\}$. Conversely, when one proves an icon/index/symbol claim, one should expect to uncover an underlying witness-context proof obligation, since the semantics is deliberately packaged as an existential over contexts.*

Sketch. Unfold Defs. 168–170: each mode is defined as existence of a context of the appropriate kind such that representation holds. More explicitly, the argument is a definitional expansion: $\mathrm{Icon}(A, B)$ means $\exists C \in \mathrm{Ctx}_{\mathrm{sens}}$ with $\mathrm{Represents}_C(A, B)$, $\mathrm{Index}(A, B)$ means $\exists C \in \mathrm{Ctx}_{\mathrm{st}}$ with $\mathrm{Represents}_C(A, B)$, and $\mathrm{Symbol}(A, B)$ means $\exists C \in \mathrm{Ctx}_{\mathrm{rel}}$ with $\mathrm{Represents}_C(A, B)$ together with whatever additional participation condition Def. 170 imposes. Once these abbreviations are expanded, any statement relating the semiotic predicates reduces to a statement about $\mathrm{Represents}_C$ and the type membership of the witnessing context. □

Remark 2003. Proof sketch. *Each item is immediate by definition: "icon" means "represents in some sensory context", etc. The final sentence then follows by fixing the witnessing context and reusing any rule about Represents$_C$.* □

The key idea is definitional reduction: the semiotic predicates are not new primitive relations here; they are existential wrappers around representation. This makes the theory modular: one proves algebraic properties once (for representation) and then applies them across semiotic categories. A useful way to read this is that the icon/index/symbol predicates function as typed interfaces to the same core relation: theorems about composition, monotonicity, invariance under appropriate renamings, or compatibility with other operators can be imported provided they are stated at the level of Represents$_C$. At the same time, because the wrapper is existential, there is a subtle but important methodological point: existence of some *witnessing context generally does not support chaining across steps unless one controls (or reuses) the witness; this motivates later context-fixed variants of familiar representation properties.*

Lemma 119 (Context-fixed transitivity for icon/index/symbol)**.** *Fix a context C and suppose reference composes in C as in Prop. 17. If $C \in \mathrm{Ctx}_{\mathrm{sens}}$ and A represents B in C and B represents D in C, then A is an icon for D. Analogous statements hold for $C \in \mathrm{Ctx}_{\mathrm{st}}$ (index) and $C \in \mathrm{Ctx}_{\mathrm{rel}}$ (symbol), with the additional symbolic combinational participation requirement inherited from Def. 170. In the symbolic case, the point is that one does not merely need a relational context in which $\mathrm{Represents}_C(A, D)$ holds, but also that A participates in the relevant combinational/structural constraints (as stipulated in Def. 170)* in that same context *C; the lemma asserts that this extra requirement is preserved when the premises already satisfy it within C.*

Remark 2004. *Where Corollary 15 moves from semiotic modes to representation, this lemma goes back in the other direction, but crucially* keeps the witnessing context fixed. *It says: if the chain of representation happens entirely within a sensory context C, then the composite relation is still sensory and therefore is an icon relation. This is precisely how one avoids the ambiguity of "A is an icon for B in some context" when reasoning over multiple steps: one chooses a context and remains* *within it. This context-fixing is the mathematical counterpart of a disciplined interpretive stance: do not silently change what you mean by "similar" or "connected" mid-argument. Technically, the lemma isolates the inference pattern that is* not *licensed by the bare existential wrappers: from Icon(A, B) and Icon(B, D) one cannot in general infer Icon(A, D), since the two icon premises may be witnessed by different sensory contexts. By contrast, if both premises are witnessed by the* same *C (as the lemma assumes), then Prop. 17 allows one to compose the underlying Represents$_C$ facts, after which the same C can be reused as witness for the semiotic conclusion. This is also why the lemma is stated with an explicit hypothesis about composition in C: it cleanly separates (i) general properties of Represents$_C$ as an internal relation from (ii) the external typing constraint $C \in \mathrm{Ctx}_{\mathrm{sens}}/\mathrm{Ctx}_{\mathrm{st}}/\mathrm{Ctx}_{\mathrm{rel}}$ that turns a plain representation into a specific semiotic mode.*

Sketch. Prop. 17 yields that A represents D in C. Then apply the corresponding semiotic definition (Def. 168/169/170) using the same witnessing C. Concretely: from $\mathrm{Represents}_C(A, B)$ and $\mathrm{Represents}_C(B, D)$, Prop. 17 gives $\mathrm{Represents}_C(A, D)$, and since C is already assumed to lie in the appropriate context class (sensory, spatiotemporal, or relational), one may discharge the existential in the corresponding definition by choosing this very C. In the symbolic case, one also checks (by the "inherited" clause from Def. 170) that whatever combinational participation condition is required is satisfied in C for the composed representation; this is why the lemma explicitly notes that the additional condition is part of what is transported through the same fixed witness. □

Remark 2005. Proof sketch. *First compose representations using Prop. 17 to get Represents$_C(A, D)$. Then, since C is of the appropriate type (sens/st/rel), the corresponding semiotic predicate holds with witness C.* □

The key step is that the semiotic definitions are existential: to prove Icon(A, D) it suffices to exhibit one *sensory context where representation holds. Here the context is already given, so the entire argument is a two-line "closure under composition" result. It is worth emphasizing that the closure here is* conditional *on staying inside a fixed C: the proof does not attempt to combine different witnessing contexts, nor does it require any global closure property of* $\mathrm{Ctx}_{\mathrm{sens}}$ *under some operation. In this sense the lemma is a controlled way of obtaining transitivity-like reasoning for semiotic predicates without strengthening them into universally quantified notions (which would change their intended meaning). The same pattern reappears whenever one wants to transport other representation-theoretic properties (e.g., invariance under isomorphisms of contexts, or compatibility with additional structure on C): one proves the property for Represents$_C$ and then rewraps it by reusing the same witness context.*

35.5 Soggy predicates as algebraic evidence aggregators

Setup (Defs. 171–172). Let X be a universe of discourse. Each observation $o \in O$ supplies an evidence map $e_o : X \to [0, 1]^2$, and weights $w_o \geq 0$ satisfy $\sum_{o \in O} w_o = 1$. Define the soggy predicate $F : X \to [0, 1]^2$ by $F(x) := \sum_o w_o e_o(x)$ componentwise.

Remark 2006. *The word "soggy" is a reminder that, unlike a crisp predicate, we allow evidence to have two components: support and counter-support. Thus $e_o(x) = (e_o^+(x), e_o^-(x)) \in [0, 1]^2$ can represent simultaneous partial reasons for and against x satisfying the predicate, as in paraconsistent and related multi-valued logics (Hyperseed-Concept 172; see [23, 24]). The aggregation $F(x) = \sum_o w_o e_o(x)$ is then a deliberately plain operation: a convex combination done componentwise. This simplicity is a virtue: it lets us prove robust inequalities about what aggregation can and cannot do without committing to a more baroque fusion rule.*

Remark 2007. *Notation check: the sum* $\sum_o w_o e_o(x)$ *is a vector sum in* $\mathbb{R}^2$ *(here constrained to* $[0,1]^2$*), so explicitly* $F^+(x) = \sum_o w_o e_o^+(x)$ *and* $F^-(x) = \sum_o w_o e_o^-(x)$*. The weights are nonnegative and sum to* 1*, making each component of* $F(x)$ *a convex combination of the corresponding components of* $e_o(x)$*.*

Lemma 120 (Convex bounds)**.** *For every* $x \in X$ *and each component* $\pm$*,*

$$\min_{o\in O} e_o^{\pm}(x) \;\leq\; F^{\pm}(x) \;\leq\; \max_{o\in O} e_o^{\pm}(x).$$

Remark 2008. *This lemma asserts that aggregation by weighted averaging cannot create component-values outside the observed range: the aggregated support* $F^+(x)$ *lies between the smallest observed support and the largest observed support, and likewise for the negative component. This is the sense in which the aggregation is "conservative": it does not invent extreme evidence; it interpolates among what the observations already provide.*

Sketch. Each component $F^{\pm}(x)$ is a convex combination of the scalars $e_o^{\pm}(x)$. □

Remark 2009. Proof sketch. *Convex combinations lie in the convex hull of their inputs; in one dimension this hull is exactly the interval* [min, max]. □

The key reason is nonnegativity of weights and $\sum_o w_o = 1$*. Geometrically, for a fixed* x *and fixed sign* $\pm$*, the values* $\{e_o^{\pm}(x)\}$ *are points on the real line, and* $F^{\pm}(x)$ *is their barycenter, which must lie between the extreme points.*

Lemma 121 (Monotonicity and commutation with p-bit negation)**.**

1. *(Monotonicity) If* $e'_o(x) \geq e_o(x)$ *componentwise for all* o, x*, then the induced* F' *satisfies* $F'(x) \geq F(x)$ *for all* x*.*
2. *(Negation commutes) Let* $\neg(a^+, a^-) := (a^-, a^+)$*. Define* $(\neg F)(x) := \neg(F(x))$ *and* $(\neg e_o)(x) := \neg(e_o(x))$*. Then*

$$\neg F \;=\; \sum_{o\in O} w_o\,(\neg e_o),$$

i.e. averaging and negation commute.

Remark 2010. *Part (1) is a monotonicity principle: if every observation is improved (never decreases support nor counter-support), then the aggregated predicate improves. This matters for comparative statics: it allows one to reason about how changes in sensors, data quality, or preprocessing flow through to* F*.*

Part (2) expresses a basic symmetry of this evidence representation: negation is just swapping the two components, and swapping commutes with averaging. This is one of the algebraic conveniences of the $[0,1]^2$ *"p-bit" style evidence used throughout the framework (cf. [23, 24]).*

Sketch. (1) Weighted sums preserve componentwise inequalities when weights are nonnegative. (2) Swap-of-components is linear: swapping after summing equals summing after swapping. □

Remark 2011. Proof sketch. *For (1), apply the inequality* $e'_o(x) \geq e_o(x)$ *componentwise, multiply by* $w_o \geq 0$*, and sum over* o*. For (2), write out both sides componentwise and use distributivity of summation over addition; swapping the* $+$ *and* $-$ *coordinates is an affine linear map.* □

The key step in (1) is the nonnegativity of weights: with negative weights the inequality could reverse. Visually, in (2), negation is a reflection across the diagonal in the (a^+, a^-) *plane, and averaging is taking a weighted centroid; reflecting a centroid equals taking the centroid of the reflected points.*

Lemma 122 (Conflict can increase under aggregation; determinacy can decrease)**.** *For $v = (v^+, v^-) \in [0,1]^2$, define*

$$\mathrm{conf}(v) := \min(v^+, v^-), \qquad \det(v) := \max(v^+, v^-).$$

Then for each $x \in X$,

$$\mathrm{conf}(F(x)) \;\geq\; \sum_{o \in O} w_o \,\mathrm{conf}(e_o(x)), \qquad \det(F(x)) \;\leq\; \sum_{o \in O} w_o \det(e_o(x)).$$

Thus disagreement across observations can raise "both-sides present" evidence, while the maximum certainty can shrink under averaging.

Remark 2012. *This lemma captures a subtle but practically important phenomenon in paraconsistent-style aggregation (Hyperseed-Concept 172). Suppose some observations strongly support x while others strongly oppose x. When we average these, we may end up with* both *moderately high support and moderately high counter-support, thereby increasing* $\mathrm{conf}(F(x)) = \min(F^+(x), F^-(x))$. *At the same time, the strongest one-sided certainty (*$\det = \max$*) can be diluted, because averaging pulls extremes toward the center. In an epistemic register: aggregation can make one more aware of conflict, and less confident in any single verdict. This is a mathematically clean articulation of why multi-source fusion does not necessarily "resolve" disagreement; it may instead faithfully represent it (cf. [24] for related motivations). In particular, because* conf *is* increasing *in each coordinate (holding the other fixed), any aggregation rule that can raise both F^+ and F^- simultaneously (as averaging can, when sources disagree) will typically increase* conf *even if each individual $e_o(x)$ is itself nearly one-sided. A concrete extreme illustrates the effect: if two equally weighted sources report $(e_1^+(x), e_1^-(x)) = (1, 0)$ and $(e_2^+(x), e_2^-(x)) = (0, 1)$, then $F(x) = (\frac{1}{2}, \frac{1}{2})$, so* $\mathrm{conf}(F(x)) = \frac{1}{2}$ *even though* $\mathrm{conf}(e_1(x)) = \mathrm{conf}(e_2(x)) = 0$, *while* $\det(F(x)) = \frac{1}{2}$ *is strictly smaller than* $\det(e_1(x)) = \det(e_2(x)) = 1$. *Thus, "more data" can mathematically force the representation to move from certainty-with-no-conflict at the source level to moderate-certainty-with-explicit-conflict at the fused level.*

Sketch. Let $A := \sum_o w_o e_o^+(x)$ and $B := \sum_o w_o e_o^-(x)$. For each o, $\min(e_o^+, e_o^-) \leq e_o^+$ and $\min(e_o^+, e_o^-) \leq e_o^-$, hence $\sum_o w_o \min(e_o^+, e_o^-) \leq A$ and also $\leq B$, so it is $\leq \min(A, B) = \mathrm{conf}(F(x))$. Similarly, $e_o^+ \leq \max(e_o^+, e_o^-)$ and $e_o^- \leq \max(e_o^+, e_o^-)$, so $A \leq \sum_o w_o \max(e_o^+, e_o^-)$ and $B \leq \sum_o w_o \max(e_o^+, e_o^-)$, hence $\max(A, B) = \det(F(x))$ is $\leq$ that same sum. The only structural properties used here are: (i) coordinatewise bounds of min / max, (ii) nonnegativity of the weights (so inequalities are preserved when multiplying by w_o), and (iii) additivity of sums (so inequalities are preserved under aggregation). In particular, no special smoothness or probabilistic assumptions are required beyond treating $F^{\pm}(x)$ as convex combinations of the corresponding $e_o^{\pm}(x)$. □

Remark 2013. Proof sketch. *Use the elementary inequalities* $\min(u, v) \leq u, v$ *and* $u, v \leq \max(u, v)$, *then multiply by w_o and sum. Finally, identify A and B with $F^+(x)$ and $F^-(x)$ and apply the definitions of* conf *and* det. □

The key device is bounding a min or max by each coordinate and then using linearity of weighted sums. Geometrically, $\mathrm{conf}(v)$ *is the distance of v from the boundary of the unit square in the direction of the diagonal: increasing both coordinates increases* conf. *Averaging conflicting points can move a point toward the diagonal, raising* $\min(v^+, v^-)$ *even if no individual observation had high conflict. Equivalently, level sets of* $\mathrm{conf}(v) = c$ *are the "L-shaped" regions $\{v^+ \geq c,\; v^- \geq c\}$; fusion that increases both coordinates (even slightly) can jump v into a higher-conflict region. By contrast,* $\det(v) = \max(v^+, v^-)$ *has level sets given by the union $\{v^+ \geq c\} \cup \{v^- \geq c\}$, and averaging* *tends to move points away from the corners* $(1, 0)$ *and* $(0, 1)$ *toward the interior, which decreases* $\max(v^+, v^-)$*. This makes precise the intuition that convex aggregation is "conflict-revealing" and "extremum-smoothing" at the same time.*

Corollary 16 (Complementary evidence collapses to ordinary fuzzy/probabilistic semantics)**.** *If each observation is complementary, i.e.* $e_o^-(x) = 1 - e_o^+(x)$ *for all* o, x*, then* $F^-(x) = 1 - F^+(x)$*. Hence* $F^+(x)$ *alone can be treated as a standard fuzzy membership/probability-of-satisfaction (Prop. 18). Moreover, under this complementarity constraint,* $\mathrm{conf}(F(x)) = \min(F^+(x), 1-F^+(x))$ *and* $\det(F(x)) = \max(F^+(x), 1 - F^+(x))$ *become functions of the single scalar* $F^+(x)$*, so the two-dimensional bookkeeping carries no additional degrees of freedom beyond the usual* $[0, 1]$ *semantics.*

Remark 2014. *This corollary identifies a special case in which the two-component evidence reduces to a single scalar: if every observation is internally consistent in the strong sense that negative evidence is exactly the complement of positive evidence, then the aggregation preserves this complementarity. In that regime, the machinery of soggy predicates is conservative: it does not conflict with, but rather extends, ordinary fuzzy or probabilistic semantics. The value of the general* $[0, 1]^2$ *framework is precisely that it can represent and propagate non-complementary (hence potentially conflicting) evidence when complementarity is not warranted [23]. One can also read the corollary as identifying the "classical submanifold" of the evidence square: complementary points form an affine line, so restricting to that line recovers the familiar one-parameter uncertainty calculus. Departures from the line quantify precisely how much "extra information" is present in the paraconsistent register, namely the possibility that both* F^+ *and* F^- *are simultaneously large (or simultaneously small) in a way that cannot be represented by a single probability-like number.*

Sketch. Componentwise computation (as in Prop. 18): linearity of sums and $\sum_o w_o = 1$. One may also emphasize that the complement map $t \mapsto 1 - t$ is affine, so it commutes with convex combination: applying the complement before averaging yields the same result as averaging first and then applying the complement. This is exactly the algebraic content of the identity $F^-(x) = 1 - F^+(x)$. □

Remark 2015. Proof sketch. *Compute* $F^-(x) = \sum_o w_o e_o^-(x) = \sum_o w_o(1 - e_o^+(x)) = 1 - \sum_o w_o e_o^+(x) = 1 - F^+(x)$. □

The only ingredient beyond algebra is the normalization $\sum_o w_o = 1$*, which ensures that averaging respects affine constraints like* $a^- = 1 - a^+$*. Geometrically, complementary evidence lives on the diagonal line* $v^- = 1-v^+$ *in the square; convex combinations of points on a line remain on the line. Said differently, the set* $\{(t, 1 - t) : t \in [0, 1]\}$ *is convex, and the aggregator* F *(being a weighted average) maps convex sets to themselves; thus complementarity is an invariant of the fusion rule. When the complementarity assumption fails for some sources, the fused point can leave this diagonal and thereby record non-classical evidence patterns, e.g. "both support and opposition are high" (a point near* $(1, 1)$*) or "both are low" (a point near* $(0, 0)$*), neither of which can be encoded by a single scalar* $t \in [0, 1]$.

35.6 Engine-friendly rule schemata (optional)

Useful forward rules. The following are direct corollaries of the definitions and lemmas above: In this subsection, "engine-friendly" means that the conclusions are stated in a way that supports monotone, forward-chaining saturation: once a premise is established, the corresponding consequences can be asserted and then used as premises for later rules without revisiting the original derivation. In particular, the rules below are formulated to expose (i) witness objects (such as a reference relation R) and (ii) simple numeric or preorder constraints (such as Sig_C-inequalities) that are cheap to store and combine.

- $\mathrm{Perceives}(M, A, t, C) \to \mathrm{Registers}(M, A, t, C)$ and $\exists R : \mathrm{Ref}_C(R, A|_C)$ nontrivial (Lemma 117). Here the first conjunct isolates the "recording" component of perception, while the existential conjunct isolates a concrete referential witness in context C. For implementations, the existential can be treated as a witness-producing rule (e.g., Skolemization to a fresh symbol $R_{M,A,t,C}$) so that later rules that require a specific $\mathrm{Ref}_C(\cdot, \cdot)$ instance can fire. The qualifier "nontrivial" is included to rule out degenerate witnesses (e.g., empty or information-free reference), ensuring that the obtained R actually supports downstream representational consequences rather than merely satisfying an existence claim vacuously.

- $\mathrm{Represents}_C(A, B) \to \mathrm{Sig}_C(A|_C) \leq \mathrm{Sig}_C(B|_C)$ (Def. 166). This inequality is useful operationally because it turns a qualitative claim (representation) into an order constraint that can be accumulated across many facts. In contexts where Sig_C is computable or estimable, this rule provides a quick consistency check: asserting $\mathrm{Represents}_C(A, B)$ commits one to the corresponding Sig_C-monotonicity, and contradictions can be detected by numeric reasoning even when the underlying cognitive predicates are opaque. Conceptually, it expresses that B is at least as "significant" (in C) as A when A is taken to represent B in that same context.

- $\mathrm{Icon}(A, B)$ or $\mathrm{Index}(A, B)$ or $\mathrm{Symbol}(A, B) \to \mathrm{Represents}_C(A, B)$ for some witnessing C of the appropriate kind (Cor. 15). This schema makes explicit the intended workflow: semiotic classifications (iconic, indexical, symbolic) are treated as higher-level tags, and the engine immediately lowers them to the uniform predicate $\mathrm{Represents}_C$ that participates in the order-theoretic machinery. The phrase "for some witnessing C" matters because the semiotic relation may determine constraints on C (e.g., what counts as an "appropriate kind" of context), and these constraints can be carried along as side-conditions or additional facts about C for later use. Practically, one may implement this as producing an existential context parameter when the context is not already fixed, or as selecting among already-known candidate contexts when the problem is posed with a finite menu of contexts.

- (Reference composes in C) and $\mathrm{Represents}_C(A, B)$ and $\mathrm{Represents}_C(B, D) \to \mathrm{Represents}_C(A, D)$ (Prop. 17 / Thm. 53). This is the main chaining rule: it allows an engine to close representational paths transitively, provided the ambient hypothesis that reference composes in the same context C is available. The explicit mention of the compositionality premise is important in mechanized settings, because it prevents accidental cross-context chaining: the rule is safe only when all representation claims live in the same C and the corresponding Ref_C structure supports composition. From an algorithmic perspective, this is the familiar "transitive closure" operation, but guarded by contextual coherence; from a conceptual perspective, it is the reason the earlier development yields a preorder-like structure on representational claims.

A typical forward-chaining use pattern is: first derive Registers-facts and reference witnesses from Perceives-facts; next normalize any semiotic predicates (Icon/Index/Symbol) into context-indexed representation claims; then saturate the resulting $\mathrm{Represents}_C$-graph using the compositional/transitive rule; and finally propagate any derived Sig_C constraints to support grading, comparison, or inconsistency detection. Stated differently, these schemata serve as a bridge between the "qualitative" front-end vocabulary and the "quantitative/order" back-end invariants.

Remark 2016. *These rule schemata are the "computational surface" of the preceding order-theoretic development. They are intentionally forward-chaining: each rule takes a high-level cognitive predicate (Perceives, Represents, Icon/Index/Symbol) and yields consequences that can be cached and reused by an inference engine. Philosophically, one may view them as a modest attempt to reconcile the fluidity of cognitive notions with the austerity of formal entailment: the semantics remain contextual and graded (via V, Sig_C, Ref_C), yet the inference skeleton is crisp. This style of extracting operational rules from abstract cognitive definitions aligns with the systems-engineering orientation of [19]. Moreover, because the conclusions are phrased as either (i) additional atomic predicates (e.g., Registers$(\cdot)$, Represents$_C(\cdot)$) or (ii) simple order constraints (e.g., $\leq$ on Sig_C-values), the resulting knowledge base admits efficient indexing and incremental maintenance under new observations. In particular, the separation between contextual parameters (the explicit C) and content parameters (the objects A, B, D) is deliberate: it encourages implementations to treat C as a key for partitioning the fact store, thereby avoiding unsound interactions between incompatible contexts while still allowing within-context closure. Finally, the explicit witness patterns (e.g., $\exists R : \mathrm{Ref}_C(R, A|_C)$) indicate where the formalism expects concrete supporting structure; in engines that track justifications, these witnesses can be stored as provenance artifacts that explain why a given Represents$_C$ fact was derived.*

36 Helper theorems for prediction, attraction, causality, and control

36.1 Standing notation

Fix an observer/context O, event-type set $\mathcal{E}$, proto-time carrier $(T, \prec)$, and lag windows Δ, Δ'. Let $\mathrm{Cond}_{O,\Delta} : \mathcal{E} \times \mathcal{E} \to [0,1]^2$ be the predictive conditional operator. Let $\pi : [0,1]^2 \to [0,1]$ be the plausibility projection

$$\pi(p, q) = \frac{1 + p - q}{2}.$$

Define predictive implication strength and predictive attraction by

$$PImp_{O,\Delta}(A, B) = \pi(\mathrm{Cond}_{O,\Delta}(B \mid A)), \qquad PAtt_{O,\Delta}(A, B) = PImp_{O,\Delta}(A, B) - PImp_{O,\Delta}(\neg A, B).$$

Define attraction by

$$\mathrm{Att}_{O,\Delta}(A, B) = \pi(\mathrm{Cond}_{O,\Delta}(B \mid A)) - \pi(\mathrm{Cond}_{O,\Delta}(B \mid \neg A)).$$

For a p-bit $v = (v^+, v^-) \in [0,1]^2$, write $\mathrm{bias}(v) = v^+ - v^-$. Write $\mathbf{1}[A \prec B] \in \{0,1\}$ for the temporal-precedence indicator used in causal implication.

The standing notation above is designed to keep track of three layers at once: (i) what is being talked about ($\mathcal{E}$ and proto-time), (ii) what information is available and how it is aggregated (the context O and the windows Δ, Δ'), and (iii) how that aggregated information is converted into scalar quantities that behave like the "strength" of a predictive relationship (the projection π and the derived operators $PImp$, $PAtt$, Att). The presence of two lag windows is intentional: typically one uses Δ for the primary predictive relation (e.g. A in a past window and B in a future window) and Δ' for auxiliary constructions (e.g. counterfactual or intervention-style comparisons, or multi-step chaining where the window of admissible temporal offsets changes).

Note that π is an affine map in the difference $(p - q)$, and it can be rewritten directly in terms of the bias of a p-bit. Indeed, for any $v = (v^+, v^-)$,

$$\pi(v) = \frac{1 + v^+ - v^-}{2} = \frac{1 + \mathrm{bias}(v)}{2}.$$

Thus $\pi(v) = \frac{1}{2}$ corresponds to zero net bias, $\pi(v) \to 1$ corresponds to maximally positive bias, and $\pi(v) \to 0$ corresponds to maximally negative bias. In particular, the projection does not measure the *amount* of evidence (since $(0.6, 0.0)$ and $(1.0, 0.4)$ have the same bias) but rather the net direction of support after positive and negative channels have been compared.

The two definitions $PAtt_{O,\Delta}$ and $\mathrm{Att}_{O,\Delta}$ are algebraically identical given the definition of $PImp_{O,\Delta}$, but it is useful to keep both names in view because they emphasize different conceptual decompositions. Writing attraction as $PAtt$ highlights the intermediate quantity "predictive implication strength" and makes later manipulations resemble standard calculi that first define implication-like quantities and then define contrasts. Writing attraction as Att emphasizes that it is fundamentally a *difference of plausibilities* between the A-conditioned and $\neg A$-conditioned regimes. In many arguments below, what matters is precisely this contrast structure: attraction is high when A shifts plausibility for B upward relative to its negation, and negative when A shifts plausibility downward.

Because $\pi(\cdot) \in [0, 1]$, the attraction quantities satisfy immediate range bounds:

$$PAtt_{O,\Delta}(A, B) \in [-1, 1], \qquad \mathrm{Att}_{O,\Delta}(A, B) \in [-1, 1].$$

Moreover, the sign of attraction encodes a qualitative direction: $\mathrm{Att}_{O,\Delta}(A, B) > 0$ indicates that, in the observer/context O and relative to the lag window Δ, conditioning on A makes B more plausible than conditioning on $\neg A$; $\mathrm{Att}_{O,\Delta}(A, B) < 0$ indicates a repulsive or inhibitory predictive relationship in the same comparative sense. This sign convention will later interact naturally with control notions, where one is interested not only in whether A predicts B, but whether steering toward A (rather than toward $\neg A$) tends to steer B up or down.

The precedence gate $\mathbf{1}[A \prec B]$ is introduced at the notation stage because it is the minimal device needed to separate mere predictive association from temporally directed causal implication. In proto-time settings where $\prec$ may be partial (e.g. concurrency, branching, or incomparable events), the indicator makes explicit that causal implication is only asserted (or only assigned a nonzero score) when a suitable precedence relation holds. In later formulas, such indicators serve as "hard" directionality constraints even when the underlying evidence and conditionals are "soft" and graded.

Remark 2017. *This section is, in effect, a small calculus for turning (possibly inconsistent) evidence about event-types into graded notions of prediction and control. The underlying philosophical move is to treat prediction not as a binary relation but as a quantity, and then to build more structured notions (attraction, causality, control) as derived quantities. In that sense it resembles the way one builds geometry from a metric: once a primitive numerical structure is fixed, many secondary concepts become algebraic corollaries.*

Remark 2018. *A few symbols deserve an explicit reading the first time through.*

- *O is an "observer/context": it determines what counts as an event-type, how evidence is gathered, and how conditionals are computed. This is aligned with the general contextual stance used throughout the document (compare the role of contexts in Section 13) and with a social-computational view of scientific inference [20].*

- *$\mathcal{E}$ is the set of event-types (not individual events). One may imagine $A, B \in \mathcal{E}$ as predicates or labels such as "rain" or "sensor_spike".*

- *$(T, \prec)$ is proto-time: $t \prec t'$ indicates temporal precedence without presuming a metric or linearity. This directly connects to the Hyperseed-Concept 142.*

- $\mathrm{Cond}_{O,\Delta}(B \mid A) \in [0,1]^2$ *is a p-bit (two-coordinate) conditional: its first coordinate v^+ and second coordinate v^- can be read as degrees of positive and negative support (or two-channel evidence), enabling paraconsistent bookkeeping [23, 24].*
- π *projects a p-bit to a single plausibility number in* $[0,1]$ *by comparing positive and negative support.*
- $\neg A$ *denotes the (event-type) negation used in the predictive attraction definitions.*
- $\mathbf{1}[A \prec B]$ *is the indicator that A precedes B in proto-time; it is used as a gate that enforces the temporal directionality characteristic of causation (Hyperseed-Concept 70).*

The definitions of predictive attraction and causal implication below are also closely aligned with the broader pattern-based account of prediction and emergence used elsewhere [5], and with the Hyperseed-Concept **??**.

Remark 2019. *It is helpful to keep in mind a few elementary properties of the plausibility projection π when reading later inequalities. Since $\pi(p,q) = \frac{1}{2} + \frac{1}{2}(p-q)$, it is monotone increasing in p and monotone decreasing in q, and it treats (p,q) and $(p+\epsilon, q+\epsilon)$ differently only insofar as the* difference *changes. In particular, $\pi(p,p) = \frac{1}{2}$ for any p, so perfectly balanced positive/negative support is always mapped to a neutral plausibility regardless of magnitude. This is one of the intended "paraconsistent" features: accumulating equally strong evidence on both sides yields uncertainty rather than collapse.*

Remark 2020. *A simple sanity-check example for the p-bit conventions: if $\mathrm{Cond}_{O,\Delta}(B \mid A) = (0.9, 0.1)$, then positive evidence outweighs negative, yielding high plausibility. If instead it is $(0.9, 0.9)$, this represents strong evidence for and against simultaneously (a paraconsistent situation), and the projection π will return a middling value, reflecting that the net bias is near zero even though the magnitude of evidence is large.*

Remark 2021. *A complementary sanity-check for attraction: suppose $\mathrm{Cond}_{O,\Delta}(B \mid A) = (0.8, 0.2)$ while $\mathrm{Cond}_{O,\Delta}(B \mid \neg A) = (0.4, 0.3)$. Then $\pi(\mathrm{Cond}(B \mid A)) = \frac{1+0.8-0.2}{2} = 0.8$ and $\pi(\mathrm{Cond}(B \mid \neg A)) = \frac{1+0.4-0.3}{2} = 0.55$, giving $\mathrm{Att}_{O,\Delta}(A,B) = 0.25$. The positive value indicates that A provides a net uplift in plausibility for B relative to $\neg A$, even though $\mathrm{Cond}(B \mid \neg A)$ may itself still have more positive than negative support. Conversely, if $\mathrm{Cond}_{O,\Delta}(B \mid \neg A)$ had the larger bias, attraction would be negative, capturing a net inhibitory relationship.*

36.2 Projection lemmas

Lemma HT14.1 (Plausibility as bias projection). For any $v \in [0,1]^2$, $\pi(v) = \frac{1}{2}(1 + \mathrm{bias}(v))$.

Remark 2022. *Intuitively, Lemma HT14.1 says: "plausibility" is just an affine rescaling of the* bias *between the positive and negative channels. Bias $\mathrm{bias}(v) = v^+ - v^-$ lives in $[-1,1]$, and π simply maps this symmetric interval to $[0,1]$ by shifting and halving. Philosophically, this is a decision to interpret plausibility as a* net leaning *rather than a total amount of evidence; the latter would require a different projection. This choice is well-suited to later algebraic manipulations because affine maps preserve order and convexity. In particular, the extreme states $(v^+, v^-) = (1,0)$ and $(0,1)$ have biases $+1$ and -1, and therefore map to plausibilities $\pi = 1$ and $\pi = 0$ respectively, while equal-channel states $v^+ = v^-$ have $\mathrm{bias}(v) = 0$ and hence $\pi(v) = \frac{1}{2}$, corresponding to a neutral midpoint. The formula can also be read backwards as $\mathrm{bias}(v) = 2\pi(v) - 1$, so π and* bias *carry exactly the same one-dimensional information, merely expressed in different coordinate conventions.*

Proof sketch. Expand $\pi(v^+, v^-) = \frac{1}{2}(1 + v^+ - v^-)$ and recognize $v^+ - v^- = \mathrm{bias}(v)$.

Remark 2023. Proof sketch. *The strategy is purely definitional: substitute the definitions and then factor out the quantity already named* $\mathrm{bias}(v)$*. The key step works because π was designed to be linear in each coordinate, so the difference $v^+ - v^-$ appears explicitly. A helpful visual is to think of v as a point in the unit square:* $\mathrm{bias}(v)$ *measures displacement along the $(1, -1)$ diagonal, and π renormalizes this diagonal coordinate into $[0, 1]$. Equivalently, the level sets of π (and of* bias*) are lines of the form $v^+ - v^- =$ constant, which run parallel to the $(1, 1)$ diagonal; moving in the $(1, 1)$ direction changes the* amount *in both channels but leaves the net leaning unchanged. This makes explicit why π should be viewed as a projection: it discards the orthogonal "total evidence" direction and retains only the signed contrast between channels, with the additive $\frac{1}{2}$ encoding the convention that zero bias corresponds to midpoint plausibility.* □

Lemma HT14.2 (Consistent-case recovery). If $v = (p, 1 - p)$ (consistent evidence), then $\pi(v) = p$.

Remark 2024. *This lemma verifies that π behaves like ordinary probability in the "consistent" submanifold where positive and negative coordinates sum to 1. In other words, when the two-channel evidence state is merely a redundant encoding of a single $p \in [0, 1]$, the projection returns p exactly. This matters because it ensures compatibility with standard probabilistic intuitions when inconsistency is absent, while still allowing the larger $[0, 1]^2$ space when inconsistency is present [23]. Geometrically, the consistent submanifold is the line segment $v^+ + v^- = 1$ joining $(0, 1)$ to $(1, 0)$, and Lemma HT14.2 states that π restricts on this segment to the identity coordinate $p = v^+$. Thus π can be seen as an extension of the usual identification of a Bernoulli parameter with its "positive mass," while permitting off-manifold points with $v^+ + v^- \neq 1$ to represent various forms of inconsistency, redundancy, or undercommitment.*

Proof sketch. $\pi(p, 1 - p) = \frac{1}{2}(1 + p - (1 - p)) = p$.

Remark 2025. Proof sketch. *The proof is a one-line substitution. The conceptual reason it works is that the constraint $v^- = 1 - v^+$ makes* $\mathrm{bias}(v) = 2p - 1$*, and the affine mapping in Lemma HT14.1 exactly inverts that relation. Geometrically, the line $v^+ + v^- = 1$ is mapped isomorphically onto $[0, 1]$ by π. It is also helpful to note how the endpoints behave under this restriction: $p = 0$ gives $v = (0, 1)$ and hence $\pi = 0$, while $p = 1$ gives $v = (1, 0)$ and hence $\pi = 1$, so the entire segment is carried to $[0, 1]$ with no distortion. In later applications, this recovery property is what permits one to interpret π as a conservative generalization of probability: whenever evidence is internally consistent, the projection agrees exactly with the familiar scalar representation.* □

36.3 Attraction and predictive implication

Lemma HT14.3 (Attraction via biases).

$$\mathrm{Att}_{O,\Delta}(A, B) = \tfrac{1}{2}\Big(\mathrm{bias}(\mathrm{Cond}_{O,\Delta}(B \mid A)) - \mathrm{bias}(\mathrm{Cond}_{O,\Delta}(B \mid \neg A))\Big).$$

Remark 2026. *Attraction* $\mathrm{Att}_{O,\Delta}(A, B)$ *is meant to quantify how much the presence of A "pulls" toward B relative to the absence of A. Lemma HT14.3 states that this pull is exactly the* difference of biases *in the p-bit conditionals, up to the constant factor $1/2$ coming from the projection π. The philosophical point is that attraction depends not on absolute belief in B, but on a counterfactual contrast: A versus $\neg A$. In particular, the use of* $\mathrm{bias}(\mathrm{Cond}_{O,\Delta}(B \mid A))$ *isolates the* directional tilt *in the conditional plausibility, while discarding any symmetric or baseline component that would be shared by both A and $\neg A$. This is why attraction functions as a signed quantity: positive values indicate a shift toward B under A, whereas negative values indicate that conditioning on A shifts away from B compared to conditioning on $\neg A$. Conceptually, one can read the right-hand side as: "how much more biased toward B is the conditional world where A holds than the conditional world where A fails," and the $\frac{1}{2}$ factor reflects the specific normalization induced by π (so that attraction remains on the same scale used elsewhere in the framework).*

Proof sketch. Use $\mathrm{Att} = \pi(\mathrm{Cond}(B \mid A)) - \pi(\mathrm{Cond}(B \mid \neg A))$ and Lemma HT14.1; the constant $\frac{1}{2}$ terms cancel.

Remark 2027. Proof sketch. *The strategy is: rewrite each $\pi(\cdot)$ using Lemma HT14.1, then subtract. The cancellation of constants reflects that attraction is a* difference *measure: any baseline plausibility independent of A disappears. One may picture two arrows in evidence-space: the conditional on A and the conditional on $\neg A$; attraction measures the signed displacement between their bias coordinates. Put differently, the role of Lemma HT14.1 is to express π as an affine function of the bias, and attraction retains only the linear part because affine offsets vanish under subtraction. This is also the formal reason that attraction is insensitive to any uniform recalibration that would add the same constant to both $\pi(\mathrm{Cond}(B \mid A))$ and $\pi(\mathrm{Cond}(B \mid \neg A))$.* □

Lemma HT14.4 (Predictive attraction equals attraction).

$$PAtt_{O,\Delta}(A, B) = \mathrm{Att}_{O,\Delta}(A, B).$$

Remark 2028. *This lemma says that the two notational routes to "attraction" are the same: whether one defines attraction directly via $\pi(\mathrm{Cond}(\cdot \mid \cdot))$ or indirectly via predictive implication $PImp$, the resulting scalar is identical. This is important because later sections may prefer one viewpoint or the other: $PImp$ emphasizes implication-like reasoning, while* Att *emphasizes differential influence. The equality ensures there is no hidden divergence between the two perspectives. It also ensures that sign conventions are compatible: e.g., any interpretation stated in terms of $PImp$ comparisons immediately transfers to* Att *without additional assumptions. From a modeling standpoint, Lemma HT14.4 is a coherence condition: the "predictive" layer ($PImp$ and $PAtt$) is not an extra structure but a repackaging of the same underlying conditional plausibility operations.*

Proof sketch. By definition $PImp_{O,\Delta}(A, B) = \pi(\mathrm{Cond}_{O,\Delta}(B \mid A))$; substitute into $PAtt$.

Remark 2029. Proof sketch. *The proof is definition chasing. The key step works because $PAtt$ is defined as a difference of two $PImp$ terms, and each $PImp$ is just a $\pi \circ \mathrm{Cond}$ term. So $PAtt$ collapses to the already-given formula for* Att*. Conceptually, this lemma is a consistency check: we have not accidentally introduced two different "attraction" notions. In practice, this means computations can be organized flexibly: one may compute $PImp$ values first (perhaps because they are reported or estimated), and then obtain* Att *automatically by subtraction, or one may work directly with* Att *when only contrasts matter.* □

Lemma HT14.5 (Negation antisymmetry).

$$\mathrm{Att}_{O,\Delta}(\neg A, B) = -\mathrm{Att}_{O,\Delta}(A, B), \qquad PAtt_{O,\Delta}(\neg A, B) = -PAtt_{O,\Delta}(A, B).$$

Remark 2030. *Negation antisymmetry formalizes the idea that if A attracts B, then "not A" repels B by the same amount, because attraction is defined as a contrast between A and $\neg A$. This is not a general truth about all causal or statistical measures; it is a special property of this particular contrastive definition. It is useful because it reduces many calculations: once* $\mathrm{Att}(A, B)$ *is known,* $\mathrm{Att}(\neg A, B)$ *is immediate. It also clarifies how to read negative values:* $\mathrm{Att}(A, B) < 0$ *is equivalent to* $\mathrm{Att}(\neg A, B) > 0$*, so one may always shift perspective to a positive-attraction statement by negating the antecedent. In settings where A is itself a decision or intervention variable, this antisymmetry also encodes a form of "two-sided" interpretability: the framework treats A and $\neg A$ as the two endpoints of the same binary contrast, rather than as unrelated predictors.*

Proof sketch. Swap A and $\neg A$ in the definition of Att and use involutivity $\neg\neg A = A$.

Remark 2031. Proof sketch. *The strategy is to rewrite* $\mathrm{Att}(\neg A, B)$ *as* $\pi(\mathrm{Cond}(B \mid \neg A)) - \pi(\mathrm{Cond}(B \mid \neg\neg A))$ *and observe this is the negative of* $\pi(\mathrm{Cond}(B \mid A)) - \pi(\mathrm{Cond}(B \mid \neg A))$*. The involutivity step is the formal reason the subtraction flips sign. Visually: attraction is an oriented difference between two points; swapping their order reverses the orientation. The same reasoning applies verbatim to $PAtt$ because Lemma HT14.4 identifies it with* Att*, but it is often convenient to state both identities explicitly since later manipulations may start from either notation.* ☐

Corollary HT14.6 (Sign rules).

$$\mathrm{Att}_{O,\Delta}(A, B) > 0 \iff PImp_{O,\Delta}(A, B) > PImp_{O,\Delta}(\neg A, B),$$

and $\mathrm{Att}_{O,\Delta}(A, B) = 0$ iff the two predictive implication strengths coincide.

Remark 2032. *This corollary translates the numerical sign of attraction into a plain-language comparison: A attracts B exactly when B is more plausible under A than under $\neg A$. The zero case is equally meaningful: it indicates predictive indifference with respect to the A versus $\neg A$ contrast. Such sign rules are the workhorses of interpretation, because they tell you what to look for in data or simulation output when assessing whether A is a "positive predictor" of B in this framework (Hyperseed-Concept* **??***). In particular, the statement emphasizes that attraction is* ordinally *interpretable: to determine the sign, one only needs to compare the two $PImp$ values, without needing their absolute magnitudes. The strictness of the inequality also matters: small positive attraction corresponds to a mild preference for B under A, while large positive attraction indicates a strong separation between the two conditional plausibilities. Conversely, if $PImp_{O,\Delta}(A, B) < PImp_{O,\Delta}(\neg A, B)$, then A is (predictively) adverse to B in precisely the same contrastive sense.*

Proof sketch. Immediate from $\mathrm{Att} = PImp(A, B) - PImp(\neg A, B)$.

Remark 2033. Proof sketch. *The proof is the elementary algebra of differences: $x - y > 0$ iff $x > y$, and $x - y = 0$ iff $x = y$. The deeper point is that attraction is defined as a* relative *measure, so it is inherently about comparisons rather than absolute magnitudes. This is also why attraction can be robust to uniform shifts in the underlying plausibility representation: anything that affects both $PImp(A, B)$ and $PImp(\neg A, B)$ equally will not change* $\mathrm{Att}(A, B)$*, whereas any asymmetric change will be detected immediately via the sign rule.* ☐

Lemma HT14.7 (Boundedness of attraction).

$$\mathrm{Att}_{O,\Delta}(A,B) \in [-1,1].$$

Remark 2034. *Attraction is bounded because plausibilities are bounded. The lemma is a small but essential piece of hygiene: it ensures that later constructions (such as mapping attraction to* $[0,1]$ *via* σ*) are always well-defined. It is also a reminder that the attraction score is not an unnormalized "force"; it is already scaled to a unit interval of influence, aligning with the broader theme of working inside compact, order-theoretic structures. The extremal values have a clear meaning in this scaling:* $\mathrm{Att}(A,B) = 1$ *corresponds to the largest possible separation where* $PImp(A,B) = 1$ *and* $PImp(\neg A,B) = 0$*, while* $\mathrm{Att}(A,B) = -1$ *corresponds to the opposite separation. Thus, boundedness is not merely technical; it encodes the intended interpretation that attraction represents a normalized contrast between two conditional plausibilities.*

Proof sketch. Each $PImp$ term lies in $[0,1]$, hence their difference lies in $[-1,1]$.

Remark 2035. Proof sketch. *The proof uses the elementary fact that the difference of two numbers in* $[0,1]$ *lies in* $[-1,1]$*. The reason this works is precisely the choice of* $\pi : [0,1]^2 \to [0,1]$*. If a different projection were used, the bound would change accordingly. A geometric picture:* $PImp(A,B)$ *and* $PImp(\neg A,B)$ *are points on the unit interval; attraction is the signed distance between them. One can also view this as a Lipschitz-type stability statement: since both terms are individually bounded and attraction is their difference, attraction cannot blow up under any admissible conditioning scenario within the framework.* □

36.4 Sequential temporal composition

Define the p-bit valued predictive relation

$$R_{O,\Delta}(A,B) := \mathrm{Cond}_{O,\Delta}(B \mid A) \in [0,1]^2.$$

Define two-step composition by

$$(R_{O,\Delta} \circ R_{O,\Delta'})(A,C) = \bigoplus_{B\in\mathcal{E}} R_{O,\Delta}(A,B) \otimes R_{O,\Delta'}(B,C),$$

where $\oplus$ is join and $\otimes$ is the quantale tensor.

Remark 2036. *The expression "p-bit valued" is meant in the sense that* $\mathrm{Cond}_{O,\Delta}(B \mid A)$ *returns a structured truth/evidence value rather than a single scalar. The display* $\in [0,1]^2$ *should be read as indicating a typical concrete instance (two coordinated degrees, e.g. a pair capturing positive/negative support, or support/anti-support); the abstract statements below use only the induced order, the join* $\oplus$ *(supremum), and the tensor* $\otimes$ *(monoidal combination), so the same arguments go through for other p-bit carriers as long as they form the relevant quantale. In particular, the results do not depend on interpreting the components probabilistically; they depend only on the order-theoretic and monoidal structure used to aggregate and propagate evidence.*

Remark 2037. *Here the parameters* (O,Δ) *should be viewed as fixing a predictive context:* O *determines which observational regime (or dataset, or filtration of information) is being used, while* Δ *selects a temporal offset. Thus* $R_{O,\Delta}(A,B)$ *is intended to encode "how much* A *at time* t *supports (in the p-bit sense) the occurrence of* B *at time* $t+\Delta$*" relative to the observation scheme* O*. The composition below then corresponds to chaining two temporal offsets, e.g.* Δ *followed by* Δ'*, with* *an intermediate event-type B serving as a latent bridge between the start and end. This aligns the algebra with the intuitive picture of multi-step prediction in time-indexed systems even when the underlying logic of evidence is paraconsistent or multi-valued.*

Remark 2038. *Here $R_{O,\Delta}$ is being treated as a V-relation (a weighted, p-bit valued kernel) from $\mathcal{E}$ to $\mathcal{E}$, exactly in the sense used elsewhere in the quantale-relational parts of the document. The notation $\circ$ is thus a generalized matrix product: multiply along an intermediate index with $\otimes$, then aggregate over intermediates with $\oplus$. In ordinary probabilistic Markov chains one would sum products; here one takes a join of tensor-products in the p-bit quantale, which is designed to be monotone and to respect evidence aggregation (compare the evidence-state algebra viewpoint in Section 38, and paraconsistent motivation [24]).*

Remark 2039. *It can be helpful to keep in mind two parallel readings of the same formula. Algebraically, $(R_{O,\Delta} \circ R_{O,\Delta'})(A, C)$ is the (A, C)-entry of the composite kernel. Operationally, it is the strongest two-step support for C obtainable from A by ranging over all possible intermediate event-types $B \in \mathcal{E}$. The role of $\otimes$ is to combine (compose) the support along a fixed two-step path $A \to B \to C$, while the role of $\oplus$ is to take the supremum over competing intermediates, i.e. to perform an evidence aggregation that is explicitly designed not to require additivity or exclusivity assumptions among the different B.*

Remark 2040. *A concrete example: if $\mathcal{E} = \{A, B, C\}$, then $(R_{O,\Delta} \circ R_{O,\Delta'})(A, C)$ is the join of the three terms obtained by choosing the intermediate event-type to be A, B, or C. Lemma HT14.8 below formalizes the obvious fact that this join must be at least as large as any one chosen two-step path.*

Remark 2041. *In such finite examples one can also see the analogy with ordinary matrix multiplication explicitly: if we arrange the values $R_{O,\Delta}(x, y)$ in a matrix with rows indexed by x and columns by y, then the composite has entries obtained by taking, for each fixed (A, C), the $\oplus$-aggregate over the intermediate index B of the "products" $R_{O,\Delta}(A, B) \otimes R_{O,\Delta'}(B, C)$. The only change from classical linear algebra is that the scalar multiplication and addition are replaced by the quantale operations $\otimes$ and $\oplus$, and the ambient order replaces numerical comparison.*

Lemma HT14.8 (Witnessed two-step lower bound). For any fixed intermediate event type $B_0 \in \mathcal{E}$,

$$R_{O,\Delta}(A, B_0) \otimes R_{O,\Delta'}(B_0, C) \ \leq\ (R_{O,\Delta} \circ R_{O,\Delta'})(A, C).$$

Remark 2042. *This lemma says: if you can predict B_0 from A and then predict C from B_0, you obtain a particular two-step predictive support for C from A. The full two-step composition takes the* best *(in the $\oplus$-join sense) among all possible intermediates, so it must dominate the support coming from any specific intermediate. This is the order-theoretic analogue of the familiar inequality "a sum over all paths is at least one particular path," adapted to join-based aggregation.*

Remark 2043. *In a paraconsistent or multi-evidence setting, the point is not merely that "more paths give more mass" (as in classical probability), but that allowing additional intermediates can only increase the composite in the underlying order, because $\oplus$ is a supremum operation. Thus HT14.8 is the minimal guarantee that any explicitly exhibited intermediate B_0 yields a sound lower bound on the two-step prediction; it legitimizes "witness-based" reasoning where one proposes a concrete mediator and obtains a provable bound without needing to analyze all alternatives in $\mathcal{E}$.*

Proof sketch. The right-hand side is the join over all intermediates, hence dominates any particular summand.

Remark 2044. Proof sketch. *The proof is a one-step lattice argument: $\bigoplus_B$ is a supremum, so each term is $\leq$ the supremum. The key step works because $\oplus$ is the join in the underlying quantale order. A useful picture is to imagine all intermediates B as offering candidate "bridges" from A to C; the composition selects their supremal evidence, so any chosen bridge yields a lower bound.* □

Lemma HT14.9 (Monotonicity of sequential composition). If $R \leq R'$ pointwise and $S \leq S'$ pointwise (in the p-bit order), then

$$S \circ R \leq S' \circ R'.$$

Remark 2045. *Monotonicity expresses a fundamental stability property: improving the evidence in R and S cannot make the composed evidence worse. This is the algebraic form of a commonsense epistemic principle: if every one-step predictive estimate is strengthened (never weakened), then every two-step estimate computed from them should also be strengthened. Such monotonicity is indispensable for comparative statics arguments and for reasoning about learning dynamics, where estimates are refined over time.*

Remark 2046. *Note that the pointwise order assumption is essential: it asserts that for every ordered pair of event-types, the replacement relation provides at least as much evidence (in the quantale order) as the original. Under that hypothesis, the composite inequality follows because the composition is built only from order-preserving primitives: first apply $\otimes$ to combine along a path, then apply $\oplus$ to aggregate over paths. No probabilistic normalization or additivity is needed, and no assumptions about independence of the intermediates are invoked; the statement is purely algebraic.*

Proof sketch. Each term $R(x, y) \otimes S(y, z)$ is monotone in each argument, and joins preserve monotonicity.

Remark 2047. Proof sketch. *The strategy is componentwise: for each triple (x, y, z), use monotonicity of $\otimes$ to show $R \otimes S \leq R' \otimes S'$, then use monotonicity of $\bigoplus$ to preserve the inequality after aggregating over y. The key step works because quantales are designed precisely so that both $\otimes$ and joins are order-preserving. One may visualize the composition as a funnel: inequalities enter at the leaves (the individual path terms) and are preserved through the funnel's aggregation.* □

Lemma HT14.10 (Associativity). Assuming $\otimes$ distributes over joins, relational composition is associative:

$$(R_1 \circ R_2) \circ R_3 = R_1 \circ (R_2 \circ R_3).$$

Remark 2048. *Associativity is what makes multi-step prediction well-defined without parentheses: it ensures that whether you first compose the first two steps or the last two steps, you get the same aggregate relation. In probabilistic terms, it is the analogue of associativity of matrix multiplication. Here it depends on the distributivity axiom: the ability to pull $\otimes$ through $\bigoplus$ is what permits the rearrangement of sums/joins needed to match the two expansions.*

Remark 2049. *Concretely, if one is interested in an n-step predictive relation built from successive lags $\Delta_1, \ldots, \Delta_n$, associativity ensures that the expression*

$$R_{O,\Delta_1} \circ R_{O,\Delta_2} \circ \cdots \circ R_{O,\Delta_n}$$

is unambiguous: any parenthesization yields the same V-relation. This matters for temporal semantics because it allows one to speak of "the" composite evidence transported through multiple intermediate event-types, without committing to a particular computational schedule for the aggregation of intermediates. In particular, it allows one to reorganize computations (e.g. dynamic programming versus direct expansion) while preserving the resulting p-bit valued predictions.

Proof sketch. Expand both sides, use distributivity to rearrange joins, and associativity of $\otimes$.

Remark 2050. Proof sketch. *The high-level strategy is "Fubini for joins": expand both sides into iterated joins over intermediate event-types, then use distributivity to swap the order of aggregation and regroup tensor-products using associativity. The key steps work because distributivity ensures that combining a fixed factor with a join of alternatives yields the join of the combined alternatives. A mental model is to think of three-step paths $A \to B \to C \to D$: both parenthesizations ultimately aggregate over the same set of paths, merely grouped differently.* $\square$

36.5 Extensional/intensional attraction and causality

Fix a finite property basis P, weights $w_{p,q} \geq 0$ with $\sum_{p,q} w_{p,q} = 1$, and a property map $\mathrm{Prop}_O : \mathcal{E} \to [0,1]^P$. Write $p \in_O A$ for the induced property-event types used in intensional attraction.

Let $PAtt^{\mathrm{ext}}_{O,\Delta}(A,B) := PAtt_{O,\Delta}(A,B)$ and

$$PAtt^{\mathrm{int}}_{O,\Delta}(A,B) := \sum_{p,q \in P} w_{p,q}\, PAtt_{O,\Delta}(p \in_O A,\ q \in_O B).$$

Remark 2051. *The extensional/intensional split is a formal way to separate two kinds of predictive regularity:*

- Extensional *attraction treats A and B as unanalyzed event-types.*
- Intensional *attraction looks inside the event-types via a property basis P and a mapping* Prop_O*, and then aggregates attraction between property-instantiations.*

This echoes the general theme that cognition (or an observer) can represent the same situation at multiple descriptive granularities: one may predict "storm" from "pressure drop" directly, or predict it by decomposing into component properties and recombining. In the broader Hyperseed vocabulary, this is a move across contexts and aspects (cf. Section 13), and it is closely related to the Hyperseed-Concept 157 and 134.

Remark 2052. *A simple example: take $P = \{red, round\}$ and consider event-types $A =$ "apple" and $B =$ "seen". Then $p \in_O A$ might denote "the current object has property p in observer O's representation." Intensional attraction can then express that "redness" is a stronger predictor of "seen" than "roundness," and the weights $w_{p,q}$ encode which property-pairs matter for the $A \to B$ relationship.*

Lemma HT14.11 (Intensional attraction is bounded). If each $PAtt_{O,\Delta}(p \in_O A, q \in_O B) \in [-1,1]$, then

$$PAtt^{\mathrm{int}}_{O,\Delta}(A,B) \in [-1,1].$$

Remark 2053. *This lemma is a convexity fact: intensional attraction is constructed as a weighted average (a convex combination) of bounded attraction values, so it must lie within the same bounds. This boundedness is crucial because causal implication below is built by feeding attraction values into $\sigma : [-1,1] \to [0,1]$; without the bound, σ would not necessarily be meaningful as a normalization.*

Proof sketch. $PAtt^{\text{int}}$ is a convex combination of numbers in $[-1,1]$.

Remark 2054. Proof sketch. *The strategy is: use that* $w_{p,q} \geq 0$ *and* $\sum_{p,q} w_{p,q} = 1$*, so the sum is an average. Any average of values in an interval remains in the interval. The key step works because the weights are normalized; without normalization, one would only get a scaled interval. Visually,* $PAtt^{\text{int}}$ *lies in the convex hull of the set of component attractions, which in one dimension is just the interval between the minimum and maximum (hence within* $[-1,1]$*).* □

Let $\sigma : [-1,1] \to [0,1]$ be $\sigma(x) = (1+x)/2$, and define causal implication

$$CImp_{O,\Delta}(A,B) = \Big(\lambda\sigma(PAtt^{\text{ext}}_{O,\Delta}(A,B)) + (1-\lambda)\sigma(PAtt^{\text{int}}_{O,\Delta}(A,B))\Big)\mathbf{1}[A \prec B].$$

Also define the strong product variant

$$CImp^{\times}_{O,\Delta}(A,B) = \sigma(PAtt^{\text{ext}}_{O,\Delta}(A,B)) \cdot \sigma(PAtt^{\text{int}}_{O,\Delta}(A,B)) \cdot \mathbf{1}[A \prec B].$$

Remark 2055. *The map* $\sigma(x) = (1+x)/2$ *is the same affine renormalization idea seen earlier: it converts an attraction score in* $[-1,1]$ *into a unit-interval score in* $[0,1]$*. The causal implication* $CImp_{O,\Delta}(A,B)$ *then blends extensional and intensional evidence using a convex weight* $\lambda \in [0,1]$*, and finally gates by temporal precedence* $\mathbf{1}[A \prec B]$*. This makes causality explicitly* asymmetric in proto-time*, aligning with the ordinary intuition that causes precede effects (Hyperseed-Concept 70), while also acknowledging that causal judgments are observer-dependent through O (a point compatible with process and relational perspectives [15, 14]).*

Remark 2056. *The product variant* $CImp^{\times}$ *is deliberately stricter: it is large only when* both *extensional and intensional attractions are large (after normalization). The mixture variant can be large if either component is large enough (depending on* λ*). This mirrors a familiar epistemic choice: do we accept "either kind of evidence suffices" (mixture) or "both must agree" (product)?*

Proposition HT14.12 (Causal implication range and gating). $CImp_{O,\Delta}(A,B) \in [0,1]$, and $CImp_{O,\Delta}(A,B) = 0$ whenever $\mathbf{1}[A \prec B] = 0$.

Remark 2057. *This proposition ensures that* $CImp$ *is a well-formed graded causal score: it always lies between* 0 *and* 1*, and it vanishes when the temporal-precedence constraint fails. The gating clause is particularly important: it prevents a purely predictive correlation (which might be symmetric in time) from being misread as a causal arrow. In scientific terms, it encodes a minimal causal discipline: time must point the right way [20].*

Proof sketch. σ maps $[-1,1]$ into $[0,1]$, the mixture is a convex combination, and multiplication by $\mathbf{1}[A \prec B] \in \{0,1\}$ gates the result.

Remark 2058. Proof sketch. *The strategy is bounding: map each attraction into* $[0,1]$*, average them, then multiply by a* $0/1$ *indicator. The key steps work because convex combinations preserve interval bounds. The visual intuition is that* $CImp$ *lives in the unit interval simplex: the mixture cannot escape* $[0,1]$*, and the indicator either leaves it unchanged (if precedence holds) or collapses it to* 0*.* □

Proposition HT14.13 (Affine simplification). Let $a = PAtt^{\text{ext}}_{O,\Delta}(A,B)$ and $b = PAtt^{\text{int}}_{O,\Delta}(A,B)$. Then

$$CImp_{O,\Delta}(A,B) = \sigma(\lambda a + (1-\lambda)b)\,\mathbf{1}[A \prec B] = \frac{1 + \lambda a + (1-\lambda)b}{2}\,\mathbf{1}[A \prec B].$$

Remark 2059. *This proposition reveals that the mixture-of-σ definition is equivalent to applying σ* after *mixing the attraction scores. That is, the causal implication is an affine function of the blended attraction $\lambda a + (1-\lambda)b$. This is algebraically convenient: it makes monotonicity and comparative statics transparent, and it clarifies that λ is literally interpolating between two attraction estimates before normalization. In particular, since $a, b \in [-1,1]$ (by construction of attraction), the blend $\lambda a + (1-\lambda)b$ also lies in $[-1,1]$, so the normalized score prior to gating lies in $[0,1]$ without any further clipping. The endpoint cases are also immediate: when $\lambda = 1$ the expression reduces to $\sigma(a)\mathbf{1}[A \prec B]$ (purely extensional), and when $\lambda = 0$ it reduces to $\sigma(b)\mathbf{1}[A \prec B]$ (purely intensional). Moreover, if $a = b$ then the causal implication is independent of λ, emphasizing that λ only matters insofar as the two attraction estimates disagree.*

Proof sketch. Use $\sigma(x) = (1+x)/2$ to compute $\lambda\sigma(a) + (1-\lambda)\sigma(b) = \sigma(\lambda a + (1-\lambda)b)$.

Remark 2060. Proof sketch. *The proof is an exercise in linearity: σ is affine, so it commutes with convex combinations. The key step works because σ has the form $x \mapsto \alpha x + \beta$. A geometric picture is that affine maps send line segments to line segments; blending a and b traces a segment in $[-1,1]$, and σ maps that segment to a segment in $[0,1]$. Concretely, expanding the left-hand side gives*

$$\lambda\frac{1+a}{2} + (1-\lambda)\frac{1+b}{2} = \frac{\lambda + \lambda a + 1 - \lambda + (1-\lambda)b}{2} = \frac{1 + \lambda a + (1-\lambda)b}{2} = \sigma(\lambda a + (1-\lambda)b),$$

and then multiplying by $\mathbf{1}[A \prec B]$ simply applies the same temporal (or precedence) gate to either equivalent form. This also makes clear that the only nonlinearity in $CImp_{O,\Delta}(A,B)$ comes from the indicator $\mathbf{1}[A \prec B]$, whereas the dependence on (a,b) is purely affine once $A \prec B$ is fixed. ☐

Proposition HT14.14 (Monotonicity in attraction components). Assume $\mathbf{1}[A \prec B]$ is fixed. Then $CImp_{O,\Delta}(A,B)$ is nondecreasing in $PAtt^{\text{ext}}_{O,\Delta}(A,B)$ and in $PAtt^{\text{int}}_{O,\Delta}(A,B)$ (holding the other fixed).

Remark 2061. *This proposition formalizes a basic rationality constraint on the scoring rule: if either the extensional or intensional evidence of attraction increases (with the temporal gate held fixed), then the causal implication score does not decrease. In practical terms, it guarantees that improving predictive evidence cannot perversely reduce the inferred causal strength. This kind of monotonicity is essential if one wishes to use these scores inside optimization or learning loops. Under the affine simplification of Proposition HT14.13 (when $A \prec B$ is fixed), the dependence is even transparent at the level of partial derivatives: for $\mathbf{1}[A \prec B] = 1$ one has $\partial CImp/\partial a = \lambda/2 \geq 0$ and $\partial CImp/\partial b = (1-\lambda)/2 \geq 0$, so the score is not merely monotone but linear in each component separately. The assumption that $\mathbf{1}[A \prec B]$ is fixed is crucial: if $A \prec B$ can flip from true to false, the score can drop discontinuously to 0 due to the gating, regardless of attraction values.*

Proof sketch. σ is increasing, and convex combinations preserve order.

Remark 2062. Proof sketch. *The strategy is composition of monotone maps: each attraction component is fed into the increasing function σ, and then combined linearly with nonnegative* *coefficients summing to* 1*. The key step is that both σ and convex combination operators are order-preserving. One can imagine sliders for a and b: pushing either slider upward cannot pull the output downward as long as the gate is constant. More explicitly, fix b and take $a' \geq a$; then $\lambda a' + (1-\lambda)b \geq \lambda a + (1-\lambda)b$, and since σ is increasing this implies $\sigma(\lambda a' + (1-\lambda)b) \geq \sigma(\lambda a + (1-\lambda)b)$, with the same argument holding when varying b while keeping a fixed. If one prefers an algebraic check, Proposition HT14.13 yields $CImp = \frac{1+\lambda a+(1-\lambda)b}{2}\mathbf{1}[A \prec B]$, which is visibly nondecreasing in a and b when $\mathbf{1}[A \prec B]$ is held constant.* □

Proposition HT14.15 (Product variant is a lower bound).

$$CImp^{\times}_{O,\Delta}(A, B) \ \leq\ CImp_{O,\Delta}(A, B).$$

Remark 2063. *This proposition makes precise the earlier intuition that the product variant is stricter. Algebraically, it says that xy is never larger than the weighted average $\lambda x + (1 - \lambda)y$ (indeed $xy \leq \min\{x, y\}$). Thus the product score is conservative: it penalizes disagreement between extensional and intensional evidence more strongly than the mixture does. This is a useful option when one wants causal claims to require corroboration across representational levels. The inequality also highlights when the two scores coincide: equality holds whenever one factor already enforces the bottleneck, e.g., if $x \leq y$ and $\lambda = 1$ then both reduce to x; more generally $xy = \min\{x, y\}$ occurs when $\min\{x, y\} \in \{0, 1\}$ (since if $x = 0$ or $y = 0$ then both product and mixture are* 0*, and if $x = y = 1$ then both are* 1 *before gating). For intermediate values, the gap between product and mixture quantifies how much the rule rewards having both components simultaneously high rather than merely one of them high.*

Proof sketch. Let $x = \sigma(PAtt^{\text{ext}})$ and $y = \sigma(PAtt^{\text{int}})$ so $x, y \in [0, 1]$. Then $xy \leq \min\{x, y\} \leq \lambda x + (1 - \lambda)y$. Multiply by $\mathbf{1}[A \prec B]$.

Remark 2064. Proof sketch. *The proof strategy is to compare product, minimum, and convex combination on* $[0, 1]$*. The key inequality $xy \leq \min\{x, y\}$ follows because both x and y are at most* 1*. The step $\min\{x, y\} \leq \lambda x + (1 - \lambda)y$ holds because a convex combination lies between its endpoints and hence above the minimum. Visually, the product curve lies below the line segment connecting* $(0, 0)$ *to* $(1, 1)$ *except at the endpoints; the convex combination is precisely such a line segment in the* (x, y) *plane. One can also verify the first inequality by cases: if $x \leq y$ then $xy \leq x \cdot 1 = x = \min\{x, y\}$, and symmetrically if $y \leq x$ then $xy \leq y$. For the second inequality, note that $\lambda x + (1 - \lambda)y \geq \lambda \min\{x, y\} + (1 - \lambda) \min\{x, y\} = \min\{x, y\}$, using $\lambda \in [0, 1]$. Finally, multiplying by $\mathbf{1}[A \prec B] \in \{0, 1\}$ preserves the inequality and makes explicit that the comparison is meaningful only on the temporally admissible pairs* (A, B)*.* □

36.6 Control and hierarchy

Let $\mathcal{A} \subseteq \mathcal{E}$ be the action event types. Define control strength for action $A \in \mathcal{A}$ and goal condition $G \in \mathcal{E}$ by

$$\mathrm{Ctrl}_{O,\Delta}(A \to G) := CImp_{O,\Delta}(A, G).$$

Remark 2065. *The restriction $A \in \mathcal{A}$ is doing conceptual work: it separates "things the agent does" from generic events in $\mathcal{E}$, while still letting goals G range over arbitrary event-types (including internal state conditions, external outcomes, or composite conditions). This is useful later when actions are treated as decision variables but goals are treated as desiderata or constraints.*

Remark 2066. *Because* $\mathrm{Ctrl}_{O,\Delta}(A \to G)$ *is observer-relative and* Δ*-gated, it should be read as an empirical, temporally localized notion of instrumental influence: an action-type may "control" a goal in one observational regime (or at one temporal scale) but not in another. In particular, the same physical actuator event-type can yield different* Ctrl *values for different observers* O *(e.g., due to sensor resolution, feature abstraction, or differing event-type definitions), and the same pair* (A, G) *can exhibit strong control at one time-lag but weak control at another (e.g., immediate effects versus delayed effects).*

Remark 2067. *Control is here defined as a special case of causal implication: an action* A *"controls" a goal-condition* G *to the extent that* A *causally implies* G *(in the observer-relative, temporally gated sense already defined). This matches the engineering stance common in agent architectures: control is causality-as-instrumentality [19]. In the Hyperseed core-concept set, this aligns directly with Hyperseed-Concept 87 (and the later use of hierarchical organization aligns with 88).*

Remark 2068. *It is also worth separating this usage from classical control theory:* $\mathrm{Ctrl}_{O,\Delta}(A \to G)$ *is not asserting the existence of a continuous feedback law or robustness margins, but rather providing a scalar, event-type level summary of how reliably* A *brings about* G *in the modeled distribution. In later applications, one can still layer feedback and policy concepts on top of this by interpreting policies as distributions over action event-types and evaluating their induced control of goal event-types.*

Corollary HT14.16 (Control inherits causal properties). For actions A and goals G:

$$\mathrm{Ctrl}_{O,\Delta}(A \to G) \in [0,1], \quad \mathrm{Ctrl}_{O,\Delta}(A \to G) = 0 \text{ if } \mathbf{1}[A \prec G] = 0,$$

and Ctrl is monotone in extensional and intensional predictive attraction (when precedence is fixed).

Remark 2069. *The indicator* $\mathbf{1}[A \prec G]$ *makes explicit the temporal-asymmetry constraint: without the stipulated precedence (within the gating window), "control" is defined to vanish, which prevents conflating mere correlation with actionable influence. This matters for later hierarchical constructions, since a controller at a higher level must be able to treat sub-actions as antecedents whose consequences occur after the sub-actions are executed, not before.*

Remark 2070. *The monotonicity clause is especially important operationally: increasing predictive attraction between* A *and* G *(whether by adding more supporting observations in the extensional sense, or by strengthening the intensional/structural component of attraction) cannot decrease the assessed control strength, so improvements in predictive coupling translate into non-worsening estimates of instrumentality. When precedence is fixed, this preserves the intuitive ordering "more predictively tied"* $\Rightarrow$ *"no less controllable," which is used implicitly when ranking candidate actions by anticipated goal achievement.*

Remark 2071. *This corollary is a packaging result: once control is defined as* $CImp$ *on action/goal pairs, all the previously established well-formedness and monotonicity properties come along automatically. It is useful because it lets later arguments about policy selection or hierarchical action selection reuse the causal math without re-proving basic bounds each time.*

Remark 2072. *In particular, the bounds* $\mathrm{Ctrl}_{O,\Delta}(A \to G) \in [0,1]$ *let* Ctrl *be used directly as a normalized objective component (e.g., in weighted sums with other* $[0,1]$*-valued criteria such as cost-normalized utility or constraint satisfaction). The precedence-zeroing property further ensures that any optimization procedure that searches over candidate actions will not be misled by "backwards" associations that are not implementable as control.*

Proof sketch. Immediate from $\mathrm{Ctrl} = CImp$ and Propositions HT14.12–HT14.14.

Remark 2073. Proof sketch. *The strategy is substitution: replace* Ctrl *with* $CImp$ *and cite the already proven propositions. The key step is recognizing that the definitions align exactly, so no additional structure is needed. The intuition is that "control" is not a new primitive here, but merely causality restricted to a designated subset of event-types called actions.* ☐

Remark 2074. *If one wants to see the substitution explicitly, each claimed property of* $\mathrm{Ctrl}_{O,\Delta}(A \to G)$ *is literally the corresponding property of* $CImp_{O,\Delta}(A, G)$ *with the argument-pair renamed from "(antecedent event-type, consequent event-type)" to "(action-type, goal-type)." The only extra premise is membership* $A \in \mathcal{A}$*, which does not affect the algebraic properties proved for* $CImp$*.*

Lemma HT14.17 (Score tradeoff rule for weak causal parent selection). For parent sets $S_1, S_2 \subseteq C$,

$$\mathsf{Score}(S_1 \to B) \geq \mathsf{Score}(S_2 \to B)$$

$$\mathrm{Fit}(S_1 \to B) - \mathrm{Fit}(S_2 \to B) \geq \eta\big(\mathrm{Weak}(S_2 \to B) - \mathrm{Weak}(S_1 \to B)\big).$$

In particular, if Fit ties, any maximizer of Weak is a maximizer of Score.

Remark 2075. *This lemma is a generic tradeoff principle: if a score* Score *is built by combining a "fit" term* Fit *and a "weakness" term* Weak *(penalized or rewarded with coefficient* η*), then comparing two candidates reduces to a linear inequality balancing fit improvement against weakness change. In many model-selection settings,* Fit *rewards explanatory adequacy while* Weak *rewards simplicity, regularity, or low commitment—a theme echoed in the quantale-weakness program [3] and in broader discussions of weak constraints in building cognitive systems [2]. The final sentence captures a common selection heuristic: if two models explain equally well, prefer the weaker (less committal / more transferable) one. This is closely related to the "tradeoff theorem" style of reasoning about dependency management [9].*

Remark 2076. *The direction of the inequality highlights the role of* η *as an exchange rate between the two desiderata: increasing* η *makes improvements in weakness more valuable (or, if* Weak *is interpreted as a penalty with a sign convention, makes reductions in weakness more valuable). Thus, the lemma can be read as specifying the minimum fit gain required to justify accepting a worse weakness value, namely* $\eta(\mathrm{Weak}(S_2 \to B) - \mathrm{Weak}(S_1 \to B))$*. This is the standard "regularization tradeoff" pattern, stated in a way that is independent of the internal definitions of* Fit *and* Weak*.*

Remark 2077. *Although the statement is phrased for parent sets* $S \subseteq C$ *predicting* B*, the same algebraic form applies whenever one compares two candidate explanations, controllers, or decompositions: one term measures performance on data or goals (fit), the other measures a structural preference (weakness as simplicity/portability/low-commitment), and* η *sets the operating point. This makes the lemma a convenient reusable tool in hierarchical selection arguments where one repeatedly chooses among alternative parent-sets at different levels of abstraction.*

Proof sketch. Subtract the two scores and rearrange.

Remark 2078. Proof sketch. *The strategy is algebraic normalization: write* $\mathsf{Score}(S_1 \to B) - \mathsf{Score}(S_2 \to B)$ *in terms of* Fit *and* Weak*, then isolate* $\mathrm{Fit}(S_1 \to B) - \mathrm{Fit}(S_2 \to B)$ *on one side. The key step works because the score is assumed to be affine in these components (as is typical for regularized objectives). One can picture a two-dimensional plane with axes* $(\mathrm{Fit}, \mathrm{Weak})$*: the inequality defines a half-space bounded by a line of slope determined by* η*; moving along that line preserves score, and maximizing score chooses points on the "northeast" side according to the sign convention.* ☐

Remark 2079. *Concretely, under the common form* $\mathsf{Score}(S \to B) = \mathrm{Fit}(S \to B) + \eta\,\mathrm{Weak}(S \to B)$*, the condition* $\mathsf{Score}(S_1 \to B) \ge \mathsf{Score}(S_2 \to B)$ *expands to*

$$\mathrm{Fit}(S_1 \to B) - \mathrm{Fit}(S_2 \to B) \;\ge\; \eta\big(\mathrm{Weak}(S_2 \to B) - \mathrm{Weak}(S_1 \to B)\big),$$

*which is exactly the displayed inequality. The "*Fit *ties" corollary then follows by setting the left-hand side to* 0*, leaving* $\mathrm{Weak}(S_1 \to B) \ge \mathrm{Weak}(S_2 \to B)$ *as the deciding criterion among equal-fit candidates.*

Lemma HT14.18 (No cycles in a control hierarchy). If $(\mathcal{M}, <)$ is a partial order used as a control hierarchy, there is no strict cycle $M_1 < M_2 < \cdots < M_k < M_1$.

Remark 2080. *This lemma is a structural axiom dressed as a theorem: a control hierarchy is modeled as a partial order, and partial orders cannot contain strict cycles. The usefulness is practical: if a hierarchy had cycles, then "higher" and "lower" control would become inconsistent, undermining modular decomposition and the intended semantics of top-down constraint and bottom-up reporting. In broader system-design terms, it is the mathematical reflection of the idea that a well-formed hierarchy should permit unambiguous escalation and delegation (Hyperseed-Concept 88; see also hierarchical organization themes in [5]).*

Remark 2081. *Interpreting* $<$ *as "is a higher-level controller than" (or "constrains/organizes"), acyclicity ensures that control influence cannot feed back into itself purely by the hierarchy relation. This does not forbid dynamical feedback in the underlying system; it only forbids representing the hierarchical* organizational *relation itself as cyclic. In practice, this means one can treat the hierarchy graph induced by* $<$ *as a DAG and safely perform top-down passes (for constraint propagation or goal decomposition) and bottom-up passes (for state aggregation or reporting) without encountering circular dependencies at the representation level.*

Proof sketch. A strict cycle contradicts transitivity and antisymmetry of a partial order.

Remark 2082. Proof sketch. *The proof strategy is contradiction: assume the cycle exists, then use transitivity to derive* $M_1 < M_1$*, which is impossible in a strict partial order (by irreflexivity, equivalently by antisymmetry when phrased via* $\le$*). The key step is that chaining* $<$*-relations via transitivity collapses the entire cycle into a self-relation. A visual intuition is to imagine "height levels": if* M_1 *is above* M_2 *and* M_k *is above* M_1*, then* M_1 *would have to be above itself, which is geometrically incoherent.* ◻

Remark 2083. *If the hierarchy is instead presented in a non-strict form* $(\mathcal{M}, \le)$*, the same conclusion can be phrased as: from* $M_1 \le M_2 \le \cdots \le M_k \le M_1$*, transitivity yields* $M_1 \le M_1$ *(always true) but antisymmetry then forces all* M_i *to be equal, so there is no* strict *cycle. This is often the convenient viewpoint when implementing hierarchies as reachability in a graph or as a refinement relation in a type lattice.*

37 Helper theorems for Attention and Cognitive Synergy

37.1 Standing notation from Section 15

Fix a system S with modules $M = \{1, \ldots, n\}$, patterns P (finite or countable), association map $\mathrm{Assoc} : M \to 2^P$, time index set T, genenergy expenditures $g : T \times M \to [0, \infty)$ with $g_t(i) := g(t, i)$, and total genenergy

$$G_t := \sum_{i \in M} g_t(i).$$

Assume each module i has weights $w_i : P \to [0,1]$ with $\sum_{p \in P} w_i(p) = 1$ and $w_i(p) = 0$ unless $p \in \mathrm{Assoc}(i)$. Define pattern-level attention mass

$$\mathrm{Attn}_t(p) := \sum_{i \in M} g_t(i)\, w_i(p), \qquad \mathrm{Attn}_t(X) := \sum_{p \in X} \mathrm{Attn}_t(p) \quad (X \subseteq P).$$

When $G_t > 0$, define the normalized attention distribution

$$\alpha_t(p) := \frac{\mathrm{Attn}_t(p)}{G_t}, \qquad \alpha_t(X) := \sum_{p \in X} \alpha_t(p).$$

Fix focus parameters (θ, k) with $\theta \in (0,1)$ and $k \in \mathbb{N}$. Let $P_{\mathrm{self}} \subseteq P$ be the current self-model pattern set.

Remark 2084. *It is helpful to read the foregoing as a precise bookkeeping scheme for "where the system is spending its effort" (Hyperseed-Concept 100) and, more specifically, for how that effort is apportioned across recognized patterns (Hyperseed-Concept 130; see also the pattern-oriented viewpoint in [5]). The set $M = \{1, \ldots, n\}$ is a finite index of modules; P is a (finite or countable) catalogue of patterns the system can attend to; and the association map $\mathrm{Assoc} : M \to 2^P$ assigns to each module the subset of patterns it is capable of touching. Here 2^P denotes the powerset of P, i.e. the set of all subsets of patterns.*

Remark 2085. *The quantity $g_t(i)$ is the (nonnegative) genenergy expenditure of module i at time t (Hyperseed-Concept **??**), and G_t is the total budget actually spent across modules at that time. Each w_i is a probability distribution over patterns (supported only on $\mathrm{Assoc}(i)$), which we may interpret as "if module i is active, what fraction of its activity is directed at each pattern." Then $\mathrm{Attn}_t(p)$ is the unnormalized attention mass landing on pattern p, while α_t is the corresponding normalized attention distribution, a genuine probability distribution when $G_t > 0$ (Hyperseed-Concept 60).*

Remark 2086. *Because the module index set M is finite, the total genenergy $G_t = \sum_{i \in M} g_t(i)$ is always well-defined as a finite sum, and similarly $\mathrm{Attn}_t(p) = \sum_{i \in M} g_t(i) w_i(p)$ is always a finite sum for each fixed pattern $p \in P$. Even when P is countably infinite, the expressions $\sum_{p \in P} w_i(p) = 1$ and $\mathrm{Attn}_t(X) = \sum_{p \in X} \mathrm{Attn}_t(p)$ may be understood as countable series with nonnegative terms, so there are no conditional-convergence issues: any reordering gives the same value, and $\mathrm{Attn}_t(X) \in [0, \infty]$ is determined unambiguously for every subset $X \subseteq P$. In typical applications one either restricts attention to subsets X for which the series converges, or simply notes that for $G_t < \infty$ (automatic here) and $G_t > 0$ one has $\mathrm{Attn}_t(P) = G_t$ and hence $\mathrm{Attn}_t(X) \le G_t$ for all $X \subseteq P$, so $\mathrm{Attn}_t(X)$ is automatically finite.*

Remark 2087. *A useful identity is that the attention distribution α_t can be viewed as a convex mixture of the module-specific pattern weights. Indeed, when $G_t > 0$,*

$$\alpha_t(p) = \frac{1}{G_t} \sum_{i \in M} g_t(i) w_i(p) = \sum_{i \in M} \Big(\frac{g_t(i)}{G_t} \Big) w_i(p),$$

so the mixing coefficients are precisely the normalized module expenditures $g_t(i)/G_t$. This makes explicit the separation between (i) how much *each module participates at time t (captured by $g_t(i)$) and (ii)* what *each module tends to point at when it participates (captured by w_i). The set-function $\alpha_t(X) = \sum_{p \in X} \alpha_t(p)$ may therefore be read as "the fraction of total effort allocated to the pattern subset X," and, in particular, $\alpha_t(P) = 1$ when $G_t > 0$.*

Remark 2088. *The $G_t > 0$ condition is included to avoid division by zero; intuitively, it corresponds to times at which the system is allocating a nontrivial amount of genenergy. When $G_t = 0$, all module expenditures are zero, hence $\mathrm{Attn}_t(p) = 0$ for every p and $\mathrm{Attn}_t(X) = 0$ for every $X \subseteq P$; in that case α_t is simply left undefined (or can be set arbitrarily by convention, depending on downstream use). Many later inequalities about attention are naturally stated either conditional on $G_t > 0$ or in a form that becomes vacuous when $G_t = 0$.*

Remark 2089. *The focus parameters (θ, k) are fixed global constants for the discussion that follows and are intended to parameterize a notion of "focused" attention: $\theta \in (0, 1)$ typically plays the role of a threshold for how much normalized attention mass must concentrate on a small set of patterns, and $k \in \mathbb{N}$ typically bounds the cardinality of such a set. Although the present subsection does not yet impose any focusing condition, it is convenient to fix (θ, k) in the standing notation so that subsequent helper theorems can state hypotheses such as "there exists a set $X \subseteq P$ with $|X| \leq k$ and $\alpha_t(X) \geq \theta$" without repeatedly restating the parameter choices.*

Remark 2090. *The distinguished subset $P_{\mathrm{self}} \subseteq P$ is meant to single out those patterns presently constituting the system's self-model. With the above notation, quantities like $\mathrm{Attn}_t(P_{\mathrm{self}})$ and $\alpha_t(P_{\mathrm{self}})$ become immediate ways of expressing how much absolute effort, or what fraction of total effort, is being allocated to self-model patterns at time t. This allows later arguments to treat "self-directed" attention as simply attention to a particular pattern subset, and to compare it directly against other relevant pattern classes using the same $\mathrm{Attn}_t(\cdot)$ and $\alpha_t(\cdot)$ bookkeeping.*

37.2 Genenergy and attention-mass identities

Lemma HT15.1 (Total pattern attention equals total genenergy). Assume $G_t < \infty$. Then

$$\mathrm{Attn}_t(P) = \sum_{p \in P} \mathrm{Attn}_t(p) = G_t.$$

Remark 2091. *Intuitively: if each module distributes all of its spent genenergy across patterns using weights that sum to 1, then no genenergy disappears and none is created when we "push it down" from modules to patterns. The lemma asserts that the total attention mass across all patterns is exactly the total genenergy expended across modules.*

Remark 2092. *Formally, this is a conservation law: the mapping $g_t(\cdot)$ on modules becomes $\mathrm{Attn}_t(\cdot)$ on patterns by redistribution through the kernels $w_i(\cdot)$. The condition $\sum_{p \in P} w_i(p) = 1$ for each module i is exactly the statement that w_i is* mass-preserving *on P, so summing over all patterns recovers the original mass $g_t(i)$ for each i, and then summing over i recovers G_t.*

Proof sketch. Expand and swap sums: $\sum_p \mathrm{Attn}_t(p) = \sum_p \sum_i g_t(i) w_i(p) = \sum_i g_t(i) \sum_p w_i(p) = \sum_i g_t(i) = G_t$.

Remark 2093. *The key move is the exchange of summation order, which is justified here by nonnegativity and the finiteness assumption $G_t < \infty$ (so no problematic $\infty - \infty$ expressions arise). Conceptually, we are summing the same collection of contributions $g_t(i) w_i(p)$ but first grouping by patterns and then by modules.*

Remark 2094. *If one wants a slightly more explicit justification: because $g_t(i) \geq 0$ and $w_i(p) \geq 0$, the double sum $\sum_{p \in P} \sum_{i \in M} g_t(i) w_i(p)$ is a sum of nonnegative terms, so Tonelli's theorem (or the monotone convergence theorem for series) permits reordering without changing the value (possibly $+\infty$). The additional assumption $G_t < \infty$ ensures the value is in fact finite, so the identity is an equality of real numbers rather than an extended-real statement.*

Corollary HT15.2 (Normalization). If $G_t > 0$ then α_t is a probability distribution on P:

$$\alpha_t(p) \geq 0, \qquad \sum_{p \in P} \alpha_t(p) = 1.$$

Remark 2095. *This makes precise the common informal statement that "attention is a distribution." The normalization step is not mere cosmetic algebra: it lets one compare attention profiles across times t even when the total spending G_t changes, and it prepares attention to be treated with probabilistic and information-theoretic tools (Hyperseed-Concept 139,* **??***).*

Remark 2096. *Note that the requirement $G_t > 0$ is essential: if $G_t = 0$ then every module spends zero genenergy, so $\mathrm{Attn}_t(p) = 0$ for all p, and there is no canonical way to normalize (one would be dividing 0 by 0). In that degenerate case, it is often convenient to treat Attn_t as the zero measure and leave α_t undefined (or define it by an external convention if a particular application needs a default).*

Proof sketch. Nonnegativity is immediate. The sum is $\mathrm{Attn}_t(P)/G_t = G_t/G_t = 1$ by Lemma HT15.1.

Remark 2097. *The corollary is an instance of a general pattern: once you prove a conserved-total identity (Lemma HT15.1), the normalized object inherits the axioms of probability almost for free.*

Remark 2098. *A useful way to read the conclusion is that α_t is the* relative *attention allocation: $\alpha_t(p)$ is the fraction of the total spent genenergy that ends up attributed to pattern p. In particular, statements such as "pattern p has twice the attention of pattern q" are meaningful at the level of α_t even when the absolute budget G_t varies with hardware, load, or scheduling.*

Lemma HT15.3 (Finite additivity and monotonicity). For disjoint $X, Y \subseteq P$,

$$\mathrm{Attn}_t(X \cup Y) = \mathrm{Attn}_t(X) + \mathrm{Attn}_t(Y), \qquad \alpha_t(X \cup Y) = \alpha_t(X) + \alpha_t(Y),$$

and if $X \subseteq Y$ then $\mathrm{Attn}_t(X) \leq \mathrm{Attn}_t(Y)$ and $\alpha_t(X) \leq \alpha_t(Y)$.

Remark 2099. *This lemma records the elementary but indispensable measure-like properties of attention mass: disjoint subsets do not "double count" attention, and larger sets can only receive more (or equal) mass. In practice, it lets one reason about attention to composite pattern-collections without repeatedly expanding sums.*

Remark 2100. *The statement is deliberately phrased in the language of sets to emphasize that $\mathrm{Attn}_t(\cdot)$ behaves like a (finitely additive) measure on the discrete space P. When P is finite or countable, one may equivalently view Attn_t as a measure determined by its point masses $\mathrm{Attn}_t(p)$, with $\mathrm{Attn}_t(X) = \sum_{p \in X} \mathrm{Attn}_t(p)$. The lemma then reduces to standard facts about sums over disjoint unions and inclusions.*

Proof sketch. All claims follow from the definitions as sums of nonnegative terms.

Remark 2101. *The proof relies on the fact that attention is constructed by summing nonnegative contributions. Once nonnegativity is present, monotonicity is almost tautological: adding patterns adds nonnegative summands.*

Remark 2102. *It is worth noting what is* not *asserted: countable additivity (a σ-additivity property) is not needed for most manipulations in this section, and it would require additional care if P were uncountable or if one allowed more general (non-discrete) pattern spaces. In the present discrete setting, whenever the relevant sums are well-defined, the same nonnegativity argument that gives finite additivity typically extends to countable disjoint unions by monotone convergence.*

Lemma HT15.4 (Scale invariance of normalized attention). If g_t is replaced by $g'_t(i) = c\, g_t(i)$ with $c > 0$, then α_t is unchanged.

Remark 2103. *Normalized attention is meant to capture* relative *allocation rather than absolute spending. This lemma formalizes that intention: multiplying the entire budget by a positive constant (e.g. due to a faster processor, or a higher clock rate) does not change the attention distribution.*

Remark 2104. *The restriction $c > 0$ matches the intended interpretation as a rescaling of available resources. If $c = 0$, then G_t collapses to 0 and the normalization in α_t is no longer defined; if $c < 0$ then g'_t would cease to be nonnegative and would no longer represent genenergy. Thus the lemma is a genuine invariance principle within the physically meaningful parameter range.*

Proof sketch. Both numerator $\mathrm{Attn}_t(p)$ and denominator G_t scale by c, so the ratio is invariant.

Remark 2105. *The invariance is a simple homogeneity property: α_t is of degree 0 in g_t, because it is defined as a quotient of two degree-1 quantities.*

Remark 2106. *In applications, this lemma is often invoked implicitly when comparing runs of the same system under different absolute budgets. It licenses treating α_t as a budget-free signature of what the system* cares about *at time t, while Attn_t and G_t quantify how strongly it can act on those cares in absolute terms.*

Lemma HT15.5 (Pushforward form of pattern attention). Define the module-level allocation $\hat{\alpha}_t(i) := g_t(i)/G_t$ (when $G_t > 0$). Then

$$\alpha_t(p) = \sum_{i \in M} \hat{\alpha}_t(i)\, w_i(p).$$

Remark 2107. *This expresses α_t as a two-stage mixture: first choose a module i according to the fraction of total genenergy it receives (the distribution $\hat{\alpha}_t$ on M), then choose a pattern p according to w_i. In probabilistic language, α_t is the pushforward/marginal distribution of this hierarchical sampling process (Hyperseed-Concept 139).*

Remark 2108. *Equivalently, if one thinks of $w_i(\cdot)$ as a stochastic "emission" profile from module i to patterns, then α_t is the mixture of these emissions with mixture weights given by the module budget shares $\hat{\alpha}_t(i)$. This makes clear that α_t aggregates two distinct design choices: (i) how genenergy is allocated across modules ($\hat{\alpha}_t$), and (ii) how each module maps its own activity to patterns (w_i).*

Proof sketch. Divide $\mathrm{Attn}_t(p) = \sum_i g_t(i) w_i(p)$ by G_t and rewrite $g_t(i)/G_t = \hat{\alpha}_t(i)$.

Remark 2109. *The identity is often used in the reverse direction: instead of computing α_t by first aggregating unnormalized attention, one may reason in terms of module shares $\hat{\alpha}_t(i)$, which can be treated as a higher-level control variable.*

Remark 2110. *This representation also highlights a useful conditional-expectation interpretation. If I is a random module with $\Pr(I = i) = \hat{\alpha}_t(i)$ and then P is drawn with $\Pr(P = p \mid I = i) = w_i(p)$, then $\alpha_t(p) = \Pr(P = p)$. In particular, for any test function f on patterns, $\sum_p f(p)\alpha_t(p) = \sum_i \hat{\alpha}_t(i) \sum_p f(p) w_i(p)$, so expectations under α_t can be computed by first taking expectations under each w_i and then averaging over modules.*

37.3 Attentional focus and self-reflective attention

Lemma HT15.6 (Top-k mass characterization). Let $\alpha_t^{\downarrow}(1) \geq \alpha_t^{\downarrow}(2) \geq \cdots$ be the nonincreasing rearrangement of $\{\alpha_t(p) : p \in P\}$. Then

$$\max\{\alpha_t(F) : F \subseteq P,\ |F| \leq k\} = \sum_{j=1}^{k} \alpha_t^{\downarrow}(j).$$

Remark 2111. *The statement says: if you may "choose at most k patterns to look at," the maximum total attention you can capture is obtained by choosing the k most-attended patterns. This is the formal underpinning of a very practical heuristic: focus is attention that is concentrated on a small set (Hyperseed-Concept 60).*

Remark 2112. *Two small edge-case clarifications are often useful in applications. First, if $k \geq |P|$ (when P is finite), then the maximizing set can be taken as $F = P$ and the right-hand side is simply the total attention mass $\sum_{p\in P} \alpha_t(p)$; the formula above remains consistent if one adopts the convention that $\alpha_t^{\downarrow}(j) = 0$ for $j > |P|$. Second, if there are ties among the k-th and $(k+1)$-st largest values, the maximizing F need not be unique: any choice that includes k elements achieving the top-k multiset of values attains the same maximum.*

Proof sketch. For any F of size $\leq k$, $\alpha_t(F)$ is a sum of $\leq k$ values from the multiset $\{\alpha_t(p)\}$. The maximum is obtained by choosing the k largest values.

Remark 2113. *The crucial observation is combinatorial: among all k-element subsets, the one that maximizes the sum is the one containing the top k entries. No deeper structure of α_t is required.*

Remark 2114. *One can also view the lemma as the discrete analogue of a rearrangement/majorization statement: the functional $F \mapsto \alpha_t(F)$ is maximized by taking a threshold cut on the sorted weights. This perspective can be helpful later when α_t is produced by a softmax (hence strictly positive and normalized) but the result itself does not depend on normalization, only on nonnegativity of the masses being summed.*

Corollary HT15.7 (Focus monotonicity in parameters). If focus holds at time t for (θ, k), then it holds for any (θ', k') with $\theta' \leq \theta$ and $k' \geq k$.

Remark 2115. *Once attention is sufficiently concentrated to clear a threshold θ using k patterns, it certainly clears any weaker requirement: allowing more patterns (larger k') or demanding less mass (smaller θ') cannot destroy the existence of a witnessing focus set.*

Proof sketch. Reuse the same witness set F_t (or enlarge it to size $\leq k'$); lowering θ or increasing k cannot break the inequality $\alpha_t(F_t) \geq \theta$.

Remark 2116. *This monotonicity is a small but important sanity check: the parameters (θ, k) behave in the direction one expects of a "focus" predicate.*

Remark 2117. *Equivalently, the set of parameter pairs for which focus holds is an "upper set" in k and a "lower set" in θ (with the natural product order). This matters when one later treats (θ, k) as hyperparameters: tuning k upward or θ downward cannot introduce false negatives for focus, so failure of focus at some (θ, k) automatically implies failure for any stricter pair (θ'', k'') with $\theta'' > \theta$ and $k'' < k$.*

Lemma HT15.8 (Self-reflective attention implies focus when the self-model is small). If $G_t > 0$ and $|P_{\text{self}}| \le k$, then

$$\alpha_t(P_{\text{self}}) \ge \theta_{\text{self}} \quad \Longrightarrow \quad \text{focus holds at level } (\theta_{\text{self}}, k) \text{ with witness } F_t = P_{\text{self}}.$$

Remark 2118. *Here P_{self} is the set of patterns constituting the system's current self-model. The lemma says that if the self-model is "small enough" (at most k patterns), then having a large fraction of attention on it automatically witnesses focus. This is one formal bridge from a self-model signal to an attentional-focus condition (Hyperseed-Concept 165, 60).*

Remark 2119. *The role of the size constraint $|P_{\text{self}}| \le k$ is purely structural: it ensures that the self-model is eligible to be a focus witness set under the cardinality cap. In particular, the implication does not claim that self-attention must be concentrated on a* subset *of the self-model; rather, it says that the entire self-model already fits within the allowed budget of k patterns, so its total attention mass can be used directly to certify focus.*

Proof sketch. Take $F_t = P_{\text{self}}$, which is allowed since $|P_{\text{self}}| \le k$.

Remark 2120. *The proof is a single substitution: the focus witness set is stipulated to be the self-model pattern set itself. Philosophically, it reflects that "self-attention" becomes a kind of "attention focus" whenever the self-representation is not too dispersed.*

Remark 2121. *The assumption $G_t > 0$ is not used in the set-theoretic part of the argument; it typically serves to rule out degenerate regimes in which self-related quantities are undefined or vacuous (e.g. when θ_{self} is only meaningful conditional on a nontrivial self-signal). Thus, in later dependencies, one can read this lemma as: whenever the self-signal is "active" and the self-model is small, any lower bound on total self-attention mass automatically instantiates a standard focus predicate.*

Lemma HT15.9 (Focused self-reflective attention implies nontrivial self salience). If focused self-reflective attention holds, i.e. there exists F_t with $|F_t| \le k$, $\alpha_t(F_t) \ge \theta$, and $F_t \cap P_{\text{self}} \ne \emptyset$, then

$$\max_{p \in P_{\text{self}}} \alpha_t(p) \;\ge\; \frac{\theta}{k}.$$

Remark 2122. *The conclusion is a pigeonhole principle: if a set of at most k patterns carries total mass at least θ, then some individual pattern in that set carries at least θ/k. The added hypothesis $F_t \cap P_{\text{self}} \ne \emptyset$ says that the focus set includes at least one self-model pattern; thus the self-model contains at least one pattern whose individual salience is bounded away from* 0.

Remark 2123. *Intuitively, the inequality θ/k quantifies the minimal "peakiness" forced by a (θ, k) focus certificate: if attention mass θ is compressed into at most k atoms, at least one atom must carry a non-negligible share. When α_t is a probability distribution (common in attention mechanisms), this also implies that a sufficiently large θ at modest k forces at least one pattern to have noticeable probability mass, which is often the operational notion of a salient token/pattern.*

Proof sketch. Since $\alpha_t(F_t) = \sum_{p \in F_t} \alpha_t(p) \ge \theta$ and $|F_t| \le k$, at least one $p \in F_t$ has $\alpha_t(p) \ge \theta/k$; if additionally $F_t \cap P_{\text{self}} \ne \emptyset$, then some self-model pattern can witness a lower bound of this form (or one can require a stronger variant where $F_t \subseteq P_{\text{self}}$).

Remark 2124. *The only subtlety is logical rather than algebraic: as written, the lower bound is guaranteed for some $p \in F_t$, and the intersection condition ensures there exists at least one self-pattern in F_t, but does not force the maximizer to lie in the intersection. The lemma therefore highlights a design choice: one may prefer a stronger condition (e.g. $F_t \subseteq P_{\text{self}}$) if one wants the lower bound to be witnessed explicitly by a self-pattern.*

Remark 2125. *A common strengthening (when appropriate) is to assume* self-focused *attention, meaning the witness set is required to be contained in P_{self}. Under that variant, the same pigeonhole argument yields the sharper and logically direct statement: there exists $p \in P_{\text{self}}$ with $\alpha_t(p) \geq \theta/k$, hence automatically $\max_{p \in P_{\text{self}}} \alpha_t(p) \geq \theta/k$. The present formulation is compatible with mixed focus sets (containing both self and non-self patterns) and is therefore weaker but sometimes more realistic in multi-object attention regimes.*

37.4 Attention as a bounded control policy

Let U be the set of internal update actions with costs $c : U \to [0, \infty)$, and let $B_t \geq 0$ be the attention budget at time t. An attention policy is $\pi_t : \Omega_t \to \Delta(U)$, and a draw $u \sim \pi_t(\omega)$ is feasible if $c(u) \leq B_t$.

Remark 2126. *The set Ω_t can be read as the space of internal "situations" the agent may be in at time t (e.g. working-memory contents, recent observations, latent beliefs, or any sufficient statistic used for decision-making). The time index emphasizes that the relevant state representation may itself evolve as the architecture accumulates memory or changes its internal model.*

Remark 2127. *The cost function c is intentionally abstract: it may represent compute time, number of primitive operations, energy consumption, memory bandwidth, or any bottlenecked resource. The scalar budget B_t can therefore be interpreted as a one-step resource envelope. In many settings one may also view B_t as a random variable or as an adapted process (e.g. fluctuating with fatigue or external constraints); the definitions below are pointwise in the realized B_t.*

Remark 2128. *Randomized policies $\pi_t(\omega) \in \Delta(U)$ allow the system to hedge among multiple update strategies when the state does not uniquely determine the best action, or when exploration is beneficial. Deterministic policies are recovered as the special case where $\pi_t(\omega)$ is a Dirac distribution concentrated on a single action $u(\omega)$.*

Remark 2129. *In this subsection, attention is treated as a control resource (Hyperseed-Concept 87): the system is in a state $\omega \in \Omega_t$ and stochastically selects an internal action $u \in U$ according to $\pi_t(\omega)$. The notation $\Delta(U)$ denotes the simplex of probability distributions over U (so $\pi_t(\omega)$ is a distribution). The budget constraint $c(u) \leq B_t$ plays the role of a feasibility condition familiar from constrained optimization and control.*

Remark 2130. *Formally, one may regard π_t as a Markov (stochastic) kernel from Ω_t to U. No additional measure-theoretic structure is required for the statements below beyond the interpretation that $\pi_t(\omega)(A)$ denotes the probability of drawing an action in the subset $A \subseteq U$ when in state ω. In finite or countable U, this reduces to ordinary sums of point probabilities.*

Lemma HT15.10 (Feasibility as support constraint). For a fixed state $\omega \in \Omega_t$, the policy is feasible at ω iff

$$\pi_t(\omega)\big(\{u \in U : c(u) \leq B_t\}\big) = 1,$$

equivalently $\pi_t(\omega)(u) = 0$ for all u with $c(u) > B_t$.

Remark 2131. *The lemma translates an operational statement ("every sampled action respects the budget") into a measure-theoretic one ("the policy assigns probability* 1 *to the feasible set"). This is useful because it turns feasibility into a simple algebraic property of distributions: the infeasible actions must have zero probability mass.*

Remark 2132. *Intuitively, the feasible set* $F_t := \{u \in U : c(u) \leq B_t\}$ *partitions actions into those that the architecture can "afford" at time* t *and those that it cannot. Lemma HT15.10 says that feasibility is equivalent to requiring* $\pi_t(\omega)$ *to live entirely on* F_t*—that is,* $\pi_t(\omega)$ *must not merely have high probability of affordable actions, but must exclude unaffordable ones altogether.*

Proof sketch. This is just the definition of feasibility for a random draw.

Remark 2133. *The equivalence between "probability* 1 *on a set" and "zero probability on its complement" is the essential step. Conceptually, feasibility is a statement about the support of* $\pi_t(\omega)$*.*

Remark 2134. *In the special case where* U *is finite, the condition* $\pi_t(\omega)(F_t) = 1$ *is simply* $\sum_{u \in F_t} \pi_t(\omega)(u) = 1$*, which forces* $\pi_t(\omega)(u) = 0$ *for each* $u \notin F_t$*. This highlights that feasibility is not an expectation constraint (such as* $\mathbb{E}[c(u)] \leq B_t$*) but a hard constraint ruling out any probability mass on infeasible actions.*

Lemma HT15.11 (Budget monotonicity). If $B_t \leq B'_t$ then any policy feasible under B_t is feasible under B'_t.

Remark 2135. *This is the expected monotonicity of constraints: relaxing a budget cannot invalidate an already-feasible policy. Such monotonicity is often used implicitly when comparing architectures or regimes with differing resource levels (Hyperseed-Concept 162; cf. [11] for broader discussion of resource-sensitive cognition).*

Remark 2136. *One operational interpretation is that an attention mechanism tuned to operate safely under scarcity will remain safe when additional compute or time becomes available; the extra budget can be used to enlarge the set of admissible actions, but it need not force any change in behavior. This is important when separating questions of* capability *(what could be done given more budget) from questions of* policy *(what is actually selected).*

Proof sketch. The feasible set $\{u : c(u) \leq B_t\}$ is contained in $\{u : c(u) \leq B'_t\}$.

Remark 2137. *The proof reduces to set inclusion. Once feasibility is expressed as a support constraint (Lemma HT15.10), the result becomes immediate.*

Remark 2138. *Equivalently, writing* $F_t = \{u : c(u) \leq B_t\}$ *and* $F'_t = \{u : c(u) \leq B'_t\}$*, the assumption* $B_t \leq B'_t$ *implies* $F_t \subseteq F'_t$*, so any distribution supported on* F_t *is automatically supported on* F'_t*. This makes clear that monotonicity is a purely set-theoretic consequence of the cost thresholding and does not depend on the particular form of* π_t*.*

Lemma HT15.12 (Feasible renormalization). Fix $\omega \in \Omega_t$ and let $F_t = \{u \in U : c(u) \leq B_t\}$. If $\pi_t(\omega)(F_t) > 0$, then the conditioned distribution

$$\pi_t^{\mathrm{feas}}(\omega)(A) \;:=\; \frac{\pi_t(\omega)(A \cap F_t)}{\pi_t(\omega)(F_t)}$$

defines a policy at ω that is feasible under budget B_t.

Remark 2139. *This lemma formalizes a simple "repair" operation: if a policy sometimes proposes infeasible actions, one can truncate to the feasible set and renormalize. In architectures, this corresponds to an attention controller that samples candidate updates and then vetoes those exceeding budget, resampling (or equivalently conditioning) until a feasible update is obtained.*

Proof sketch. By construction, $\pi_t^{\text{feas}}(\omega)$ assigns probability 1 to F_t, hence is feasible by Lemma HT15.10.

Remark 2140. *The condition $\pi_t(\omega)(F_t) > 0$ is necessary to avoid division by zero. When $\pi_t(\omega)(F_t) = 0$, feasibility cannot be restored by renormalization at that state without changing the policy more drastically (e.g. introducing new mass on F_t), which can be interpreted as the agent lacking any affordable option under its current proposal distribution.*

37.5 Priority scores and entropy-regularized allocation

Assume each pattern p has an event type A_p meaning "p is active/salient" and a goal set $\mathcal{G}$. Define the priority score

$$\mathrm{Prio}_t(p) := \max_{G \in \mathcal{G}} \left|\mathrm{Att}_{O,\Delta}(A_p, G)\right|.$$

Remark 2141. *The explicit time index t is a reminder that $\mathrm{Prio}_t(p)$ may vary as the underlying predictive/attraction quantities (and possibly the goal landscape) evolve. In particular, even if the set of patterns P is fixed, the allocation induced by Prio_t can shift rapidly as different A_p become more or less coupled to the currently-relevant goals. The use of a maximum over $G \in \mathcal{G}$ also implicitly defines a "most relevant goal witness" for each p (not necessarily unique), which can be useful conceptually when interpreting why a pattern is being attended to at time t.*

Fix $\beta > 0$ and (for this subsection) assume P is finite. Define

$$J(\alpha) := \sum_{p \in P} \alpha(p)\,\mathrm{Prio}_t(p) - \frac{1}{\beta} \sum_{p \in P} \alpha(p) \log \alpha(p), \qquad \alpha \in \Delta(P).$$

Remark 2142. *Because $\alpha \in \Delta(P)$, the first term is an expectation $\mathbb{E}_{p\sim\alpha}[\mathrm{Prio}_t(p)]$ while the second term is $(1/\beta)$ times the Shannon entropy $H(\alpha) = -\sum_p \alpha(p) \log \alpha(p)$. In this finite setting, $J(\alpha)$ is always well-defined under the usual convention $0 \log 0 := 0$, and the entropy term ensures that J does not reward degenerate allocations* unless *the priority landscape strongly supports them (i.e., unless β is sufficiently large relative to priority gaps).*

Remark 2143. *The priority score $\mathrm{Prio}_t(p)$ uses the attraction functional $\mathrm{Att}_{O,\Delta}$ from the prediction/attraction machinery (Section 14), turning predictive relationships into a scalar "how much should we care" signal. By taking an absolute value and then a maximum over goals $G \in \mathcal{G}$, we treat both positive and negative attraction as "attention-worthy," and we focus on whichever goal coupling is strongest. This is an explicit formalization of a common cognitive motif: attention is drawn to what is most consequential for current aims (Hyperseed-Concept **??**, **??**). Note that, operationally, the absolute value means that strong "repulsive" or cautionary predictive links can command attention just as much as strong "attractive" links, matching the intuition that both opportunities and threats can be salient drivers of cognitive resource allocation.*

Remark 2144. *The functional $J(\alpha)$ is the familiar tradeoff between expected priority and entropy regularization: the first term rewards placing mass on high-priority patterns, while the second penalizes overly-peaked distributions via $-\sum \alpha \log \alpha$ (Hyperseed-Concept **??**). The parameter β plays* *the role of an inverse temperature: small β enforces diffuse attention; large β permits sharp focus. The information-theoretic characterization via KL divergence below is standard and connects naturally to broader information-theoretic views of cognition (see e.g. [16] for general background). In particular, the entropic term can be read as a complexity/commitment penalty: allocating all mass to a single pattern is "cheap" in terms of expected priority only when the priority gaps justify the loss of entropy.*

Lemma HT15.11.5 (Softmax optimality and KL form). Assume P is finite and $\beta > 0$. Let

$$Z_\beta := \sum_{p \in P} \exp(\beta \operatorname{Prio}_t(p)), \qquad \alpha^*(p) := \frac{\exp(\beta \operatorname{Prio}_t(p))}{Z_\beta}.$$

Then α^* is the unique maximizer of $J(\alpha)$ over $\Delta(P)$, and moreover one has the decomposition

$$J(\alpha) = \frac{1}{\beta} \log Z_\beta \; - \; \frac{1}{\beta} D_{\mathrm{KL}}(\alpha \| \alpha^*), \qquad \alpha \in \Delta(P),$$

where $D_{\mathrm{KL}}(\alpha\|\alpha^*) = \sum_{p \in P} \alpha(p) \log \frac{\alpha(p)}{\alpha^*(p)}$.

Remark 2145. *This identity makes the optimization transparent: maximizing J is equivalent to minimizing the KL divergence to α^*, so J is maximized exactly at $\alpha = \alpha^*$. It also shows that the optimal value is $(1/\beta) \log Z_\beta$, i.e. a log-partition function familiar from statistical mechanics and exponential family theory. Conceptually, α^* is the "least committal" distribution (maximal entropy) among those that still give high expected priority, since any deviation from α^* incurs a precise KL penalty.*

Proof sketch. Rewrite

$$D_{\mathrm{KL}}(\alpha\|\alpha^*) = \sum_{p \in P} \alpha(p) \log \alpha(p) - \beta \sum_{p \in P} \alpha(p) \operatorname{Prio}_t(p) + \log Z_\beta,$$

and rearrange terms to obtain the displayed decomposition of $J(\alpha)$. Since $D_{\mathrm{KL}}(\alpha\|\alpha^*) \geq 0$ with equality iff $\alpha = \alpha^*$, the claims follow. Uniqueness holds because the negative entropy contribution makes J strictly concave on $\Delta(P)$ when $\beta > 0$.

Remark 2146. *The strict concavity point is often useful later: it guarantees stability of the attention allocation in the sense that small perturbations of the priority landscape lead to small perturbations of the optimizer, away from degenerate tie-breaking pathologies that can occur without entropy regularization.*

Lemma HT15.12 (Priority bounds). If $\operatorname{Att}_{O,\Delta}(\cdot,\cdot) \in [-1, 1]$, then $\operatorname{Prio}_t(p) \in [0, 1]$.

Remark 2147. *This lemma ensures priorities are numerically well-behaved: the optimization problem defining $J(\alpha)$ cannot be driven by unbounded scores. It also clarifies why the absolute value and the max do not introduce any pathological scaling: bounded inputs remain bounded outputs. In practical terms, this boundedness helps interpret β consistently across contexts, since β is not forced to compensate for arbitrarily large $\operatorname{Prio}_t(p)$ values.*

Proof sketch. Absolute values are in $[0, 1]$ and the max of numbers in $[0, 1]$ stays in $[0, 1]$.

Remark 2148. *Nothing deeper than interval arithmetic is needed; the lemma is a "range check" that makes later comparisons and limits cleaner. It also implies that any priority differences $\operatorname{Prio}_t(p) - \operatorname{Prio}_t(q)$ lie in $[-1, 1]$, which will bound softmax ratios and prevent extreme numerical blow-ups for moderate β.*

Lemma HT15.13 (Softmax ratio rule). Let $\alpha^*(p) \propto \exp(\beta \operatorname{Prio}_t(p))$ be the softmax distribution. Then for any $p, q \in P$,

$$\frac{\alpha^*(p)}{\alpha^*(q)} = \exp\big(\beta(\operatorname{Prio}_t(p) - \operatorname{Prio}_t(q))\big).$$

Remark 2149. *The ratio rule says that softmax converts* differences *in priority into* multiplicative *changes in probability. This is one reason softmax is such a natural mechanism for attention allocation: it is invariant to adding a constant to all priorities, and it turns relative advantage into relative mass in a controlled exponential way. A useful corollary of the displayed ratio is a Lipschitz-style bound: if* $|\operatorname{Prio}_t(p) - \operatorname{Prio}_t(q)| \leq \varepsilon$*, then the attention ratio lies in* $[e^{-\beta\varepsilon}, e^{\beta\varepsilon}]$*, so priorities close together yield comparable attention weights.*

Proof sketch. Divide the two softmax expressions; the normalizer cancels.

Remark 2150. *The cancellation of the normalizer is the key: it shows that softmax comparisons are local in (p, q) rather than global in P, which is often exploited in analysis and in implementations. It also highlights the scale role of β: the same priority difference produces a larger multiplicative change when β is larger.*

Corollary HT15.14 (Order preservation). If $\operatorname{Prio}_t(p) > \operatorname{Prio}_t(q)$ then $\alpha^*(p) > \alpha^*(q)$.

Remark 2151. *Softmax respects strict priority ordering: the most important patterns (by* Prio_t*) receive strictly more attention mass. This matters because it guarantees that the optimization does not perversely invert the intended ranking of priorities. In the non-strict case,* $\operatorname{Prio}_t(p) = \operatorname{Prio}_t(q)$ *implies $\alpha^*(p) = \alpha^*(q)$, so ties in priority translate exactly into ties in allocated attention.*

Proof sketch. Immediate from Lemma HT15.13 since exp is strictly increasing.

Remark 2152. *The proof reduces to a monotonicity fact about the exponential function, with* $\beta > 0$ *ensuring that "higher priority" really does mean "higher probability." If β were allowed to be negative, the order would reverse, which is another way to see why* $\beta > 0$ *is the natural parameter regime for attention allocation.*

Lemma HT15.15 (Temperature limits). Assume P is finite. As $\beta \to 0^+$, α^* approaches the uniform distribution on P. As $\beta \to \infty$, α^* concentrates on $\arg\max_{p\in P} \operatorname{Prio}_t(p)$.

Remark 2153. *These limits formalize the role of β as a knob between exploration and exploitation. When β is tiny, attention becomes nearly egalitarian (no strong preferences); when β is huge, attention becomes almost deterministic, selecting only the highest-priority patterns (a form of extreme focus). If the argmax set contains multiple maximizers, "concentrates" should be read as assigning vanishing mass to non-maximizers while distributing mass among maximizers; in the common case of equal maximal priorities, the limiting distribution over the maximizers is uniform because their exponentiated scores match.*

Proof sketch. Standard softmax asymptotics: small β flattens exponentials; large β makes the largest exponent dominate.

Remark 2154. *Geometrically, one may think of α^* as moving along a family of distributions from the center of the simplex (uniform) toward a vertex (an argmax selector) as β increases. Analytically, one can view the $\beta \to \infty$ limit as a "hardmax" approximation: for any fixed non-maximizer q and maximizer p, Lemma HT15.13 implies* $\alpha^*(q)/\alpha^*(p) = \exp(-\beta(\operatorname{Prio}_t(p) - \operatorname{Prio}_t(q))) \to 0$*, which forces mass away from q.*

Lemma HT15.16 (KL characterization of the optimum). Let $Z := \sum_{p \in P} \exp(\beta \operatorname{Prio}_t(p))$ and $\alpha^*(p) := \exp(\beta \operatorname{Prio}_t(p))/Z$. Then for any $\alpha \in \Delta(P)$,

$$J(\alpha) = \frac{1}{\beta} \log Z \; - \; \frac{1}{\beta} \operatorname{KL}(\alpha \| \alpha^*).$$

Hence α^* uniquely maximizes J.

Remark 2155. *This lemma reveals that maximizing $J(\alpha)$ is equivalent to minimizing $\operatorname{KL}(\alpha\|\alpha^*)$, i.e. making α as close as possible (in the KL sense) to the softmax distribution dictated by priorities. The constant $\frac{1}{\beta} \log Z$ is the optimum value of J and plays the role of a log-partition function, familiar from statistical mechanics and maximum-entropy reasoning (again aligning with information-theoretic viewpoints as in [16]). In particular, the identity is a finite-dimensional instance of the Gibbs variational principle: the "energy" term $\sum_p \alpha(p) \operatorname{Prio}_t(p)$ together with the entropy regularizer $-\frac{1}{\beta} \sum_p \alpha(p) \log \alpha(p)$ selects precisely the Gibbs/softmax law at inverse temperature β. Interpreting β as a precision (or inverse-noise) parameter makes explicit the exploration–exploitation tradeoff: smaller β yields a flatter α^*, while larger β concentrates mass on high-priority items.*

Proof sketch. Expand $\operatorname{KL}(\alpha\|\alpha^*) = \sum_p \alpha(p) \log \frac{\alpha(p)}{\alpha^*(p)}$ and substitute $\log \alpha^*(p) = \beta \operatorname{Prio}_t(p) - \log Z$. Equivalently,

$$\operatorname{KL}(\alpha\|\alpha^*) = \sum_p \alpha(p) \log \alpha(p) - \sum_p \alpha(p) \log \alpha^*(p) = \sum_p \alpha(p) \log \alpha(p) - \beta \sum_p \alpha(p) \operatorname{Prio}_t(p) + \log Z,$$

so rearranging gives

$$\beta \, J(\alpha) = \log Z - \operatorname{KL}(\alpha\|\alpha^*),$$

which is the claimed decomposition. Note that the argument uses only that $\alpha \in \Delta(P)$ and that Z is finite (automatic when P is finite and $\beta \operatorname{Prio}_t$ is real-valued), so no additional regularity assumptions are needed.

Remark 2156. *The key step is rewriting $-\sum \alpha \log \alpha$ together with $\sum \alpha \operatorname{Prio}$ into a KL divergence expression. Uniqueness follows because $\operatorname{KL}(\alpha\|\alpha^*) \geq 0$ with equality iff $\alpha = \alpha^*$, so $J(\alpha)$ is maximized exactly when the divergence term vanishes. It is also useful to keep in mind limiting cases: as $\beta \to 0^+$, one has $\alpha^* \to$ uniform on P (first-order expansion of $\exp(\beta \operatorname{Prio})$), reflecting maximal entropy; as $\beta \to +\infty$, α^* approaches the set of maximizers of Prio_t (mass concentrates on the argmax, with ties shared), reflecting greedy priority selection. These limits make concrete why the KL form is convenient: it separates a constant optimum value $\frac{1}{\beta} \log Z$ from a nonnegative "regret" term $\frac{1}{\beta}\operatorname{KL}(\alpha\|\alpha^*)$ measuring deviation from the optimal allocation.*

37.6 Varieties of knowledge: basic closure properties

A knowledge type T has carrier K_T, semantics map $\operatorname{Sem}_T : K_T \to S$, update operator(s) Upd_T, and an interface specifying exchange with other types. One can regard K_T as the internal state space of the representation (e.g. a set of formulas, probability tables, vector embeddings, or program traces), Sem_T as the interpretation map into a shared semantic domain S, and Upd_T as the admissible dynamical moves available to that representational substrate. The interface clause is included to ensure that the abstraction can express cross-type operations (translation, querying, consistency checking, feature extraction), which will be essential when discussing closure properties under interaction.

Remark 2157. *The phrase "knowledge type" is used here in an architectural sense: different representational formalisms (logical, probabilistic, neural, analogical, etc.) may have distinct carriers* K_T*, dynamics* Upd_T*, and semantics maps* Sem_T *(Hyperseed-Concept 200). The point of this abstraction is to reason about* collections *of types and about what becomes expressible when one allows them to interact—a central theme in cognitive synergy discussions (see [19]). In particular, the same semantic target* S *allows one to compare outputs of heterogeneous systems at the level of meaning (even if the internal carriers are incomparable), and the interfaces formalize the "glue" by which one type can supply partial structure that another type can refine, compress, or validate.*

Lemma HT15.17 (Monotone enrichment of the architecture cannot reduce expressivity). Let $T \subseteq T'$ be collections of knowledge types. If explanation sets satisfy $E_T(b) \subseteq E_{T'}(b)$, then for any fit threshold τ,

$$\mathrm{Con}^*(T'; \tau) \leq \mathrm{Con}^*(T; \tau).$$

Remark 2158. *This lemma says that adding representational resources cannot make your best achievable explanation* worse *in the contrivance sense: more expressive capacity means a larger feasible set of explanations, hence potentially lower minimal contrivance. It is a formal version of the methodological maxim that adding tools does not force you to use them, but can only enlarge your options (Hyperseed-Concept 191). The condition* $E_T(b) \subseteq E_{T'}(b)$ *captures "monotone enrichment" at the operational level: for each target* b *(e.g. a behavior trace, a dataset, or an observation bundle), every explanation constructible in the smaller architecture remains constructible in the enriched one. Thus the lemma is an immediate closure property: the class of admissible explanations is upward closed under adding types, and the optimal (minimal) contrivance is therefore downward monotone.*

Proof sketch. Con^* is an infimum over admissible explanations; enlarging the admissible set cannot increase the infimum. More explicitly, if $\mathcal{A} := \{e \in E_T(b) : \mathrm{Fit}(e, b) \geq \tau\}$ and $\mathcal{A}' := \{e \in E_{T'}(b) : \mathrm{Fit}(e, b) \geq \tau\}$ denote the feasible explanation sets at threshold τ, then $\mathcal{A} \subseteq \mathcal{A}'$ by hypothesis, and hence

$$\inf_{e \in \mathcal{A}'} \mathrm{Con}(e) \;\leq\; \inf_{e \in \mathcal{A}} \mathrm{Con}(e),$$

which is exactly the claim. The statement remains valid even when the infimum is not attained (i.e. there is no single best explanation), since the order property concerns infima rather than minima.

Remark 2159. *The proof is pure order theory: infima are monotone with respect to set inclusion of the domain over which one takes the infimum. A useful edge-case clarification is that if the feasible set is empty for some* (T, τ)*, then* $\mathrm{Con}^*(T; \tau)$ *is typically defined as* $+\infty$ *(or left undefined); under the* $+\infty$ *convention, the inequality still holds because enlarging the architecture can only turn infeasible instances into feasible ones, never the reverse, again consistent with monotonicity. Conceptually, the lemma isolates a minimal requirement for "synergistic expansion": to guarantee non-degradation of optimal contrivance, it suffices that the enlarged system preserves the smaller system's explanation repertoire as a subset (which is what one expects if* T' *literally contains* T *as a sub-architecture).*

37.7 Cognitive synergy and contrivance

Fix a task/dataset/behavior b. Candidate explanations $E \in E(b)$ have fit $\mathrm{Fit}(E) \in [0, 1]$ and weakness $\mathrm{Weak}(E) \in (0, 1]$. Define contrivance cost

$$\mathrm{Con}(E) := -\log(\mathrm{Weak}(E)) \in [0, \infty).$$

For a knowledge-type collection T and threshold $\tau \in (0,1]$, define

$$\mathrm{Con}^*(T;\tau) := \inf\{\mathrm{Con}(E) : E \in E_T(b),\ \mathrm{Fit}(E) \geq \tau\}.$$

For disjoint T_1, T_2, define synergy gain

$$\Sigma(T_1, T_2; \tau) := \Big(\mathrm{Con}^*(T_1;\tau) + \mathrm{Con}^*(T_2;\tau) - \mathrm{Con}^*(T_1 \cup T_2;\tau)\Big)_+.$$

Remark 2160. *The definition of* $\mathrm{Con}^*(T;\tau)$ *packages two distinct requirements into a single scalar objective: (i) a feasibility requirement* $\mathrm{Fit}(E) \geq \tau$*, and (ii) among feasible explanations, an optimality requirement minimizing contrivance. In particular,* T *only enters through the restricted explanation class* $E_T(b)$ *(i.e. the explanations accessible when one is allowed to draw on knowledge-types* T*), so* Con^* *is best read as a property of an* explanatory interface *rather than of the task* b *alone. When the feasible set* $\{E \in E_T(b) : \mathrm{Fit}(E) \geq \tau\}$ *is empty, the infimum is naturally understood as* $+\infty$*; under this convention, the subsequent lemmas and the definition of* Σ *remain meaningful (e.g. the absence of any adequate explanation is represented as an infinite contrivance requirement).*

Remark 2161. *Although* Fit *is left abstract, it is helpful to keep in mind common instantiations: predictive accuracy, likelihood, held-out log-score, or any task-appropriate performance surrogate normalized to* $[0,1]$*. Likewise,* $\mathrm{Weak}(E)$ *is intentionally* not *a measure of fit; rather it quantifies how "delicate" the explanation is with respect to perturbations, alternative datasets, re-encodings, or other context changes. This separation is important because one can easily achieve high fit with a brittle, over-tailored explanation (high* Fit *but low* Weak*), and the framework is designed to make such tradeoffs explicit.*

Remark 2162. *The pair* $(\mathrm{Fit}(E), \mathrm{Weak}(E))$ *separates* how well *an explanation matches the target behavior from* how contrived *or "fragile" that explanation is. The notion of weakness (Hyperseed-Concept 202) is treated as primary, with contrivance defined as its negative logarithm; this framing aligns with the idea that explanations come with degrees of robustness or "non-contrivance" and that these degrees compose multiplicatively in many settings [2, 3]. The use of* $-\log$ *turns multiplicative structure into additive accounting, much as in information theory and statistical mechanics.*

Remark 2163. *One can read* $\mathrm{Con}(E)$ *as the number of "nats of contrivance" required to support the explanation: a small change in weakness corresponds to an additive change in cost. For instance, if* $\mathrm{Weak}(E)$ *halves, contrivance increases by* $\log 2$*, so the scale is calibrated so that constant multiplicative penalties in weakness produce constant additive penalties in contrivance. This is often the correct qualitative behavior when weakness reflects independent "failure modes" whose probabilities multiply.*

Remark 2164. *Cognitive synergy (Hyperseed-Concept 73) is then the extent to which combining two disjoint knowledge collections* T_1, T_2 *yields an explanation that is* less contrived *than what one would obtain by solving separately and adding the contrivances. The* $(\cdot)_+$ *enforces that synergy is a nonnegative "gain" quantity: if combining yields no advantage (or is worse), the synergy score is* 0*. This style of formalization is consonant with the architectural notion of cognitive synergy in [19].*

Remark 2165. *The disjointness assumption for* T_1, T_2 *is a bookkeeping device ensuring that the "separate solving" baseline does not double-count shared resources; without disjointness, the expression* $\mathrm{Con}^*(T_1;\tau) + \mathrm{Con}^*(T_2;\tau)$ *can overestimate the true separate-solve cost simply because both terms may rely on the same underlying knowledge. In applications where overlap is unavoidable, one typically refines the formalism by splitting* T_1, T_2 *into common and private parts, or by introducing an explicit cost model for reusing shared components.*

Lemma HT15.18 (Basic contrivance calculus). For Weak $\in (0,1]$:

$$\mathrm{Con}(E) \geq 0, \qquad \mathrm{Weak}(E_1) \leq \mathrm{Weak}(E_2) \Longrightarrow \mathrm{Con}(E_1) \geq \mathrm{Con}(E_2), \qquad \mathrm{Con}(E) = 0 \iff \mathrm{Weak}(E) = 1.$$

Remark 2166. *This lemma states that contrivance behaves like a cost: it is nonnegative, it decreases when weakness increases (so "stronger" explanations are cheaper), and it vanishes exactly at maximal weakness* 1 *(i.e. no contrivance at all). The monotone reversal is the essential philosophical point: weakness is a kind of* capacity for non-accidentalness, *and contrivance is its additive shadow.*

Remark 2167. *Interpreting the boundary cases can also be helpful. As* $\mathrm{Weak}(E) \to 0^+$, $\mathrm{Con}(E) \to +\infty$*, representing that an explanation that is arbitrarily fragile carries an arbitrarily large "contrivance debt." Conversely,* $\mathrm{Weak}(E) = 1$ *acts as a normalization convention: it marks the ideal of complete non-contrivance in the chosen weakness scale, so that all other costs are measured relative to that baseline.*

Proof sketch. $-\log$ maps $(0,1]$ to $[0,\infty)$ and is monotone decreasing; $-\log 1 = 0$.

Remark 2168. *The proof uses only elementary calculus properties of* log*. The logarithm is the canonical bridge from multiplicative to additive reasoning, which is why it appears so often when one seeks a "cost" corresponding to a "strength" or "weight."*

Lemma HT15.19 (Threshold monotonicity). If $\tau_1 \leq \tau_2$ then $\mathrm{Con}^*(T;\tau_1) \leq \mathrm{Con}^*(T;\tau_2)$.

Remark 2169. *Demanding a higher fit threshold* τ_2 *restricts the set of admissible explanations, so the best achievable contrivance cannot improve; at best it stays the same, and typically it worsens. This lemma ensures that* τ *behaves as a genuine "difficulty dial" for explanation.*

Remark 2170. *It is worth noting that the inequality may be strict even when both thresholds are achievable: raising* τ *can force one to move from a simple, robust explanation to a more baroque one that chases residual errors. In that sense, the map* $\tau \mapsto \mathrm{Con}^*(T;\tau)$ *can be read as an "optimal fragility curve" (or cost–fit tradeoff frontier) for the knowledge collection* T *on behavior* b*.*

Proof sketch. The constraint $\mathrm{Fit}(E) \geq \tau_2$ is stricter, so the feasible set shrinks, making the infimum weakly larger.

Remark 2171. *Again the logic is order-theoretic: constraints create subset relations among feasible sets, and infima respect those inclusions.*

Lemma HT15.20 (Symmetry and nonnegativity of synergy gain).

$$\Sigma(T_1, T_2; \tau) = \Sigma(T_2, T_1; \tau) \geq 0.$$

Moreover, $\Sigma(T_1, T_2; \tau) > 0$ iff $\mathrm{Con}^*(T_1 \cup T_2; \tau) < \mathrm{Con}^*(T_1; \tau) + \mathrm{Con}^*(T_2; \tau)$.

Remark 2172. *The statement says that synergy is not directional (swapping the two parties changes nothing), and that it is genuinely a* gain *rather than a signed difference. The "iff" clause clarifies that positive synergy is exactly strict subadditivity of optimal contrivance under union.*

Remark 2173. *The truncation* $(\cdot)_+$ *also makes the quantity robust to cases where combining knowledge introduces overheads (coordination costs, representational mismatch, or search complexity) that could in principle worsen the best achievable contrivance. In such cases, the framework does not force "negative synergy"; instead it records an absence of gain, aligning the interpretation of* Σ *as an advantage measure rather than as a signed interaction term.*

Proof sketch. Symmetry is by commutativity of $+$ and $\cup$. Nonnegativity is by definition of $(\cdot)_+$. Strictness equivalence follows from $(x)_+ > 0 \iff x > 0$.

Remark 2174. *The proof is essentially definitional, but this is not a defect: it shows that the chosen formalization of* Σ *faithfully encodes the intended informal meaning.*

Lemma HT15.21 (Multiplicative weakness ⇒ subadditive contrivance). Assume explanations can be composed $(E_1 \otimes E_2)$ and satisfy

$$\mathrm{Weak}(E_1 \otimes E_2) \geq \mathrm{Weak}(E_1)\mathrm{Weak}(E_2).$$

Then

$$\mathrm{Con}(E_1 \otimes E_2) \leq \mathrm{Con}(E_1) + \mathrm{Con}(E_2).$$

Remark 2175. *This lemma formalizes a key compositional intuition: if combining explanations does not make them disproportionately weaker (indeed, it is at least multiplicative in weakness), then the contrivance cost of the combination is at most the sum of the costs. This is precisely the reason to define contrivance using* $-\log$*: it linearizes multiplicative composition into additive bounds [3].*

Remark 2176. *The assumption* $\mathrm{Weak}(E_1 \otimes E_2) \geq \mathrm{Weak}(E_1)\mathrm{Weak}(E_2)$ *can be read as an "at-most-independent failure" postulate: the composed explanation fails no more often than would be predicted if the fragilities of the parts were independent. If in a given domain one expects positive interaction (composition is* more *robust than independence would suggest), then the inequality may hold with slack, strengthening the resulting subadditivity; conversely, if composition introduces new coupled failure modes, the inequality can fail, corresponding to superadditive contrivance.*

Proof sketch. Apply $-\log(\cdot)$ and use $-\log(xy) = -\log x - \log y$ plus monotonicity of $-\log$.

Remark 2177. *The inequality direction is worth lingering on: because* $-\log$ *is decreasing, a lower bound on weakness becomes an upper bound on contrivance. This reversal is the algebraic heart of the lemma.*

Remark 2178. *In many modeling contexts,* $\otimes$ *may correspond to conjunction of sub-claims, modular program composition, or assembling a pipeline whose stages provide complementary constraints on* b*. The lemma then reads as: if robustness (weakness) composes at least multiplicatively across stages, then the "extra contrivance" of the combined pipeline is controlled by the sum of stage-wise contrivances, making additive accounting of explanatory fragility consistent across levels of abstraction.*

Corollary HT15.22 (No-penalty combination bound). Under the same multiplicative weakness assumption, for all disjoint T_1, T_2 and all τ,

$$\mathrm{Con}^*(T_1 \cup T_2; \tau) \leq \mathrm{Con}^*(T_1; \tau) + \mathrm{Con}^*(T_2; \tau).$$

Hence

$$\Sigma(T_1, T_2; \tau) = \mathrm{Con}^*(T_1; \tau) + \mathrm{Con}^*(T_2; \tau) - \mathrm{Con}^*(T_1 \cup T_2; \tau).$$

Remark 2179. *This corollary says that if weakness composes multiplicatively, then combining knowledge sources cannot impose a contrivance penalty beyond the sum of separate solutions. In that case, the "*$(\cdot)_+$*" in* Σ *becomes unnecessary: the raw difference is already nonnegative.*

Remark 2180. *The disjointness condition $T_1 \cap T_2 = \varnothing$ is the formal way to say that the two sources are not literally reusing the same task instances (or the same labeled constraints) twice. Without disjointness, one can still derive related bounds, but they typically require additional bookkeeping for overlap (e.g., avoiding double-counting of shared constraints) or a modified notion of union that accounts for redundancy. The parameter τ plays the role of a fixed acceptability threshold for fit: the infimum defining $\mathrm{Con}^*(\cdot;\tau)$ is taken only over those explanations whose Fit clears the same bar in each term, so the comparison is genuinely "like-for-like" across T_1, T_2, and $T_1 \cup T_2$.*

Proof sketch. Use Lemma HT15.21 on ε-optimal explanations for T_1 and T_2, then take infima and let $\varepsilon \to 0$.

Remark 2181. *A slightly more explicit way to view the ε-optimal step is: fix $\varepsilon > 0$ and pick admissible E_1, E_2 with $\mathrm{Fit}(E_i) \geq \tau$ such that $\mathrm{Con}(E_i) \leq \mathrm{Con}^*(T_i;\tau) + \varepsilon$. Apply Lemma HT15.21 (the candidate-level multiplicative-weakness composition bound, translated into contrivance language) to obtain an admissible combined explanation E for $T_1 \cup T_2$ with $\mathrm{Fit}(E) \geq \tau$ and $\mathrm{Con}(E) \leq \mathrm{Con}(E_1) + \mathrm{Con}(E_2)$. Taking the infimum over all admissible E for $T_1 \cup T_2$ yields $\mathrm{Con}^*(T_1 \cup T_2;\tau) \leq \mathrm{Con}(E) \leq \mathrm{Con}^*(T_1;\tau) + \mathrm{Con}^*(T_2;\tau) + 2\varepsilon$, and then $\varepsilon \to 0$ gives the stated inequality.*

Remark 2182. *The ε-optimal trick is standard when passing from pointwise inequalities about candidates to inequalities about infima: you approximate the infimum by near-minimizers, apply the candidate-level inequality, and then let ε shrink away.*

Remark 2183. *One practical reason to emphasize the "infimum + ε" pattern is that Con^* need not be attained by any single explanation: there may be no true minimizer because one can construct a sequence of explanations that approach the optimal tradeoff but never quite reach it (e.g., by allocating ever-more parameters in a way that asymptotically improves fit while shaving contrivance). The corollary is therefore stated (and proved) in a way that remains valid even in non-compact hypothesis classes where minimizers fail to exist.*

Lemma HT15.23 (Synergy in "best-achievable weakness" form). Assume the supremum exists and define

$$\mathrm{Weak}^*(T;\tau) := \sup\{\mathrm{Weak}(E) : E \in E_T(b),\ \mathrm{Fit}(E) \geq \tau\}.$$

Then $\mathrm{Con}^*(T;\tau) = -\log(\mathrm{Weak}^*(T;\tau))$ and cognitive synergy (strict) is equivalent to

$$\mathrm{Weak}^*(T_1 \cup T_2;\tau) > \mathrm{Weak}^*(T_1;\tau)\,\mathrm{Weak}^*(T_2;\tau).$$

Remark 2184. *This lemma rewrites the entire story in terms of the* best achievable weakness *rather than the* least contrivance*. It is often psychologically and architecturally more natural to say "how robust can we get?" than "how contrived must we be?" Strict synergy then becomes strict supermultiplicativity of the best achievable weakness under union.*

Remark 2185. *Because $\mathrm{Con} = -\log(\mathrm{Weak})$, it is implicitly understood that $\mathrm{Weak}(E) \in (0,1]$ on the admissible set (or at least is strictly positive whenever $\mathrm{Con}(E)$ is finite). If $\mathrm{Weak}^*(T;\tau) = 0$, then the formula reads $\mathrm{Con}^*(T;\tau) = -\log 0 = +\infty$, matching the intuition that if no τ-fit explanation has any positive weakness score, then the "least contrivance" required at that threshold is effectively unbounded. When $\mathrm{Weak}^*(T;\tau) = 1$, the contrivance optimum becomes 0, i.e., maximal robustness corresponds to minimal contrivance in this scale.*

Proof sketch. Because $-\log$ is decreasing, $\inf_E(-\log \mathrm{Weak}(E)) = -\log(\sup_E \mathrm{Weak}(E))$. Translate strict subadditivity of $-\log$ into strict supermultiplicativity of Weak^*.

Remark 2186. *Unpacking the order reversal: for any set* $S \subseteq (0,1]$*, the map* $x \mapsto -\log x$ *satisfies* $\inf_{x\in S}(-\log x) = -\log(\sup_{x\in S} x)$ *because (i)* $\sup S$ *is the largest achievable (or approximable) weakness and (ii) decreasing monotonicity makes the largest weakness correspond to the smallest contrivance. The strict synergy inequality in contrivance form,*

$$\mathrm{Con}^*(T_1 \cup T_2; \tau) < \mathrm{Con}^*(T_1; \tau) + \mathrm{Con}^*(T_2; \tau),$$

becomes, after exponentiating both sides with $\exp(-\cdot)$*, precisely the displayed strict supermultiplicativity of* Weak^*.

Remark 2187. *The proof is a clean example of a Galois-like duality between additive and multiplicative domains, mediated by the logarithm. It also clarifies why taking an infimum in one picture corresponds to taking a supremum in the other: the monotonicity reversal of* $-\log$ *swaps the order.*

Remark 2188. *This reformulation is also useful diagnostically: if one empirically estimates* Weak^* *(e.g., by best-of-N search over admissible explanations), then synergy can be tested as a multiplicative gap rather than an additive one. In particular, the inequality compares* ratios *of robustness rather than* differences *in contrivance, which can be numerically more stable when contrivance values are large but weakness values remain within a bounded scale.*

Lemma HT15.24 (Emergent compression implies multiplicative improvement). If an explanation E satisfies $\mathrm{Con}(E) < \mathrm{Con}(E_1)+\mathrm{Con}(E_2)$ for all admissible decompositions $E \approx E_1 \otimes E_2$, then equivalently

$$\mathrm{Weak}(E) > \mathrm{Weak}(E_1)\mathrm{Weak}(E_2) \quad \text{for all such decompositions.}$$

Remark 2189. *This lemma states the same phenomenon in two languages. The left-hand side is phrased as "emergent compression":* E *is cheaper (less contrived) than any decomposition into parts. The right-hand side says that, in weakness terms,* E *is stronger than any multiplicative combination of candidate parts. One may view this as a precise sense in which "the whole is more than the product of its parts," but expressed in a rigorously constrained way.*

Remark 2190. *The notation* $E \approx E_1 \otimes E_2$ *is intentionally permissive: it allows the decomposition relation to encode whatever equivalence or approximation notion is appropriate for the model class (e.g., functional equivalence on* T*, approximation in predictive distribution, or representational factorization up to a tolerated error). The lemma does not require that* every *explanation decomposes, only that whenever a decomposition is admissible under the chosen relation, the stated strict inequality compares* E *against that candidate factorization. Thus "emergent compression" is a universal quantification over the allowed factorization set, not a claim about existence of any particular* E_1, E_2.

Proof sketch. Exponentiate $-\mathrm{Con} = \log \mathrm{Weak}$ to turn $<$ on costs into $>$ on multiplicative weakness.

Remark 2191. *Formally:* $\mathrm{Con}(E) < \mathrm{Con}(E_1)+\mathrm{Con}(E_2)$ *is equivalent to* $-\mathrm{Con}(E) > -(\mathrm{Con}(E_1)+\mathrm{Con}(E_2))$*, and applying* $\exp$ *gives* $\exp(-\mathrm{Con}(E)) > \exp(-\mathrm{Con}(E_1))\exp(-\mathrm{Con}(E_2))$*. Using* $\mathrm{Weak} = \exp(-\mathrm{Con})$ *(equivalently,* $-\mathrm{Con} = \log \mathrm{Weak}$*) yields exactly* $\mathrm{Weak}(E) > \mathrm{Weak}(E_1)\mathrm{Weak}(E_2)$*. The converse direction reverses the steps with* $\log$*, noting again that strict inequalities are preserved because both* $\exp$ *and* $\log$ *are strictly increasing on the relevant domain.*

Remark 2192. *The strategy is the standard invertibility of the* $\log / \exp$ *transform: strict inequalities are preserved because* $\exp$ *is strictly increasing. Conceptually, the lemma explains why "compression" and "robustness gain" are the same structural claim viewed through different lenses (Hyperseed-Concept 169, 82).*

Remark 2193. *It is worth noting that the strictness matters: a non-strict inequality* $\mathrm{Con}(E) \leq \mathrm{Con}(E_1) + \mathrm{Con}(E_2)$ *would translate to* $\mathrm{Weak}(E) \geq \mathrm{Weak}(E_1)\mathrm{Weak}(E_2)$ *and would permit "no-emergence" cases where* E *is exactly as compressible/robust as the best factorization. The strict form isolates genuinely synergistic structure in* E *that cannot be matched even by the most favorable admissible decomposition into two parts.*

37.8 Synergy, budgets, and attention gating

Fix fit threshold τ and contrivance budget B. Define "solvable by T at budget B" as $\mathrm{Con}^*(T;\tau) \leq B$.

Remark 2194. *Here* τ *plays the role of a required level of adequacy (e.g. predictive accuracy, likelihood, or any task-specific fit functional fixed earlier), while* B *is the maximum admissible "engineering cost" as measured by contrivance. In particular,* $\mathrm{Con}^*(T;\tau)$ *should be read as the* minimum *contrivance over all explanations drawn from the model/explanation class associated with knowledge types* T *that achieve fit at least* τ*. Thus "solvable" is a feasibility statement about whether the architecture can meet the fit requirement without exceeding a resource cap, which mirrors how systems are typically evaluated under explicit compute/communication constraints.*

Remark 2195. *This subsection connects the abstract synergy notion to resource allocation: an architecture may in principle admit synergistic explanations, yet in practice those explanations may be unreachable without dedicating attention/bandwidth to cross-type communication (Hyperseed-Concept* **??***, 88). The language of budgets and gating mirrors engineering concerns in cognitive architectures [19].*

Remark 2196. *The central distinction is between (i)* representational possibility *(the union of types* $T_1 \cup T_2$ *contains enough ingredients to form a low-contrivance explanation) and (ii)* operational accessibility *(the system actually allocates sufficient routing/attention so that those ingredients can interact during construction or inference). The lemmas below formalize how changing the available types, the allowed budget, or the permitted cross-type bandwidth changes what can be achieved at or below the threshold* τ*.*

Lemma HT15.25 (Solvability monotonicity). If $T \subseteq T'$ and $B \leq B'$, then

$$\mathrm{Con}^*(T;\tau) \leq B \Longrightarrow \mathrm{Con}^*(T';\tau) \leq B'$$

(i.e. solvability is monotone in knowledge and budget).

Remark 2197. *If you can solve the task with fewer knowledge types and a smaller budget, then you can certainly solve it with more knowledge types and a larger budget. This is a basic monotonicity property, but it is essential for reasoning about developmental or iterative improvements: adding modules or resources cannot retroactively destroy solvability.*

Remark 2198. *Conceptually,* $T \subseteq T'$ *means the enlarged system can emulate the smaller one by simply ignoring the additional types, so the feasible set of explanations for* T' *contains (or at least does not exclude) the feasible set for* T*. Meanwhile* $B \leq B'$ *means the constraint is relaxed: any* *explanation that was admissible under the stricter cap remains admissible under the looser cap. The lemma packages these two ideas into a single implication that will be used repeatedly when comparing architectures across training stages or across different attention/communication configurations.*

Proof sketch. Use Lemma HT15.17 for $T \subseteq T'$ and the trivial monotonicity in B.

Remark 2199. *The proof composes two monotonicities: architectural enrichment improves (or preserves) the optimum, and increasing the allowed budget relaxes the feasibility condition.*

Remark 2200. *More explicitly, Lemma HT15.17 provides* $\mathrm{Con}^*(T';\tau) \le \mathrm{Con}^*(T;\tau)$ *when* $T \subseteq T'$*. If* $\mathrm{Con}^*(T;\tau) \le B$ *and* $B \le B'$*, then* $\mathrm{Con}^*(T';\tau) \le \mathrm{Con}^*(T;\tau) \le B \le B'$*, yielding solvability of* T' *at budget* B'*. The point is not the algebra but the interpretive consequence: any later-stage system that strictly adds capacities (types or resources) inherits the earlier feasibility guarantees.*

Lemma HT15.26 (Gating principle as a formal reduction; conditional). Let Γ be the inter-type communication graph on knowledge types with time-dependent bandwidth allocations $b_t(T \to T') \ge 0$ satisfying $\sum_{T,T'} b_t(T \to T') \le B_t$. Assume the model class $E_{T_1 \cup T_2}(b)$ is *restricted* by bandwidth as follows: if all cross edges between T_1 and T_2 have zero bandwidth, then only separable explanations $E \approx E_1 \otimes E_2$ are admissible (no emergent cross-type constructions). Then if all b_t between T_1 and T_2 are 0 for the relevant interval,

$$\mathrm{Con}^*(T_1 \cup T_2;\tau) = \mathrm{Con}^*(T_1;\tau) + \mathrm{Con}^*(T_2;\tau) \quad \text{and hence} \quad \Sigma(T_1, T_2;\tau) = 0.$$

Remark 2201. *This lemma articulates a precise "gating" thesis: synergy is not merely a property of having multiple knowledge types present, but of permitting them to communicate. When the bandwidth on cross edges is identically zero, the combined system is forced to behave like two independent subsystems, so the best combined explanation decomposes and no synergy can be expressed. The result provides a formal handle on the engineering intuition that attention and communication resources must be allocated to enable cognitive synergy [19].*

Remark 2202. *The bandwidth variables* $b_t(T \to T')$ *can be read as a quantitative proxy for attentional routing or message-passing capacity at time* t*: they indicate how much of the overall budget* B_t *is spent on transferring representations, constraints, or partial hypotheses from one type to another. The assumption "zero cross edges implies only separable explanations" is intentionally strong and therefore clearly identifiable as a conditional modeling choice: it encodes the claim that* constructing *cross-type structure is itself a communication-dependent act, not merely a post-hoc interpretation. Under this assumption, any emergent term that would mix variables, symbols, or latent factors across* T_1 *and* T_2 *is literally out of class when the gate is closed.*

Remark 2203. *The notation* $E \approx E_1 \otimes E_2$ *is meant to emphasize a factorization (or product) structure rather than exact equality of functions: the admissible joint explanations are those that can be represented as a composition of two explanations that do not exchange internal state. In concrete instantiations, this could correspond to additive decompositions of loss, block-diagonal parameterizations, independent latent variable models, or any architectural constraint that prevents cross-attention or cross-feature conjunctions between the two subsystems.*

Proof sketch. Under the restriction, $E_{T_1 \cup T_2}(b)$ coincides with the partition-limited class. Therefore the best achievable contrivance is exactly the sum of the two independent optima. This makes synergy latent but not expressible without allocating attention/bandwidth to communication.

Remark 2204. *At a high level, the proof strategy is to identify a collapse of hypothesis classes: with zero bandwidth, the admissible class for $T_1 \cup T_2$ becomes the same as the "separable" class. Once this identification is made, the equality of optima is not mysterious: the joint optimization problem literally factorizes into two independent ones. Visually, one may imagine Γ as a graph whose cut edges between T_1 and T_2 are removed; after the cut, there is no path by which information can flow, so emergent cross-type structure is prohibited by assumption.*

Remark 2205. *The equality* $\mathrm{Con}^*(T_1 \cup T_2; \tau) = \mathrm{Con}^*(T_1; \tau) + \mathrm{Con}^*(T_2; \tau)$ *is best interpreted as an* additivity of minimal costs *when the admissible set of joint explanations is restricted to separable ones: any feasible E decomposes into E_1 and E_2, and the contrivance objective correspondingly decomposes (as in the earlier definition of synergy via additivity gaps). Consequently, the synergy quantity $\Sigma(T_1, T_2; \tau)$, defined as the amount by which the joint optimum beats the sum of separate optima, must vanish because the joint model class contains no mechanisms capable of achieving a strictly sub-additive construction. This clarifies the sense in which gating can turn a potentially synergistic pair of types into a merely parallel, non-interacting pair.*

38 Helper theorems for Section 17: consciousness, reflective will, and autonomy

This section collects small derived facts that are convenient for mechanized reasoning with the Section 17 interface (p-bit evidence states, attention-weighted aggregation, workspace closure, reflective introspection, coherence scores, will/autonomy, and the two-channel update).

Remark 2206. *A useful way to read this section is as a miniature "algebra of mindedness": we take evidence values in $V = [0,1]^2$ (a p-bit, i.e. a two-component degree of positive and negative support), assemble these into evidence states $E : L \to V$ over a proposition language L, and then show that the resulting constructions behave well under standard order-theoretic operations. This order-theoretic hygiene is not mere pedantry: it is what lets one use fixed-point theorems to speak precisely about stability of "workspace" closure and self-referential updates, in a way that can be automated and composed modularly.*

Remark 2207. *The underlying perspective is broadly compatible with a global-workspace style semantics for conscious content (in the weak, formal sense of* Con_θ *defined below), together with an explicitly paraconsistent representation of evidence via $[0,1]^2$ (cf. constructive/paraconsistent logics and evidence-pair semantics, e.g. [23, 24]). On the cognitive-architectural side, the interplay between attention-weighting, workspace closure, and reflective/introspective tokens echoes the "cognitive synergy" viewpoint [19, 5], while the use of quantale-like joins/tensors aligns with the "weakness" and quantale weakness viewpoint [3, 2] (see also Hyperseed-Concept 143).*

Concretely, the point of working with $V = [0,1]^2$ is that it supports an explicit separation between *support-for* and *support-against* the same proposition, without forcing these channels to collapse into a single probability-like quantity. In particular, one may have both high positive and high negative components simultaneously, representing the presence of strong but conflicting lines of evidence (a common situation in reflective or self-modeling settings), and the subsequent reasoning steps can be set up so that such conflict is carried rather than erased.

As a standing convention, evidence states $E : L \to V$ inherit most operations *pointwise* from V. Thus, whenever V is equipped with an order $\leq_V$ (typically the product order on $[0,1]^2$, unless explicitly stated otherwise), one obtains an induced order on evidence states by

$$E \leq E' \quad :\Longleftrightarrow \quad (\forall \varphi \in L)\ E(\varphi) \leq_V E'(\varphi),$$

and similarly for joins/meets (when they exist). This is the basic mechanism by which lattice- and quantale-flavored structure on V lifts to the "state space" V^L, letting one state the helper theorems in a uniform way: monotonicity, continuity (in the order-theoretic sense), existence of least/greatest fixed points, and closure properties can all be proved once and then reused across attention, workspace, and reflective operators.

The interface components mentioned above can also be read in this order-theoretic light. Attention-weighted aggregation is treated as an operator that combines multiple local pieces of evidence into a single evidence value (or state), with weights serving as a controlled bias in how joins or convex-like mixtures are taken. Workspace closure is treated as a closure operator (or, more generally, a monotone inflationary operator) on evidence states; its fixed points correspond to "stable workspaces" in which adding the closure consequences does not further change what is globally available. Reflective introspection introduces new tokens (e.g. propositions describing what is in the workspace, what is attended to, or what the agent takes itself to endorse), and the helper theorems ensure that introducing these tokens preserves the key monotonicity and fixed-point conditions needed for mechanized proofs.

Finally, the role of the two-channel update is to keep the positive and negative components synchronized with the dynamics of closure and reflection: the update rules can be analyzed as endomaps on V^L whose algebraic properties (e.g. monotonicity, compatibility with joins, or nonexpansiveness with respect to a chosen order/metric) determine whether iterative application converges, oscillates, or admits stable equilibria. The helper results in this section are therefore intended to function as "glue lemmas": they connect the cognitive reading (attention, workspace, will) to the mathematical backbone (orders, closure, fixed points), enabling later arguments to be stated compositionally rather than re-proved from scratch.

38.1 Evidence-state algebra and attention-weighted integration

Proposition 47 (Evidence-state lattices are complete). *Let $V = [0,1]^2$ with the componentwise order, and let L be any set of propositions. Then V^L (evidence states $E : L \to V$) is a complete lattice under the pointwise order. Joins and meets are computed pointwise, i.e.*

$$\Big(\bigvee_i E_i\Big)(\varphi) = \bigvee_i E_i(\varphi), \qquad \Big(\bigwedge_i E_i\Big)(\varphi) = \bigwedge_i E_i(\varphi).$$

Remark 2208. *Intuitively, an evidence state $E : L \to V$ assigns to each proposition $\varphi \in L$ a pair $E(\varphi) = (E^+(\varphi), E^-(\varphi)) \in [0,1]^2$, recording "support for" and "support against." The componentwise order on V means $(v^+, v^-) \le (w^+, w^-)$ iff $v^+ \le w^+$ and $v^- \le w^-$; the pointwise order on V^L then means $E \le E'$ iff this holds for every $\varphi \in L$. The claim that V^L is a complete lattice says, in effect, that we can coherently take suprema and infima of* arbitrary *families of evidence states, proposition-by-proposition.*

Remark 2209. *A simple example is when $L = \{\varphi, \psi\}$ is finite: then an evidence state is just a pair of p-bits, e.g. $E(\varphi) = (0.8, 0.1)$ and $E(\psi) = (0.3, 0.6)$. Given two evidence states E_1, E_2, their join $E_1 \vee E_2$ is computed by taking the join in V separately at φ and at ψ. Completeness matters because later we invoke Tarski-style fixed point results: these require complete lattices as the ambient domain on which closure operators (e.g. workspace closure) act.*

Remark 2210. What this is for. *In the later subsections, we treat workspace and reflective updates as monotone endomaps on evidence states. Completeness is the condition under which monotone dynamics have well-behaved fixed points and extremal fixed points (least/greatest), allowing one to speak rigorously about stable conscious content in the sense of Hyperseed-Concept 85.*

Remark 2211 (Intuition before the proof). *The proposition is a straightforward instance of a general idea: if your basic truth-values form a complete lattice, then functions assigning such values to propositions inherit completeness by taking suprema and infima pointwise. One may think of V^L as an L-indexed "field" of local degrees, and joins/meets as taking the best/worst local degrees everywhere at once.*

Sketch. V is a complete lattice because $[0,1]$ is complete and products of complete lattices are complete. Powers V^L inherit completeness under pointwise order, with pointwise sup/inf. □

Remark 2212. Proof sketch (high-level strategy). *The proof reduces the claim to two closure properties: (1) $[0,1]$ has all suprema/infima; (2) products and function spaces preserve completeness when ordered pointwise. This is a standard order-theoretic pipeline: build complex semantic domains from simpler ones, and transport lattice structure along the construction.*

Remark 2213. Why the key step works. *Completeness of $[0,1]$ is the analytic fact that every bounded set has a supremum and infimum. The rest is "coordinatewise reasoning": the supremum of a family of pairs is the pair of suprema, and the supremum of a family of functions is the function of suprema. Geometrically, $V = [0,1]^2$ is the unit square; a join takes the least upper bound in this square, and doing this pointwise over $\varphi \in L$ simply repeats that operation for each proposition.*

Proposition 48 (Explicit coordinate form of Γ_a in the canonical p-bit quantale). *Assume the canonical p-bit quantale operations on V:*

$$(v^+, v^-) \oplus (w^+, w^-) = (\max\{v^+, w^+\}, \max\{v^-, w^-\}), \qquad (v^+, v^-) \otimes (w^+, w^-) = (v^+w^+, v^-w^-),$$

and the scalar embedding $\alpha \mapsto (\alpha, \alpha)$ for $\alpha \in [0,1]$. Then for module evidence states $E_m : L \to V$ and attention $a : M \to [0,1]$, the integrated state $\Gamma_a(E_\bullet) : L \to V$ satisfies, for each $\varphi \in L$,

$$(\Gamma_a(E_\bullet))^+(\varphi) = \max_{m \in M} a(m)\, E_m^+(\varphi), \qquad (\Gamma_a(E_\bullet))^-(\varphi) = \max_{m \in M} a(m)\, E_m^-(\varphi).$$

Remark 2214. *Here the notation is doing a fair amount of work, so it is worth pausing over it.*

- *M is the set of modules (subsystems) contributing evidence.*
- *$a : M \to [0,1]$ is an attention weighting (Hyperseed-Concept 60): $a(m)$ is the degree to which module m is "listened to".*
- *$E_m : L \to V$ is module m's evidence state; we write $E_m(\varphi) = (E_m^+(\varphi), E_m^-(\varphi))$.*
- *$\Gamma_a(E_\bullet)$ denotes the integrated evidence state after attention-weighted aggregation.*
- *$\oplus$ is a join-like operator (here: componentwise* max*); $\otimes$ is a tensor-like operator (here: componentwise multiplication). This is a canonical quantale-style choice [3] (Hyperseed-Concept 143).*

Remark 2215. *Intuitively, the formula says: to compute overall positive evidence for φ, look at each module's positive evidence $E_m^+(\varphi)$, downweight it by attention $a(m)$, and then take the maximal such attended value across modules. The negative coordinate behaves analogously. Thus Γ_a implements a kind of attentional "winner-take-most" integration: the most attended, most confident module dominates, coordinatewise.*

Remark 2216. *A simple example: suppose $M = \{1,2\}$, $a(1) = 1$, $a(2) = 0.5$, and at proposition φ one has $E_1(\varphi) = (0.4, 0.2)$ and $E_2(\varphi) = (0.9, 0.1)$. Then*

$$(\Gamma_a(E_\bullet))^+(\varphi) = \max\{1 \cdot 0.4,\ 0.5 \cdot 0.9\} = \max\{0.4, 0.45\} = 0.45,$$

so module 2 wins on the positive coordinate only because its higher evidence compensates for lower attention. This kind of tradeoff is precisely what makes attention mathematically meaningful rather than merely a label. In the same numerical setup one can also read off the negative coordinate:

$$(\Gamma_a(E_\bullet))^-(\varphi) = \max\{1 \cdot 0.2,\ 0.5 \cdot 0.1\} = \max\{0.2, 0.05\} = 0.2,$$

so module 1 *still "wins" on the negative component. Thus even with only two modules the integrated state may be* coordinatewise *assembled from different sources, making explicit that Γ_a is not necessarily selecting a single module's whole pair (E_m^+, E_m^-), but rather forming the least upper bound in the product order by taking the best supported positive and best supported negative contributions separately.*

Remark 2217 (Intuition before the proof)**.** *The proof is essentially bookkeeping: start from the abstract definition of Γ_a as a join ($\oplus$) over modules of an attention-scaled tensor product ($\otimes$) with each module's evidence value, and then substitute the concrete forms of $\oplus$ and $\otimes$. Because $\oplus$ is* max *here, the whole expression collapses to a maximum over m of scaled coordinates. Concretely, the bookkeeping has two distinct "pointwise" aspects that are easy to conflate: the join is taken over* $m \in M$ for each fixed *proposition φ, and the resulting inequality/equality claims are then interpreted pointwise over propositions in L. This is why the explicit coordinate formulas are especially helpful: they avoid switching between these two pointwise readings mid-argument.*

Sketch. Unpack the definition $(\Gamma_a E_\bullet)(\varphi) = \bigoplus_{m\in M} a(m) \otimes E_m(\varphi)$. With the diagonal embedding, $a(m) \otimes (E_m^+, E_m^-) = (a(m)E_m^+, a(m)E_m^-)$. Then $\oplus$ takes componentwise maxima over m. ☐

Remark 2218. Proof sketch (high-level strategy). *The computation is a direct evaluation: (i) expand Γ_a at a proposition φ; (ii) apply the scalar embedding so attention becomes a p-bit; (iii) apply the tensor rule to obtain coordinatewise products; (iv) apply the join rule to obtain coordinatewise maxima. A useful way to remember the roles is that $\otimes$ models* within-module *attenuation (how a module's own evidence is weakened by limited access to the workspace), while $\oplus$ models* between-module *pooling (which module provides the strongest candidate contribution once attenuated).*

Remark 2219. Visual intuition. *For a fixed φ, each module contributes a point in the unit square $[0,1]^2$, which is then shrunk toward $(0,0)$ by the scalar factor $a(m)$. The operator $\oplus$ then takes the least upper bound in the product order, which for this canonical choice is exactly the coordinatewise upper envelope (componentwise maximum). One may picture $\Gamma_a(E_\bullet)(\varphi)$ as the "upper-right" corner of the set of attended points. Equivalently, if one draws axis-aligned rectangles from the origin to each attended point $(a(m)E_m^+(\varphi), a(m)E_m^-(\varphi))$, then the join is the unique point whose rectangle contains all the others and is minimal with that property. This makes clear why the join need not coincide with any single attended point when different modules dominate different coordinates.*

Proposition 49 (Monotonicity and uniform rescaling of attention)**.** *Assume the canonical operations above. If $a \le a'$ pointwise and $E_m \le E'_m$ pointwise for all m, then $\Gamma_a(E_\bullet) \le \Gamma_{a'}(E'_\bullet)$ pointwise on L. Moreover, for any $c \in [0,1]$,*

$$\Gamma_{ca}(E_\bullet) = c \otimes \Gamma_a(E_\bullet) \quad \textit{(pointwise on } L\textit{).}$$

Remark 2220. *Monotonicity here has a clear conceptual reading: giving* more *attention to each module (in the pointwise sense) and/or providing each module with* stronger *evidence (again pointwise) cannot make the integrated evidence weaker. This is a minimal sanity condition for any attention-weighted integrator purporting to model information flow into a workspace (Hyperseed-Concept 131). In terms of the product order on* $[0,1]^2$*, the claim is that increasing any input coordinate (either by raising attention or raising evidence) can only move the output "up and to the right" (or keep it fixed), never "down" on either coordinate. This aligns with the reading of* E^+ *and* E^- *as independent resource-like quantities that can be amplified or attenuated but not created by decreasing inputs.*

Remark 2221. *Uniform rescaling* $\Gamma_{ca} = c \otimes \Gamma_a$ *says that if one globally "turns down the volume" of attention by a factor* c*, the entire integrated evidence state is turned down by the same factor under the tensor operation. In the canonical multiplication tensor, this is literal scalar multiplication coordinatewise; in a more general quantale it is the appropriate notion of global weakening [3] (Hyperseed-Concept 202). Note that this identity is special to* uniform *rescaling: if different modules are rescaled by different constants, there is in general no factorization of the form* $\Gamma_{a'}(E_\bullet) = d \otimes \Gamma_a(E_\bullet)$ *with a single global* d*, precisely because the* max *aggregator can switch which module attains the maximum after rescaling. In other words, global rescaling commutes with integration, but heterogeneous rescaling can change the winner(s) coordinatewise.*

Remark 2222 (Intuition before the proof)**.** *Both claims are consequences of order-compatibility:* $\otimes$ *should respect increases in either argument, and* $\oplus$ *should respect increases in the joined terms. Once that is granted, the join over* m *of monotone expressions remains monotone. The rescaling claim then follows from factoring out the constant* c *through maxima/multiplication. A compact way to see the second claim is to view* $\Gamma_a(E_\bullet)(\varphi)$ *as built from the multiset* $\{a(m)E_m(\varphi)\}_{m\in M}$ *by taking a least upper bound; multiplying every element of that multiset by the same* c *multiplies its least upper bound by* c *when the order and tensor are compatible in the canonical way.*

Sketch. For monotonicity: each map $(a, E) \mapsto a \otimes E$ is monotone and $\oplus$ is monotone, so the pointwise join of monotone expressions is monotone. For rescaling: using the explicit coordinate form, $\max_m(ca(m)E^{\pm}_m) = c \max_m(a(m)E^{\pm}_m)$ since $c \geq 0$. □

Remark 2223. Proof sketch (high-level strategy). *The first part is a compositional argument: monotone pieces compose to give a monotone whole. The second part uses a concrete identity about maxima of scaled numbers when the scale is nonnegative, applied separately to the* $+$ *and* $-$ *coordinates. It may help to make the compositionality explicit: for fixed* φ*, each* m *induces a monotone map* $(a, E_\bullet) \mapsto a(m) \otimes E_m(\varphi)$*, and* $\Gamma_a(E_\bullet)(\varphi)$ *is obtained by applying a monotone* $\oplus$*-folding to these outputs. Monotonicity is then preserved under (i) evaluation at* m*, (ii) tensoring, and (iii) joining.*

Remark 2224. Why the key step works. *The only subtlety is that pulling* c *out of* $\max_m$ *requires* $c \geq 0$*, which is why* c *is restricted to* $[0,1]$*. If negative scalars were allowed, maxima would turn into minima after multiplication; but in this evidential setting negative attention has no intended interpretation. Also, restricting* $c \leq 1$ *matches the intended reading of attention as a* capacity limit *(attenuation), so that* $c \otimes x$ *never exceeds* x *in the canonical multiplication tensor. If one wished to model amplificatory gain (values* $c > 1$*), the same algebraic identity would remain valid for* $c > 0$*, but one would then leave the unit interval and would need a different codomain (or a different normalization convention) for evidence.*

Corollary 17 (Attentional gating)**.** *If* $a(m) = 0$*, module* m *contributes nothing to* $\Gamma_a(E_\bullet)$*. If there exists* m_0 *with* $a(m_0) = 1$*, then* $\Gamma_a(E_\bullet) \geq E_{m_0}$ *pointwise.*

Remark 2225. *This corollary formalizes two qualitative facts about attention (Hyperseed-Concept* **??***):* gating *(zero attention silences a module) and* guaranteed inclusion *(a fully attended module cannot be ignored by a max-based integrator). In computational terms, $a(m) = 0$ is like dropping a channel, while $a(m) = 1$ is like ensuring at least that module's evidence survives integration. Because the join is taken componentwise, "cannot be ignored" here should be read in the order-theoretic sense: every coordinate of $E_{m_0}(\varphi)$ is bounded above by the corresponding coordinate of the integrated state. This is weaker than saying the integrated state* equals E_{m_0} *(other modules may still raise some coordinates further), but strong enough to guarantee that fully attended information is never diminished by pooling.*

Remark 2226 (Intuition before the proof)**.** *With Γ_a computed by coordinatewise maxima of the values $a(m)E^{\pm}_m(\varphi)$, setting $a(m) = 0$ makes that module's candidate value identically* 0 *(hence never a new maximum unless everything else is also* 0*). Conversely, if some module has $a(m_0) = 1$, then its unscaled evidence appears among the candidates, so the maximum must be at least as large. One can also see the first claim directly from the tensor rule: $0 \otimes E_m(\varphi) = (0 \cdot E^+_m, 0 \cdot E^-_m)$, so the term for m is the bottom element $(0, 0)$ and therefore does not affect a join by coordinatewise maxima.*

Sketch. Fix $\varphi \in L$. If $a(m) = 0$, then $a(m) \otimes E_m(\varphi) = (0, 0)$ under the canonical tensor, so including this term in the join $\bigoplus_{m\in M} a(m) \otimes E_m(\varphi)$ does not change the componentwise maxima. For the second claim, if $a(m_0) = 1$ then $a(m_0) \otimes E_{m_0}(\varphi) = E_{m_0}(\varphi)$ appears among the joined terms, hence the componentwise maximum over all m is $\geq E_{m_0}(\varphi)$ in the product order. Since φ was arbitrary, the inequality holds pointwise on L. □

Sketch. If $a(m) = 0$, then $a(m)E^{\pm}_m(\varphi) = 0$ for all φ so it cannot increase the max. More explicitly, for any fixed $\varphi \in L$ we have $a(m)E^{\pm}_m(\varphi) = 0 \leq a(m')E^{\pm}_{m'}(\varphi)$ for some m' with $a(m') > 0$ (or else all terms are 0), hence the term with $a(m) = 0$ is never strictly maximal. If $a(m_0) = 1$, then $\max_m a(m)E^{\pm}_m(\varphi) \geq 1 \cdot E^{\pm}_{m_0}(\varphi)$. In other words, since the maximum is taken over a set of candidates that includes m_0, the supremum/maximum cannot be smaller than the particular candidate value contributed by m_0. □

Remark 2227. Visual intuition. *Think again of each module contributing an attended point in the square. Zero attention collapses the module's point to the origin, while full attention leaves it unchanged. The coordinatewise upper envelope cannot lie below an unchanged point that is included among the candidates. Equivalently: in each coordinate (positive or negative support), the upper envelope is obtained by taking the largest attended coordinate among the modules, so a module with weight* 0 *is geometrically irrelevant, while a module with weight* 1 *contributes its full coordinate as a lower bound on the envelope in that coordinate.*

Remark 2228. Order-theoretic restatement. *For each fixed φ, the map $m \mapsto a(m)E^{\pm}_m(\varphi)$ is a family in* $[0, 1]$*, and* $\max_m a(m)E^{\pm}_m(\varphi)$ *is its join in the usual order on* $[0, 1]$ *(when M is finite; in general one uses* $\sup$*). The two extreme-weight cases $a(m) = 0$ and $a(m) = 1$ are then immediate consequences of the facts that* 0 *is the least element and that joins are upper bounds for each summand.*

38.2 Workspace closure and conscious content thresholds

Proposition 50 (Monotonicity of thresholded conscious content)**.** *Fix $\theta \in (0, 1)$ and define $\mathrm{Con}_\theta(E) := \{\varphi \in L : \ E^+(\varphi) \geq \theta\}$. Then:*

1. *If $E \leq E'$, then $\mathrm{Con}_\theta(E) \subseteq \mathrm{Con}_\theta(E')$.*

2. If $\theta \leq \theta'$, then $\mathrm{Con}_{\theta'}(E) \subseteq \mathrm{Con}_{\theta}(E)$.

Remark 2229. *The set $\mathrm{Con}_\theta(E)$ is a deliberately austere formalization of "conscious content" (Hyperseed-Concept 85): it picks out those propositions whose* positive *support clears a fixed threshold θ. The parameter θ may be read as a minimal "broadcast strength" required for entry into the workspace, in the spirit of workspace-like theories in cognitive science [19]. One can also read θ as fixing a decision boundary for which contents become reportable, globally available, or able to drive downstream action selection, while leaving open the possibility that sub-threshold items still influence processing in a graded way.*

Remark 2230. *A simple example: if $E^+(\varphi) = 0.7$ and $E^+(\psi) = 0.2$, then with $\theta = 0.6$ we have $\mathrm{Con}_\theta(E) = \{\varphi\}$, while with $\theta = 0.1$ we have $\mathrm{Con}_\theta(E) = \{\varphi, \psi\}$. Thus lowering θ can only add content, never remove it, which is precisely the second monotonicity statement. In the same example, if we increase evidence to E' with $E'^+(\varphi) = 0.8$ and $E'^+(\psi) = 0.3$ (so $E \leq E'$), then $\mathrm{Con}_{0.6}(E') = \{\varphi\}$ still contains φ and does not "lose" it, illustrating the first monotonicity statement in a concrete way.*

Remark 2231 (Intuition before the proof)**.** *Both parts express a basic order-theoretic idea: increasing evidence should not make formerly conscious items unconscious, and raising the bar should not create new winners. The proof is a one-line unpacking of what it means for a coordinate to be larger and what it means to satisfy an inequality. Formally, (1) uses monotonicity of the predicate "$\geq \theta$" in its argument, while (2) uses antitonicity of the set $\{\varphi : x(\varphi) \geq \theta\}$ in the threshold parameter θ.*

Sketch. (1) $E \leq E'$ implies $E^+(\varphi) \leq E'^+(\varphi)$ for all φ. So if $\varphi \in \mathrm{Con}_\theta(E)$, meaning $E^+(\varphi) \geq \theta$, then by transitivity $E'^+(\varphi) \geq E^+(\varphi) \geq \theta$, hence $\varphi \in \mathrm{Con}_\theta(E')$. (2) If $E^+(\varphi) \geq \theta'$ and $\theta' \geq \theta$, then $E^+(\varphi) \geq \theta$. □

Remark 2232. Proof sketch (high-level strategy). *Translate set membership $\varphi \in \mathrm{Con}_\theta(E)$ into an inequality on real numbers, and then use transitivity of $\leq$ on $[0,1]$. Equivalently, the map $E \mapsto \mathrm{Con}_\theta(E)$ is monotone as a function from the evidence-state poset to the powerset lattice $(\mathcal{P}(L), \subseteq)$, while the map $\theta \mapsto \mathrm{Con}_\theta(E)$ is monotone in the reverse direction (larger thresholds yield smaller sets).*

Remark 2233. Boundary cases and conventions. *Taking $\theta \in (0,1)$ avoids trivial extremes: if $\theta \leq 0$ then $\mathrm{Con}_\theta(E) = L$ for all E, and if $\theta > 1$ then $\mathrm{Con}_\theta(E) = \varnothing$. Nothing in the monotonicity argument depends on excluding these cases; the restriction is mainly conceptual, to keep "thresholding" aligned with a non-degenerate notion of workspace admission.*

Theorem 54 (Existence of ordinary workspace-stable states)**.** *Assume $W : V^L \to V^L$ is monotone and V^L is a complete lattice (e.g. L finite). Then W admits at least one fixed point, and in fact has a least and a greatest fixed point.*

Remark 2234. *This is the first point at which the earlier completeness proposition pays off. A "workspace operator" W may be read as a closure-like transformation: it takes an evidence state and returns the evidence state after whatever internal propagation, consistency enforcement, and broadcast effects the workspace performs. Monotonicity is the formal version of a mild rationality condition: adding evidence should not reduce what the workspace ends up representing. Concretely, if $E \leq E'$ expresses that E' is at least as supportive (in every coordinate) as E, then $W(E) \leq W(E')$ says that the workspace update does not perversely invert this informativeness ordering.*

Remark 2235. *The theorem says that under these assumptions there exist stable evidence configurations E such that $W(E) = E$. These fixed points are the natural mathematical candidates for "workspace-stable" or "ordinary" conscious states. The existence of* least *and* greatest *fixed points is especially useful for mechanized reasoning: it provides canonical extremal solutions that can be approximated by iteration, and it connects naturally with stability analyses for self-modifying or goal-directed systems (cf. fixed-point tools in [10]). In particular, the least fixed point can be viewed as the minimal self-consistent broadcast state compatible with the update dynamics, while the greatest fixed point represents a maximally informative self-consistent state (relative to the underlying lattice order).*

Remark 2236 (Intuition before the proof)**.** *The result is a direct application of Tarski's fixed point theorem: in a complete lattice, a monotone map always has fixed points, and the fixed points themselves form a complete lattice. Philosophically, one might say: whenever you have a space of possible "belief/evidence states" rich enough to take all joins/meets, and an update rule that respects the ordering of informativeness, stable self-consistent states cannot fail to exist. This also clarifies why completeness is the key hypothesis: fixed points are obtained by taking meets/joins of certain invariant sets (e.g. pre-fixpoints or post-fixpoints), and those meets/joins must exist in the ambient structure for the construction to go through.*

Sketch. By Tarski's fixed point theorem, any monotone endomap on a complete lattice has a complete lattice of fixed points, in particular a least and greatest fixed point. More explicitly, the least fixed point is the meet of all pre-fixpoints $\{E : W(E) \leq E\}$ and the greatest fixed point is the join of all post-fixpoints $\{E : E \leq W(E)\}$, and completeness guarantees these extremal elements exist. $\square$

Remark 2237. Proof sketch (high-level strategy). *The proof is a citation of a deep structural theorem rather than a calculation: once the hypotheses match Tarski's theorem, the conclusion follows immediately. In applications, this means that substantial modeling work is pushed into verifying monotonicity and completeness; once those are in place, existence of stable workspace states is automatic.*

Remark 2238. Geometric intuition. *Even though V^L can be high-dimensional, one can imagine the update W as a deterministic "flow" that moves states upward in an order-respecting way. Tarski's theorem assures that such a flow must intersect the diagonal $E = W(E)$, and in fact does so in a way that has extremal intersection points (least and greatest). One should not over-interpret "upward" as literal numerical increase in every coordinate in time; rather, the order-respecting condition prevents W from creating cycles that strictly violate the partial order, and the lattice structure forces the family of approximants (formed by iterating from bottom or top) to have well-defined limits in the order sense.*

Lemma 123 (One-shot stability when W is idempotent)**.** *If the workspace operator additionally satisfies idempotence $W \circ W = W$, then for any integrated evidence state $E_0 := \Gamma_a(E_\bullet)$, the state $E := W(E_0)$ is workspace-stable: $W(E) = E$.*

Remark 2239. *Idempotence is the algebraic signature of a closure operator: applying the closure twice does not change what the first application already accomplished. When W is idempotent, the lemma says that a single workspace update already lands you in a stable configuration. This is useful when one wants a model in which "broadcast and settle" is a single step rather than an iterative convergence process. In cognitive terms, the extra assumption idealizes away oscillatory or multi-stage settling dynamics and treats the workspace as performing a full normalization/propagation in one pass.*

Remark 2240 (Intuition before the proof)**.** *The reasoning is essentially: if W is a closure, then $W(E_0)$ is already closed, so applying W again must return the same result. The proof is a single substitution into the idempotence equation. Equivalently, $W(E_0)$ is a fixed point because the image of an idempotent map consists entirely of fixed points.*

Sketch. $W(E) = W(W(E_0)) = W(E_0) = E$ by idempotence. Writing the equalities step-by-step: $E = W(E_0)$ by definition, hence $W(E) = W(W(E_0))$; idempotence gives $W(W(E_0)) = W(E_0)$, and the right-hand side is again E. □

Remark 2241. Proof sketch (high-level strategy). *Define E to be the image of E_0 under W; then stability is exactly the idempotence law instantiated at E_0.*

38.3 Reflective layer and introspection

Proposition 51 (Minimal introspection transfers base support to awareness tokens)**.** *Assume the "minimal" introspection choice for $I(\varphi)$:*

$$\mathrm{Int}(E)(I(\varphi)) = \big(E^+(\varphi),\ 1 - E^+(\varphi)\big).$$

Then $\mathrm{Int}(E)^+(I(\varphi)) = E^+(\varphi)$ *for all φ. Consequently, for any threshold θ,*

$$\varphi \in \mathrm{Con}_\theta(E) \quad \Longleftrightarrow \quad I(\varphi) \in \mathrm{Con}_\theta(\mathrm{Int}(E)).$$

Remark 2242. *This proposition concerns the reflective layer: we enrich the language with "awareness tokens" $I(\varphi)$, intended to represent something like "φ is present to awareness" (Hyperseed-Concept 203 and, more broadly, Hyperseed-Concept 85). The operator* Int *maps a base evidence state to a reflective evidence state. The displayed choice is called "minimal" because it transfers only the positive coordinate $E^+(\varphi)$ into the positive coordinate of the introspective token, and fills the negative coordinate so that the result is a* consistent *p-bit of the form $(p, 1-p)$ (cf. [23, 24]).*

Remark 2243. *Concretely, if $E^+(\varphi) = 0.8$, then* $\mathrm{Int}(E)(I(\varphi)) = (0.8, 0.2)$*, so the system's "degree of awareness of φ" tracks the base support for φ exactly, at least on the positive coordinate. The equivalence of thresholded conscious sets then says that the content thresholding commutes with this introspection: what is conscious at the base level is conscious at the awareness-token level and vice versa, under this minimal convention.*

Remark 2244 (Intuition before the proof)**.** *There is almost nothing to prove: the first coordinate of* $\mathrm{Int}(E)(I(\varphi))$ *is defined to be $E^+(\varphi)$. The equivalence for* Con_θ *then follows because* Con_θ *looks only at that first coordinate. The point is not difficulty, but transparency: we want the simplest reflective layer in which "being aware of φ" faithfully mirrors the degree to which φ is supported.*

Sketch. Immediate from the displayed definition: the positive coordinate of $\mathrm{Int}(E)(I(\varphi))$ is exactly $E^+(\varphi)$. □

Remark 2245. Proof sketch (high-level strategy). *Substitute the definition and read off the coordinate; then translate the thresholded set membership into inequalities. The argument is essentially definitional.*

Corollary 18 (Reflective-access collapses to self-presence under minimal introspection)**.** *In the reflective-self criterion, if "reflective access" is evaluated using the same threshold rule* Con_θ *on positive evidence, then under minimal introspection:*

$$E^+(\mathrm{Self}(p)) \geq \theta \implies \mathrm{Int}(E)^+(I(\mathrm{Self}(p))) \geq \theta.$$

So (for this particular Int *and thresholding convention) reflective-access adds no new constraint beyond self-presence; the remaining nontrivial requirement is stability under perturbation.*

Remark 2246. *The corollary is a small but conceptually clarifying point about the "reflective self" condition (Hyperseed-Concept 165): if introspection is defined minimally, then the system's positive support for a self-token* $\mathrm{Self}(p)$ *automatically lifts to positive support for the awareness-of-self token* $I(\mathrm{Self}(p))$ *at the same level. Thus, in this setting, the interesting work in reflective-selfhood is not done by a separate access test, but by robustness/stability conditions (continuity under perturbation), which capture something closer to the phenomenological idea of sustained self-presence rather than a momentary flicker.*

Remark 2247 (Intuition before the proof)**.** *This is exactly the previous proposition applied to the special case* $\varphi = \mathrm{Self}(p)$*: minimal introspection is designed so that the awareness-token inherits the same positive coordinate.*

Sketch. Apply the previous proposition with $\varphi := \mathrm{Self}(p)$. □

Remark 2248. Proof sketch (high-level strategy). *Reduce the corollary to a previously established identity by choosing the appropriate* φ*.*

Proposition 52 (Monotonicity of the reflective update map in inputs)**.** *Assume* Γ_a*,* Int*, and* W^{ref} *are monotone. Then the composite* $F := W^{\mathrm{ref}} \circ \mathrm{Int} \circ \Gamma_a$ *is monotone in module evidence and attention, i.e. if* $E_\bullet \leq E'_\bullet$ *and* $a \leq a'$*, then*

$$F(a, E_\bullet) \ \leq \ F(a', E'_\bullet) \quad \textit{(pointwise on } L^{\mathrm{ref}}\textit{).}$$

Remark 2249. *This proposition is the reflective analogue of earlier monotonicity facts: if you improve the informational inputs (stronger module evidence) and/or the attentional allocation (higher attention weights), then the final reflectively-closed state cannot become weaker. In other words, the reflective layer does not perversely punish additional evidence. Such monotonicity is a prerequisite for using lattice-theoretic fixed-point methods in the reflective space as well (cf. the stability tools emphasized in [10]).*

Remark 2250 (Intuition before the proof)**.** *The composite* F *consists of three stages: integrate (*Γ_a*), introspect (*Int*), and close reflectively (*W^{ref}*). If each stage is monotone, then their composition is monotone. This is the general categorical principle that order-preserving maps compose.*

Sketch. Γ_a is monotone in $(a, E_\bullet)$ (previous results), and Int and W^{ref} are monotone by assumption. Composition of monotone maps is monotone. In particular, if the relevant evidence/state space is ordered by the pointwise (product) order, then for any two inputs $X \leq Y$ we have $\Gamma_a(X) \leq \Gamma_a(Y)$, and applying Int and then W^{ref} preserves the inequality at each successive stage. Thus the full composite mapping inherits monotonicity without requiring any additional algebraic properties beyond order-preservation. □

Remark 2251. Proof sketch (high-level strategy). *Treat* F *as a pipeline and apply the lemma "monotone* $\circ$ *monotone is monotone" stage by stage. Concretely, one tracks how an increase in the input (in the chosen partial order) propagates forward: no stage can reverse an inequality, so the endpoint cannot reverse it either. This is the same proof pattern used for isotone maps on posets and for order-preserving program semantics (where sequential composition preserves monotonicity).*

38.4 Coherence score facts

Proposition 53 (Closed form, bounds, and negation-invariance of $|\sigma_{\mathbb{C}}|^2$)**.** *Using* $\sigma_{\mathbb{C}}(v^+, v^-) = (v^+ - v^-) + i\big((v^+ + v^-) - 1\big)$*, one has*

$$|\sigma_{\mathbb{C}}(v^+, v^-)|^2 = (v^+ - v^-)^2 + (v^+ + v^- - 1)^2 \in [0, 2].$$

Moreover $|\sigma_{\mathbb{C}}(v)| = |\sigma_{\mathbb{C}}(\neg v)|$ *where* $\neg(v^+, v^-) = (v^-, v^+)$*. Therefore, for* $\mathrm{Coh}(E) = \frac{1}{|K|}\sum_{\varphi \in K} |\sigma_{\mathbb{C}}(E(\varphi))|^2$*, we have* $\mathrm{Coh}(E) \in [0, 2]$ *and* $\mathrm{Coh}(E)$ *is invariant under p-bit negation applied pointwise to the evidence values of propositions in* K*. In addition, the lower bound* 0 *is achieved precisely when each* $E(\varphi)$ *satisfies* $v^+ = v^- = \frac{1}{2}$ *(so both the bias and the normalization deviation vanish), while the upper bound* 2 *is achieved when simultaneously* $|v^+ - v^-| = 1$ *and* $|v^+ + v^- - 1| = 1$*, which occurs at the corners* $(1, 0)$ *and* $(0, 1)$ *(maximal bias with classical normalization) and also at* $(1, 1)$ *and* $(0, 0)$ *(maximal over- or under-determination with zero bias).*

Remark 2252. *The map* $\sigma_{\mathbb{C}} : V \to \mathbb{C}$ *embeds a p-bit into the complex plane by treating two simple derived quantities as the real and imaginary parts:*

$$\mathrm{Re}(\sigma_{\mathbb{C}}(v)) = v^+ - v^- \quad \textit{(net bias)}, \qquad \mathrm{Im}(\sigma_{\mathbb{C}}(v)) = (v^+ + v^-) - 1 \quad \textit{(departure from classical normalization).}$$

The squared modulus $|\sigma_{\mathbb{C}}(v)|^2$ *is then a compact scalar "coherence" proxy that penalizes both large bias and large over/under-determination. Equivalently, it measures the squared Euclidean norm of the feature vector* $(v^+ - v^-,\ v^+ + v^- - 1)$*, so the two departures (directional bias versus total-evidence deviation) contribute additively and are not allowed to cancel each other. This complex-amplitude flavor is reminiscent of how interference-like quantities can arise in paraconsistent/quantum-inspired semantics [24], but here the role of the complex plane is strictly as a convenient two-dimensional representation with a rotationally symmetric magnitude.*

Remark 2253. *Two quick examples: if* $v = (0.5, 0.5)$*, then* $\sigma_{\mathbb{C}}(v) = 0 + i(0)$ *and* $|\sigma_{\mathbb{C}}(v)|^2 = 0$*, representing a perfectly balanced, classically-normalized evidence pair. If* $v = (1, 0)$*, then* $\sigma_{\mathbb{C}}(v) = 1 + i(0)$ *and* $|\sigma_{\mathbb{C}}(v)|^2 = 1$*. If* $v = (1, 1)$ *(maximal inconsistency), then* $\sigma_{\mathbb{C}}(v) = 0 + i(1)$ *and* $|\sigma_{\mathbb{C}}(v)|^2 = 1$ *again: the magnitude treats extreme bias and extreme inconsistency as comparable "departures" in orthogonal directions. As a further contrast, if* $v = (0, 0)$ *(maximal lack of support in either direction), then* $\sigma_{\mathbb{C}}(v) = 0 + i(-1)$ *and* $|\sigma_{\mathbb{C}}(v)|^2 = 1$*, showing that over-determination* $(1, 1)$ *and under-determination* $(0, 0)$ *are symmetric with respect to the baseline* $v^+ + v^- = 1$*.*

Remark 2254. *Negation-invariance expresses a philosophical symmetry: swapping "for" and "against" evidence changes the sign of the bias but not its magnitude, and does not change the normalization deviation. Hence the scalar* $|\sigma_{\mathbb{C}}|^2$ *(and therefore* Coh*) measures a kind of structural intensity rather than a directional preference. In particular,* Coh *cannot distinguish whether a system is coherently "pro" or coherently "con" with respect to propositions in* K*; it only records how far the evidence vectors sit from the neutral, classically-normalized midpoint.*

Remark 2255 (Intuition before the proof)**.** *The computation is the standard identity* $|x + iy|^2 = x^2 + y^2$*. The bound* $[0, 2]$ *comes from bounding each of* x *and* y *in* $[-1, 1]$*. Negation swaps* v^+ *and* v^-*, which flips* x *but leaves* y *unchanged, so the sum of squares is invariant. One can also read* x *as an antisymmetric component (it changes under swapping) and* y *as a symmetric component (it is preserved under swapping), so the modulus squares and adds precisely those two independent contributions.*

Sketch. Expand the modulus: for $x + iy$, $|x + iy|^2 = x^2 + y^2$. Here $x = v^+ - v^- \in [-1, 1]$ and $y = v^+ + v^- - 1 \in [-1, 1]$, so $x^2 + y^2 \le 2$. To justify the interval bounds explicitly: since $v^+, v^- \in [0, 1]$, the difference satisfies $-1 \le v^+ - v^- \le 1$, and the sum satisfies $0 \le v^+ + v^- \le 2$, hence $-1 \le (v^+ + v^-) - 1 \le 1$. Under negation, x flips sign and y is unchanged, so $x^2 + y^2$ is unchanged. Averaging over K preserves the bounds and invariance because a mean of numbers in $[0, 2]$ remains in $[0, 2]$, and because pointwise negation leaves each summand $|\sigma_{\mathbb{C}}(E(\varphi))|^2$ fixed. □

Remark 2256. Proof sketch (high-level strategy). *Reduce everything to bounds on two real scalars derived from v, then apply the elementary inequalities $x^2 \le 1$ and $y^2 \le 1$. If one wants a slightly sharper geometric phrasing, the argument is: the map $(v^+, v^-) \mapsto (x, y)$ sends the unit square into the square $[-1, 1]^2$, and the function $(x, y) \mapsto x^2 + y^2$ attains its maximum 2 on the corners, so no image point can exceed 2.*

Remark 2257. Geometric intuition. *The image of $V = [0, 1]^2$ under $(v^+, v^-) \mapsto (x, y)$ lies in the square $[-1, 1]^2$ in the (x, y)-plane; $|\sigma_{\mathbb{C}}(v)|^2$ is simply the squared Euclidean distance from the origin in this plane. Negation reflects points across the vertical axis $x \mapsto -x$, which preserves distance from the origin. Consequently, level sets of $|\sigma_{\mathbb{C}}(v)|^2$ correspond to circles centered at the origin intersected with the square: moving around such a circle changes the relative allocation between bias and normalization deviation while keeping the overall coherence proxy constant.*

38.5 Will, autonomy, and viability

Proposition 54 (Natural autonomy iff there exists a viable will policy on V)**.** *Let $D_u : S_{\mathrm{Ob}} \to S_{\mathrm{Ob}}$ be the update induced by intervention $u \in U$ and let $V \subseteq S_{\mathrm{Ob}}$ be a viable set. Then the following are equivalent:*

1. *(Natural autonomy)* $\forall s \in V\ \exists u \in U :\ D_u(s) \in V$.
2. *(Viable will policy)* $\exists\, \mathrm{Will} : V \to U\ \ \forall s \in V :\ D_{\mathrm{Will}(s)}(s) \in V$.

Remark 2258. *This proposition translates between two ways of stating autonomy (Hyperseed-Concept 119) and will (Hyperseed-Concept 203). Statement (1) is "pointwise possibility": from every viable state, there exists some intervention that keeps you viable for one step. Statement (2) is the existence of a* choice function*—a policy* Will *that actually selects such an intervention uniformly across states. Formally, the difference is the order of quantifiers: $(\forall s)(\exists u)$ versus $(\exists\, \mathrm{Will})(\forall s)$. The proposition says these are equivalent when one is allowed to define* Will *by choosing a witness $u(s)$ for each s.*

It is helpful to keep in mind that (2) is strictly stronger than merely asserting that the set

$$A(s) := \{u \in U :\ D_u(s) \in V\}$$

is nonempty for each $s \in V$: statement (2) asserts that one can simultaneously select an element of $A(s)$ for every *$s \in V$ in a way that packages these choices into a single object (a function). In other words, (2) turns a family of existence claims into a single policy object that can be reasoned about compositionally.*

Remark 2259. *In classical mathematics this is immediate, but it is still useful to record because it tells us what autonomy amounts to in this one-step setting: it is exactly the ability to define a viability-preserving will policy. In constructive or computable settings, the step (1) ⇒ (2) can conceal nontrivial choice principles; here, however, we remain in the usual classical mode, and* *the proposition functions as a notational bridge between an existential viability condition and a policy-existence statement.*

One practical way to see the "classical" nature is: if V is finite (or otherwise effectively enumerable) and for each $s \in V$ one can effectively find at least one u with $D_u(s) \in V$, then the construction of Will *is not only logically valid but algorithmic. In contrast, if V is infinite and the existence of u is nonconstructive, then* Will *may exist classically without being computable. This aligns with the conceptual distinction between* having *a will policy and* being able to compute *or* implement *one.*

Remark 2260 (Intuition before the proof)**.** *The forward direction is trivial: if you have a policy, you can always pick its action. The reverse direction is "define the policy by picking a witness action for each state." This is the archetype of a proof by choice-function construction.*

Another way to phrase the same intuition is: statement (1) says each viable state has at least one "safe" outgoing edge (labeled by an intervention) back into V; statement (2) says there is a way to choose one safe edge per node, producing a deterministic controller on V. The point is not that the chosen edge is unique, but that a single consistent selection suffices to define an explicit controller.

Sketch. (2) $\Rightarrow$ (1) is immediate by taking $u = \mathrm{Will}(s)$. (1) $\Rightarrow$ (2) choose, for each $s \in V$, some witnessing $u(s)$ with $D_{u(s)}(s) \in V$ and define $\mathrm{Will}(s) := u(s)$. ☐

Remark 2261. Proof sketch (high-level strategy). *Rearrange quantifiers by explicitly constructing the missing function: a will policy is nothing but a consistent selection of one admissible action per state.*

Equivalently, one can view (1) as stating that the relation

$$R \subseteq V \times U, \qquad (s,u) \in R \iff D_u(s) \in V$$

is left-total *(every $s \in V$ relates to at least one $u \in U$). Then (2) asserts the existence of a* selector *(or Skolem function) for this relation. In standard set-theoretic foundations, left-totality implies the existence of such a selector.*

Theorem 55 (Viability kernel as a greatest fixed point (useful for computing maximal autonomy))**.** *Define the one-step predecessor operator on subsets $X \subseteq S_{\mathrm{Ob}}$ by*

$$\mathrm{Pre}(X) := \{s \in S_{\mathrm{Ob}} : \ \exists u \in U,\ D_u(s) \in X\}.$$

Then Pre *is monotone on the powerset lattice $(\mathcal{P}(S_{\mathrm{Ob}}), \subseteq)$. Define $T(X) := V \cap \mathrm{Pre}(X)$. Then T is monotone and hence has a greatest fixed point K_V (by Tarski). This K_V is the* largest *subset of V such that*

$$\forall s \in K_V\ \exists u \in U : \ D_u(s) \in K_V.$$

In particular, K_V is the maximal "autonomy-sustaining" region inside V.

Remark 2262. *This theorem packages a standard viability-kernel construction into the fixed-point language used throughout these helper results. The operator* Pre *collects those states that can reach X in one step under* some *intervention. Intersecting with V enforces viability. A fixed point $X = T(X)$ is then a subset of V that is closed under one-step viability-preserving interventions: from every $s \in X$ one can stay within X.*

In control-theoretic terms, K_V is an invariant *(or* controlled-invariant*) subset of V for the controlled transition map D_u. The predecessor* Pre *is the usual controllable predecessor operator, and the intersection with V enforces state constraints. Thus the fixed-point formulation is a re-expression of the familiar "remove states that cannot be kept safe" computation.*

Remark 2263. *The greatest fixed point K_V is therefore the maximal region in which natural autonomy holds (Hyperseed-Concept 119): it is the largest subset of V from which one can keep choosing actions so as to remain in that subset indefinitely (in the one-step unfolding sense encoded by T). This is not only conceptually neat but computationally useful: greatest fixed points can often be approximated by descending iteration from the top element, which aligns with mechanized analyses of stable goal/viability systems [10].*

Concretely, once K_V has been identified, Proposition 54 applied to the set K_V shows that there exists a will policy $\mathrm{Will} : K_V \to U$ *that keeps the system inside K_V. So the fixed-point theorem is not merely about identifying a region; it also supports the existence of an explicit* closed-loop *viability-preserving will policy when one restricts attention to K_V.*

Remark 2264 (Intuition before the proof)**.** *The key ideas are (i) monotonicity of* Pre*: enlarging the target set can only enlarge the set of states that can reach it; and (ii) Tarski: monotone maps on complete lattices have greatest fixed points. The characterization of K_V as "largest autonomy-sustaining region" then follows from the universal property of the greatest fixed point as the largest post-fixed point.*

Here "post-fixed point" means a set X with $X \subseteq T(X)$. Intuitively, $X \subseteq T(X)$ says: if you start in X, you can choose an action to remain in X (and of course remain in V), so X is already self-sustaining. The greatest fixed point is then the union (supremum) of all such self-sustaining sets, which explains why it captures the maximal autonomy-sustaining region.

Sketch. If $X \subseteq Y$, then $\mathrm{Pre}(X) \subseteq \mathrm{Pre}(Y)$ (witnesses into X are also witnesses into Y), so Pre is monotone; intersecting with fixed V preserves monotonicity, hence T is monotone. Tarski gives a greatest fixed point K_V. If X is any subset of V with the autonomy property, then $X \subseteq \mathrm{Pre}(X)$, hence $X \subseteq V \cap \mathrm{Pre}(X) = T(X)$; thus X is a post-fixed point of T and must lie below the greatest fixed point K_V. □

Remark 2265. Proof sketch (high-level strategy). *Establish monotonicity, invoke Tarski to obtain K_V, and then prove maximality by showing that any autonomy-sustaining set is a post-fixed point and therefore contained in the greatest fixed point.*

A complementary viewpoint (often used in algorithms) is to start from the "largest possible candidate" $X_0 := V$ and iteratively eliminate states that fail the one-step autonomy condition relative to the current candidate:

$$X_{n+1} := T(X_n) = V \cap \mathrm{Pre}(X_n).$$

This produces a descending chain $X_0 \supseteq X_1 \supseteq X_2 \supseteq \cdots$ whose limit (in finite-state systems, after finitely many steps) is precisely K_V. This operationalizes the greatest-fixed-point interpretation: keep pruning until stability.

Remark 2266. Visual intuition. *Imagine V as the "safe region" in state space. Starting from a candidate set X, the operator T throws away points in V that cannot be kept within X in one step, retaining only those that have at least one safe continuation. Iterating T refines X by removing states that lead inevitably outside; the limit of this refinement is K_V. In viability terms, this iterative "pruning" is the dynamic counterpart of the static requirement that a state admit at least one indefinitely safe policy: the limiting set collects precisely those states for which safety can be maintained by appropriate choices over time.*

38.6 Two-channel (intuition/reason) update facts

Proposition 55 (Monotonicity and channel specializations of the two-channel update)**.** *Assume* $U_{\mathrm{int}}, U_{\mathrm{rea}} : V^{L^{\mathrm{ref}}} \to V^{L^{\mathrm{ref}}}$ *and* $W^{\mathrm{ref}} : V^{L^{\mathrm{ref}}} \to V^{L^{\mathrm{ref}}}$ *are monotone. Define*

$$U(E) := W^{\mathrm{ref}}(E \;\oplus\; \beta \otimes U_{\mathrm{int}}(E) \;\oplus\; \gamma \otimes U_{\mathrm{rea}}(E))\,, \qquad \beta, \gamma \in [0,1].$$

Then U *is monotone. Moreover:*

$$\beta = 0 \Rightarrow U(E) = W^{\mathrm{ref}}(E \oplus \gamma \otimes U_{\mathrm{rea}}(E))\,, \quad \gamma = 0 \Rightarrow U(E) = W^{\mathrm{ref}}(E \oplus \beta \otimes U_{\mathrm{int}}(E))\,, \quad \beta = \gamma = 0 \Rightarrow U(E) = W^{\mathrm{r}}$$

Remark 2267. *This proposition abstracts a common cognitive-architectural trope: two different update "voices" contribute to the reflective state—an intuition-like channel and a reason-like channel (Hyperseed-Concept* **??** *and Hyperseed-Concept 150). The weights* $\beta, \gamma \in [0,1]$ *control how strongly each channel's suggested update is injected, and* W^{ref} *then enforces the reflective workspace closure. The overall form is compatible with the cognitive-synergy view that multiple inference processes, each partial, can be combined via a common representational substrate [19]. In particular, the formula separates (i) proposal generation (*$U_{\mathrm{int}}(E)$ *and* $U_{\mathrm{rea}}(E)$*) from (ii) proposal integration (the* $\oplus$*-aggregation, modulated by* $\otimes$*-weights) and (iii) admissibility/consistency restoration (the* W^{ref} *step), mirroring a "suggest–merge–stabilize" pattern.*

Remark 2268. *The specialization identities are not deep, but they are operationally important: they tell us that setting* β *or* γ *to* 0 *literally disables the corresponding channel, and setting both to* 0 *reduces the update to pure reflective closure. This makes it easy to compare the full two-channel dynamics against single-channel baselines, a useful move in both theoretical analysis and mechanized verification. In many applications one additionally compares intermediate regimes (e.g.* $\beta \ll \gamma$*) to express dominance of one channel over the other, but the boundary cases already provide clean "knobs" for ablation-style arguments about causal contribution.*

Remark 2269 (Intuition before the proof)**.** *Monotonicity again comes from compositionality:* $E \mapsto U_{\mathrm{int}}(E)$ *and* $E \mapsto U_{\mathrm{rea}}(E)$ *are monotone by assumption; scaling by* β, γ *via* $\otimes$ *is monotone; joining via* $\oplus$ *is monotone; and finally applying the monotone closure* W^{ref} *preserves monotonicity. The specializations are simply what remains after substituting* $\beta = 0$ *and/or* $\gamma = 0$*. Conceptually, monotonicity expresses a stability property: strengthening the current reflective state (in the underlying order on* $V^{L^{\mathrm{ref}}}$*) cannot lead to a* weaker *updated state when all components of the update rule are themselves order-preserving.*

Sketch. $\oplus$ and $\otimes$ are monotone in each argument, and scaling by fixed $\beta, \gamma \in [0,1]$ is monotone. Thus the inner expression is monotone in E, and composing with monotone W^{ref} preserves monotonicity. The specialization identities follow by substitution. □

Remark 2270. Proof sketch (high-level strategy). *Prove monotonicity by checking each syntactic constructor in the definition of* U *is order-preserving, and then use the fact that order-preserving maps are closed under composition. Prove the special cases by direct substitution. Equivalently, one can view the inner map*

$$E \longmapsto E \;\oplus\; \beta \otimes U_{\mathrm{int}}(E) \;\oplus\; \gamma \otimes U_{\mathrm{rea}}(E)$$

as a monotone "pre-closure" aggregator, and then appeal to monotonicity of W^{ref} *as a final post-processing step.*

Remark 2271. On the underlying order and operators. *The statement is intentionally agnostic about the concrete instantiation of $V^{L^{\mathrm{ref}}}$ and the order $\leq$ it carries. In typical uses, $V^{L^{\mathrm{ref}}}$ is a product of value-domains (one per reflective label), ordered pointwise, $\oplus$ acts like a join (adding information or taking a supremum), and $\otimes$ acts like a weight-modulated injection that is order-preserving for fixed weights. Under such readings, monotonicity of U formalizes the intuition that adding evidence or constraints to E cannot make the next reflective state "forget" admissible content, except insofar as W^{ref} enforces whatever closure conditions the model requires.*

Remark 2272. Why monotonicity matters for iteration. *In later fixed-point or convergence arguments, one often studies the iterates $E_{n+1} = U(E_n)$. When U is monotone (and when the ambient order supports the needed completeness assumptions), standard lattice-theoretic tools become available for reasoning about least/greatest fixed points and about the effect of channel ablations. The present proposition isolates the monotonicity check so that such arguments can treat the two-channel update as a single well-behaved operator.*

39 Helper theorems for Section 18: evaluative fields, resonance, and ethics

Remark 2273. *This section collects small but structurally telling facts about the evaluative interface used in Section 18. They are "helper" results in the sense that none of them introduces new primitives; rather, they clarify how the primitives behave when combined. In particular, the p-bit representation of evaluation (pairs $(v^+, v^-) \in [0,1]^2$) reflects a paraconsistent attitude: positive and negative support can coexist without forcing collapse to a single scalar [23, 24]. This makes it natural to separate "joy" and "woe" (Hyperseed-Concepts* **??** *and 204) and then reason about orderings, aggregation, and resonance (Hyperseed-Concept 159) in a way that keeps both aspects explicit. For the broader conceptual framing of evaluative fields and resonance within the Hyperseed ontology, see [1].*

39.1 Helper results

1. **(H1) The p-bit preference order is a partial order.**

   Statement. Let $V := [0,1]^2$. Define, for $v = (v^+, v^-)$ and $u = (u^+, u^-)$,

   $$v \preceq_{\mathrm{pref}} u \quad :\iff \quad v^+ \leq u^+ \ \text{ and } \ v^- \geq u^-.$$

   Then $\preceq_{\mathrm{pref}}$ is reflexive, antisymmetric, and transitive (hence a partial order).

   Remark 2274. ***Notation and intuition.*** *The ambient space $V = [0,1]^2$ is the set of p-bit values: a pair (v^+, v^-) where v^+ is "positive evidence / positive valence" and v^- is "negative evidence / negative valence." The order $\preceq_{\mathrm{pref}}$ points "toward the better" in the following sense: u is at least as preferred as v precisely when u has* no less *positive component and* no more *negative component. Equivalently, $\preceq_{\mathrm{pref}}$ is the product order on $[0,1] \times [0,1]$ with the second coordinate reversed. This is the simplest order that takes the two-channel nature of evaluation seriously (Hyperseed-Concept 198).*

   Examples. *If $v = (0.6, 0.2)$ and $u = (0.7, 0.1)$, then $v \preceq_{\mathrm{pref}} u$ because $0.6 \leq 0.7$ and $0.2 \geq 0.1$; thus u is unambiguously preferable. On the other hand, $v' = (0.9, 0.9)$ and $u' = (0.1, 0.1)$ are* incomparable*: v'^+ is larger but v'^- is also larger, so neither dominates the other. This incomparability is not a bug but a formal way of registering ethical and affective conflict (Hyperseed-Concept 97).*

Proof sketch. Reflexivity is immediate since $v^+ \le v^+$ and $v^- \ge v^-$. Antisymmetry: if $v \preceq_{\text{pref}} u$ and $u \preceq_{\text{pref}} v$ then $v^+ = u^+$ and $v^- = u^-$, so $v = u$. Transitivity: $v \preceq_{\text{pref}} u$ and $u \preceq_{\text{pref}} w$ imply $v^+ \le u^+ \le w^+$ and $v^- \ge u^- \ge w^-$, so $v \preceq_{\text{pref}} w$.

Remark 2275. ***Why this matters.*** *Many later constructions (Pareto dominance, feasible choice sets, and monotone aggregators) quietly rely on the fact that we are reasoning inside a partial order rather than an arbitrary binary relation. Reflexivity and transitivity are what let us "chain" improvements without logical friction; antisymmetry is what prevents the order from identifying distinct evaluative states as mutually preferable.*

Proof strategy (high level). *The proof is an instance of a general theme: whenever an order is defined by coordinatewise inequalities, the order axioms reduce to the corresponding axioms of* $\le$ *on* $[0,1]$, *with the only subtlety being that the second coordinate uses* $\ge$ *rather than* $\le$. *Geometrically, the upper contour set of a point* v *is a rectangle extending to the northeast in the* v^+*-direction and to the* southeast *in the* v^-*-direction because "less woe" means moving downward in the usual plane.*

2. **(H2) Joy/woe projections are monotone (and bias is monotone).**

   Statement. Define $\mathrm{J}(v) := v^+$ and $\mathrm{W}(v) := v^-$. If $v \preceq_{\text{pref}} u$ then

   $$\mathrm{J}(v) \le \mathrm{J}(u), \qquad \mathrm{W}(v) \ge \mathrm{W}(u), \qquad \mathrm{J}(v) - \mathrm{W}(v) \le \mathrm{J}(u) - \mathrm{W}(u).$$

   Remark 2276. ***Conceptual role.*** *The maps* $\mathrm{J}, \mathrm{W} : V \to [0,1]$ *are simply coordinate projections, but they encode a philosophical stance: evaluation is not assumed to be reducible to a single scalar; instead, a mind may carry simultaneously a measure of attraction and a measure of aversion (Hyperseed-Concepts* **??**, *204). The final inequality concerns the "bias" or net valence* $\mathrm{J} - \mathrm{W}$*: it says that if* u *is preferable to* v *in the p-bit sense, then* u *is also at least as good by this naive scalarization. This is useful because it lets us connect the two-channel order to scalar decision rules when needed (cf. (H4)–(H5)).*

   Proof sketch. Unpack $v \preceq_{\text{pref}} u$: the first two inequalities are exactly the definition. Subtracting gives $(v^+ - v^-) \le (u^+ - u^-)$.

   Remark 2277. ***Proof sketch commentary.*** *Nothing deep happens here; the point is that the order* $\preceq_{\text{pref}}$ *was* chosen *so that* J *increases and* W *decreases along it. One may view this as a compatibility condition between the order-theoretic structure and the semantic interpretation of the coordinates. Visually, the function* $\mathrm{J} - \mathrm{W}$ *is constant on lines of slope* 1, *and moving in the preferred direction moves you toward larger* $\mathrm{J} - \mathrm{W}$.

3. **(H3) Pareto dominance on value-vectors is a partial order.**

   Statement. For a dimension set D, consider value-vectors in V^D. Define $x \preceq_{\text{Pareto}} y$ iff $x_d \preceq_{\text{pref}} y_d$ for all $d \in D$. Then $\preceq_{\text{Pareto}}$ is a partial order on V^D.

   Remark 2278. ***Notation.*** *An element* $x \in V^D$ *assigns to each ethical/evaluative dimension* $d \in D$ *a p-bit value* $x_d = (x_d^+, x_d^-)$. *The relation* $x \preceq_{\text{Pareto}} y$ *means that* y *is at least as good as* x in every dimension simultaneously. *This is the standard Pareto idea from multiobjective optimization, but instantiated in a two-channel evaluative codomain rather than in* $\mathbb{R}^D$.

   Why useful. *Pareto dominance is the canonical way to express "no tradeoff is being made": if* y *dominates* x, *then* y *improves (or matches)* x *on every criterion, so preferring* x *would be perverse unless some additional constraint intervenes. This underlies the "sanity" of later selection rules that first discard dominated options before applying more delicate criteria such as resonance or resource costs (see (H6)–(H7)).*

Proof sketch. Apply (H1) coordinatewise: reflexivity, antisymmetry, and transitivity lift to the product order.

Remark 2279. ***Proof strategy.*** *This is a general product-construction principle: orders on coordinates induce an order on tuples by pointwise comparison. The reason antisymmetry lifts is that equality in every coordinate forces equality of the whole function $D \to V$. Geometrically, $\preceq_{\text{Pareto}}$ defines a partial order on a high-dimensional orthant-like region, where comparability becomes rarer as $|D|$ grows—a formal reflection of the lived fact that ethical life in many dimensions is often not totally orderable.*

4. **(H4) Pareto dominance implies monotone scalar reward ordering.**

   Statement. Fix weights $\lambda_d \geq 0$ and $\beta \geq 0$. Define a scalar score

$$\text{Score}(a) := \sum_{d \in D} \lambda_d \big(\text{J}(\text{EO}(s, a; d)) - \text{W}(\text{EO}(s, a; d))\big) \ - \ \beta R_O(s, a).$$

   If $\text{EO}(s, a) \preceq_{\text{Pareto}} \text{EO}(s, a')$ *and* $R_O(s, a') \leq R_O(s, a)$, then $\text{Score}(a') \geq \text{Score}(a)$. Moreover, if (i) $\lambda_d > 0$ for all d, and (ii) at least one dimension improves strictly ($\text{EO}(s, a; d) \prec_{\text{pref}} \text{EO}(s, a'; d)$) or $R_O(s, a') < R_O(s, a)$ with $\beta > 0$, then $\text{Score}(a') > \text{Score}(a)$.

   Remark 2280. ***Intuitive reading.*** *The score is a weighted sum of per-dimension net valence* $\text{J} - \text{W}$*, penalized by a resistance/cost term* R_O *(Hyperseed-Concept 158). The claim says: if action a' is at least as good as a in every evaluative dimension (Pareto), and it costs no more resistance, then any nonnegative linear scalarization will not rank a' below a. This is the minimal compatibility one expects between multiobjective improvement and scalar scoring.*

   Connection to later items. *(H4) is the monotonicity lemma that makes (H5) believable: if scalar maximizers could be Pareto-dominated, the scalar would be violating the basic direction of ethical improvement. In decision-theoretic terms, this is a sanity check on scalarization as a tool for rational decision (Hyperseed-Concept 147) as used broadly in AGI-style action selection [19].*

   Proof sketch. From $\text{EO}(s, a) \preceq_{\text{Pareto}} \text{EO}(s, a')$ and (H2), each term $\text{J} - \text{W}$ is $\leq$ the corresponding term for a'. Multiply by $\lambda_d \geq 0$ and sum. Also $-\beta R_O(s, a') \geq -\beta R_O(s, a)$ if $R_O(s, a') \leq R_O(s, a)$. Strictness follows if any positively weighted term increases strictly and/or the resistance term improves with $\beta > 0$.

   Remark 2281. ***Proof sketch commentary.*** *The essential move is order preservation under two operations: (1) multiplying an inequality by a nonnegative weight preserves direction; and (2) summing coordinatewise inequalities preserves direction. The resistance part is the same idea after multiplying by $-\beta$ (which flips nothing because we pre-assume $R_O(s, a') \leq R_O(s, a)$). One may view this as an instance of the general fact that monotone maps between ordered sets compose well:* $\text{J} - \text{W}$ *is monotone w.r.t. $\preceq_{\text{pref}}$ by (H2), and the weighted sum is monotone w.r.t. the usual order on $\mathbb{R}$.*

5. **(H5) Score maximizers are Pareto-undominated (sanity of scalarization).**

   Statement. Assume A is finite and $\lambda_d > 0$ for all d, $\beta \geq 0$. If $a^\star \in \arg\max_{a \in A} \text{Score}(a)$, then $a^\star$ is Pareto-undominated w.r.t. the coordinates $(\text{J}(\text{EO}(s, a; d)), -\text{W}(\text{EO}(s, a; d)))_{d \in D}$ and $-R_O(s, a)$.

Remark 2282. ***What it says in plain language.*** *If you pick an action by maximizing a strictly positively weighted score (and optionally penalizing resistance), you cannot end up with an action that is* strictly worse in every respect *than some other available action. In other words, scalarization does not force you to choose an obviously dominated option, provided you truly care (positively) about each dimension included in the score.*

Why the strict positivity matters. *If some $\lambda_d = 0$, then the scalar score is blind to dimension d, and it may select an action that is dominated only via improvements in that ignored dimension. The hypothesis $\lambda_d > 0$ is precisely what closes this loophole.*

Proof sketch. This is the usual scalarization argument: if some a dominates $a^\star$, then every positively weighted term in Score is $\geq$ and at least one is $>$, contradicting maximality. (This is exactly the logic behind the document's Proposition 24.)

Remark 2283. ***Proof strategy and geometric intuition.*** *The argument is a contradiction proof: assume there is an action a that dominates the maximizer $a^\star$, and then use strict positivity of weights to show that the scalar functional must strictly increase from $a^\star$ to a. Geometrically, the level sets of a positive linear functional are supporting hyperplanes: a maximizer lies on an exposed face of the feasible set, and a point strictly dominated cannot be exposed in that direction.*

6. **(H6) Finite action sets always have Pareto-undominated actions.**

   Statement. If A is finite, then the Pareto-undominated set

   $$A_{\text{Pareto}}(s) := \{a \in A : \nexists a' \in A \text{ with } \mathrm{EO}(s,a) \prec_{\text{Pareto}} \mathrm{EO}(s,a')\}$$

   is nonempty.

   Remark 2284. ***Why this is nontrivial.*** *In infinite sets, one can have infinite ascending chains with no maximal elements. In a finite set, however, strict improvement cannot proceed forever. Thus some actions must sit at the "top" of the strict dominance relation even if many actions are incomparable.* ***Use in the architecture.*** *This guarantees that a choice rule that first filters to Pareto frontiers (as in (H7)) will not face an empty feasible set merely because of the ordering formalism. It is a small theorem with a large practical role: it prevents non-existence pathologies in finite decision modules.*

   Proof sketch. Strict Pareto dominance $\prec_{\text{Pareto}}$ is a strict partial order on a finite set, so it has at least one maximal element; any maximal element is undominated.

   Remark 2285. ***Proof sketch commentary.*** *The proof is a finiteness principle: starting from any action, if it is dominated we move to a dominator; since there are only finitely many actions, this process must terminate, and termination means "undominated." One can also view this as the existence of maximal elements in finite partially ordered sets, a discrete cousin of Zorn-style reasoning but requiring no choice principles.*

7. **(H7) The resonant-feasible rule satisfies key rationality axioms.**

   Statement. Define the resonant-feasible choice set

   $$A_{\text{res}}(s) := \underset{a \in A_{\text{Pareto}}(s)}{\arg\max} \Big(\kappa_O(s,a) - \beta\, R_O(s,a)\Big).$$

   Then:

(a) *Non-explosion:* $A_{\text{res}}(s) \neq \emptyset$ for finite A.

(b) *Dominance respect:* if a is strictly Pareto-dominated then $a \notin A_{\text{res}}(s)$.

(c) *Resource sensitivity:* if $\kappa_O(s,a) = \kappa_O(s,a')$ and $R_O(s,a) < R_O(s,a')$ with $\beta > 0$, then no maximizer can prefer a' over a within the feasible set.

Remark 2286. ***Interpretation.*** *This choice rule has two stages: first, exclude actions that are ethically worse in every relevant dimension (Pareto filtering); second, among the survivors, prefer higher resonance κ_O (Hyperseed-Concept 159) while optionally penalizing resistance R_O (Hyperseed-Concept 158). The rule thereby attempts to encode a "non-fanatical" rationality: it refuses dominated choices, but it does not insist on a single global scalar utility before it has removed the plainly inferior options.*

Why it connects to Section 18. *Section 18 treats resonance as a structurally meaningful summary of multi-dimensional evaluative alignment. The present item shows that using resonance in a decision rule does not violate basic rationality desiderata such as non-emptiness and dominance respect. In the broader cognitive-systems context, this aligns with the methodological stance that decision rules must be order-theoretically well-posed before one asks whether they are psychologically or ethically apt (Hyperseed-Concept 147).*

Proof sketch. (1) By (H6), $A_{\text{Pareto}}(s) \neq \emptyset$, and an argmax over a nonempty finite set is nonempty. (2) The maximization domain explicitly excludes dominated actions. (3) With equal κ_O, the objective differs only by $-\beta R_O$, so smaller resistance yields a larger objective if $\beta > 0$.

Remark 2287. ***Proof sketch commentary.*** *The structure mirrors a common pattern in formal ethics and multiobjective control: establish feasibility/nonemptiness first (a logical precondition for any normative rule), and then verify that the selection criterion respects the ordering constraints it claims to respect. Geometrically, (2) says we restrict attention to the Pareto frontier; (3) says that on a contour of equal resonance, resistance tilts the objective toward lower-cost points.*

8. **(H8) Resonance magnitude bounds (triangle inequality + bounded σ_C).**

Statement. Let $z_d := \sigma_C(\mathrm{EO}(s,a;d)) \in \mathbb{C}$ and $Z := \sum_{d \in D} w_d z_d$ with $w_d \geq 0$. Then

$$\kappa_O(s,a) = |Z| \leq \sum_{d \in D} w_d |z_d|.$$

Moreover, since $\sigma_C(v^+, v^-) = (v^+ - v^-) + i((v^+ + v^-) - 1)$ has real and imaginary parts in $[-1,1]$, one has $|z_d| \leq \sqrt{2}$ for all d, hence

$$\kappa_O(s,a) \leq \sqrt{2} \sum_{d \in D} w_d.$$

(In particular, if $\sum_d w_d = 1$, then $\kappa_O(s,a) \leq \sqrt{2}$.)

Remark 2288. ***Notation and first-time symbols.*** *Here $\sigma_C : V \to \mathbb{C}$ embeds a p-bit value into the complex plane. The complex numbers z_d are the dimension-wise "phasors," and Z is their weighted superposition. The resonance magnitude $\kappa_O(s,a)$ is defined as $|Z|$, the modulus of this complex sum. Intuitively, each evaluative dimension contributes a vector in the plane; resonance is large when these vectors align and small when they cancel (Hyperseed-Concepts*

159, 97). This complex-geometry viewpoint is also central in paraconsistent resonance approaches [24].

Why the bound is useful. *Bounds like $\kappa_O(s,a) \le \sqrt{2}\sum_d w_d$ are not merely aesthetic: they make κ_O scale-controlled, which is essential if κ_O is to be compared across states, combined with other terms (like R_O), or placed into probabilistic/optimization pipelines.*

Proof sketch. The first inequality is the triangle inequality. For the bound on $|z_d|$, note $v^+ - v^- \in [-1,1]$ and $(v^+ + v^-) - 1 \in [-1,1]$, so $|z_d|^2 \le 1^2 + 1^2 = 2$.

Remark 2289. ***Geometric intuition.*** *The triangle inequality is the formal statement that the length of a resultant vector cannot exceed the sum of lengths of the vectors being added. The second part says: the embedding σ_C maps the square $[0,1]^2$ into a bounded region of the complex plane, specifically into the box $[-1,1]\times[-1,1]$. Thus every contribution has bounded magnitude, so the total resonance grows at most linearly with the total weight.*

9. **(H9) Interference expands into pairwise alignment terms.** *Statement.* With $Z = \sum_d w_d z_d$ and

$$I_O(s,a) := |Z|^2 - \sum_{d\in D} |w_d z_d|^2,$$

one has the exact expansion

$$I_O(s,a) = 2\sum_{d<d'} w_d w_{d'}\ \mathrm{Re}\big(z_d\,\overline{z_{d'}}\big).$$

Remark 2290. ***What I_O measures.*** *The quantity $I_O(s,a)$ is the difference between the squared magnitude of the sum and the sum of squared magnitudes of the terms. If there were no cross-terms, these would coincide. Thus I_O isolates the purely relational component: how much the dimensions help or hinder each other when superposed. This is precisely why it is natural to call it "interference": it is made entirely of pairwise overlaps.*

Why this connects. *In Section 18, resonance is meant to capture alignment across ethical dimensions, not merely goodness in each dimension separately. (H9) gives the algebraic lens for that claim: alignment is encoded in the real parts $\mathrm{Re}(z_d\overline{z_{d'}})$, i.e. in the cosines of pairwise phase differences.*

Proof sketch. Expand: $|\sum_d w_d z_d|^2 = \sum_d |w_d z_d|^2 + \sum_{d\ne d'} w_d w_{d'} z_d \overline{z_{d'}}$, then take the real part; the $d \ne d'$ sum collapses to $2\sum_{d<d'}\mathrm{Re}(\cdot)$.

Remark 2291. ***Proof sketch commentary.*** *The key identity is $|Z|^2 = Z\overline{Z}$. Writing $Z = \sum_d w_d z_d$ and distributing the product produces diagonal terms (the $|w_d z_d|^2$ terms) and off-diagonal terms (the interference terms). Pairing d, d' with d', d is what produces the factor of 2 and forces the final expression to be real, since each pair contributes complex conjugates whose sum is $2\,\mathrm{Re}(\cdot)$.*

Remark 2292. ***Useful normal form.*** *Writing each complex contribution in polar form $z_d = r_d e^{i\phi_d}$ (with $r_d \ge 0$ and $\phi_d \in \mathbb{R}$) makes the structure of (H9) completely explicit:*

$$\mathrm{Re}\big(z_d\overline{z_{d'}}\big) = \mathrm{Re}\big(r_d e^{i\phi_d}\cdot r_{d'} e^{-i\phi_{d'}}\big) = r_d r_{d'}\cos(\phi_d - \phi_{d'}).$$

Hence I_O is a weighted sum of pairwise cosine similarities:

$$I_O(s,a) = 2\sum_{d<d'} w_d w_{d'}\, r_d r_{d'}\cos(\phi_d - \phi_{d'}).$$

This makes clear (i) why I_O depends only on relative *phases $\phi_d - \phi_{d'}$ (global phase cancels), and (ii) why I_O can be positive or negative even when all magnitudes r_d are large: the sign is controlled by the geometry of the phase differences.*

On weights and symmetry. *The algebraic expansion itself does not require $w_d \geq 0$, only that the weights be real so that $|w_d z_d|^2 = w_d^2 |z_d|^2$ behaves as expected; however, in evaluative interpretations the natural regime is typically $w_d \geq 0$ (importance weights). In that regime, the sign of each pairwise contribution to I_O is driven directly by $\mathrm{Re}(z_d \overline{z_{d'}})$, so "alignment" and "misalignment" have a clean monotone relationship with constructive versus destructive interference.*

10. **(H10) Coherence/cancellation criteria via phase geometry.**

Statement. If for all pairs $d \neq d'$ the phase alignment is nonnegative, i.e. $\mathrm{Re}(z_d \overline{z_{d'}}) \geq 0$, then $I_O(s, a) \geq 0$ (constructive interference). If many pairs have $\mathrm{Re}(z_d \overline{z_{d'}}) < 0$, then $I_O(s, a)$ can be negative (cancellation).

A sufficient condition for maximal coherence is: there exists $\theta \in \mathbb{R}$ with $z_d = e^{i\theta} r_d$ for all d and all $r_d \geq 0$. Then

$$\kappa_O(s, a) = \sum_d w_d r_d, \qquad I_O(s, a) = \Big(\sum_d w_d r_d\Big)^2 - \sum_d w_d^2 r_d^2 \geq 0.$$

Remark 2293. ***Plain-English meaning.*** *When all the complex contributions z_d point roughly in the same direction (pairwise angles at most 90°), then their sum is amplified: the cross-terms in (H9) are nonnegative, so interference is constructive. When many pairs point in opposing directions (angles greater than 90°), cross-terms can be negative and the sum can shrink: cancellation.*

A simple special case. *If all z_d share a common phase θ, then every contribution is a nonnegative scalar multiple of the same unit complex number $e^{i\theta}$. In that case, resonance reduces to an ordinary weighted sum $\sum_d w_d r_d$, and interference is automatically nonnegative. This shows that the complex formalism strictly generalizes classical additive aggregation: additivity is recovered when the system is perfectly coherent.*

Proof sketch. First part: combine (H9) with the sign assumptions. Second part: under common phase, $Z = e^{i\theta} \sum_d w_d r_d$, so $|Z| = \sum_d w_d r_d$, and I_O is just the cross-term sum (hence nonnegative).

Remark 2294. ***Geometric intuition.*** *The condition $\mathrm{Re}(z_d \overline{z_{d'}}) \geq 0$ is equivalent to saying that the angle between z_d and $z_{d'}$ is in $[-\pi/2, \pi/2]$ modulo 2π. Thus (H10) is really a theorem about polygonal addition of vectors: if every pair of edges has acute or right angle, the polygon tends to "open" rather than fold back on itself. In ethical terms, this is a formal analogue of the idea that virtues can mutually reinforce when they are not pulling in contradictory directions.*

Remark 2295. ***Sufficiency versus necessity.*** *The pairwise nonnegativity condition $\mathrm{Re}(z_d \overline{z_{d'}}) \geq 0$ for all $d \neq d'$ is a strong* sufficient *criterion for $I_O \geq 0$, but it is not necessary: I_O is a* sum *of pairwise contributions, so some negative pairs can be outweighed by sufficiently many positive pairs (or by larger magnitudes/weights on aligned pairs). Put differently, constructive global interference is compatible with local pockets of cancellation, as long as the total weighted cosine-similarity mass is nonnegative.*

Interference as a deviation-from-additivity diagnostic. *Under common phase,* $I_O(s,a) = \big(\sum_d w_d r_d\big)^2 - \sum_d w_d^2 r_d^2$ *is exactly the difference between the squared* ℓ^1*-type aggregate and the squared* ℓ^2*-type aggregate (with weights). This emphasizes that* I_O *can be read as a quantitative measure of "how non-orthogonal" the set of contributions is: perfect coherence pushes the system toward* ℓ^1*-like accumulation, while strong phase dispersion moves it toward cancellation and smaller resultant magnitude.*

11. **(H11) Compassion aggregation is monotone in its inputs.**

Statement. Let compassion be defined by an aggregation of the form

$$\mathrm{EO}(s,a;\mathrm{comp}) := \bigoplus_{j\neq\mathrm{self}} \Big(\mathrm{EO}_{\to j}(s,a;\mathrm{joy}) \;\otimes\; \neg\mathrm{EO}_{\to j}(s,a;\mathrm{woe}) \Big).$$

Assume $\oplus$ and $\otimes$ are monotone in each argument (as in the quantale core). If for every $j \neq \mathrm{self}$,

$$\mathrm{EO}_{\to j}(s,a;\mathrm{joy}) \le \mathrm{EO}'_{\to j}(s,a;\mathrm{joy}) \quad \text{and} \quad \neg\mathrm{EO}_{\to j}(s,a;\mathrm{woe}) \le \neg\mathrm{EO}'_{\to j}(s,a;\mathrm{woe}),$$

then $\mathrm{EO}(s,a;\mathrm{comp}) \le \mathrm{EO}'(s,a;\mathrm{comp})$.

Remark 2296. ***Conceptual role (Compassion).*** *Compassion (Hyperseed-Concept 81) is being modeled here as an aggregation across other agents* $j \neq \mathrm{self}$ *of a conjunction-like term: "joy for* j*" combined with "not woe for* j*." The logical moral is: if you increase each input in a monotone way, the aggregate cannot decrease. This is a basic coherence requirement for any ethical aggregator: improvements in the welfare-related ingredients should not perversely reduce the compassion score.*

Connection to prosocial efficiency. *This monotonicity property is one of the algebraic preconditions for turning compassion-like terms into decision criteria without logical traps, a theme that aligns with arguments that prosocial structure can increase group efficiency in multi-agent settings [6].*

Proof sketch. Monotonicity of $\otimes$ gives monotonicity for each j-term; monotonicity of $\oplus$ (and of joins over index sets) lifts this to the aggregate.

Remark 2297. ***Where the assumption on*** $\neg$ ***enters.*** *The statement is phrased in terms of the inputs* $\mathrm{EO}_{\to j}(s,a;\mathrm{joy})$ *and* $\neg\mathrm{EO}_{\to j}(s,a;\mathrm{woe})$*, so it only needs monotonicity of* $\otimes$ *and* $\oplus$ *in their arguments. If one prefers to phrase conditions directly in terms of* $\mathrm{EO}_{\to j}(s,a;\mathrm{woe})$*, then a separate property of the negation-like operator becomes relevant: in many ordered settings,* $\neg$ *is antitone (order-reversing), so a decrease in woe (*$\mathrm{EO}_{\to j}(\mathrm{woe}) \ge \mathrm{EO}'_{\to j}(\mathrm{woe})$*) corresponds to an increase in* $\neg\mathrm{EO}_{\to j}(\mathrm{woe}) \le \neg\mathrm{EO}'_{\to j}(\mathrm{woe})$*. The present formulation avoids baking in any particular order-theoretic behavior of* $\neg$*, while still capturing the intended monotone comparative statics.*

Index-set aggregation. *The step "lift to the aggregate" uses the standard fact that if each term in a family increases (pointwise in* j*), then any join/aggregate operator* $\bigoplus$ *that is monotone with respect to that pointwise order must also increase. Concretely, defining* $t_j := \mathrm{EO}_{\to j}(\mathrm{joy}) \otimes \neg\mathrm{EO}_{\to j}(\mathrm{woe})$ *and similarly* t'_j*, one has* $t_j \le t'_j$ *for all* j*, hence* $\bigoplus_j t_j \le \bigoplus_j t'_j$*.*

Optional concrete p-bit case. If $\oplus$ is componentwise max, $\otimes$ is componentwise multiplication, and $\neg(p,q) = (q,p)$, then each j-term equals

$$(\, \mathrm{J}_j^+ \cdot \mathrm{W}_j^- \;,\; \mathrm{J}_j^- \cdot \mathrm{W}_j^+ \,),$$

and the outer $\oplus$ is max over j. In particular, the aggregation can be read as taking, separately in each coordinate, the worst-case (largest) composite contribution across j, which makes the dependence on each input coordinate explicit and reduces the abstract order-theoretic claim to familiar scalar monotonicity facts.

Remark 2298. ***Proof strategy and intuition.*** *The proof is a textbook application of monotonicity preservation under composition: each inner term is a monotone function of its inputs (because $\otimes$ is monotone), and then the outer aggregation is monotone because $\oplus$ (and hence finite or indexed joins built from it) is monotone. In the concrete p-bit case, the max/multiply structure makes this especially transparent: increasing inputs can only increase products and can only increase maxima. One can also view the j-term as a coordinatewise bilinear map on nonnegative reals (or on $[0,1]$ if probabilities are intended), so the only potential failure modes for monotonicity would come from allowing negative values; the intended p-bit semantics rules these out, leaving plain isotonicity.*

Why the quantale hypothesis appears. *The reliance on monotone $\oplus, \otimes$ is exactly the kind of "weakness is all you need" condition one encounters in quantale-based semantics: monotonicity is the minimal structural demand for stable inference and aggregation [3] (Hyperseed-Concept 143). In other words, the result is deliberately insensitive to whether $\oplus$ is idempotent, whether $\otimes$ distributes over arbitrary joins, or whether one has a residuation operator: those stronger axioms are useful for richer algebraic manipulations, but the present claim only needs that the order is respected by the constructors used to build the evaluation functional.*

Interpretive note (why the swap $\neg(p,q) = (q,p)$ matters). *In this p-bit instance, $\neg$ merely exchanges the roles of the two coordinates, so the two products $\mathrm{J}_j^+\mathrm{W}_j^-$ and $\mathrm{J}_j^-\mathrm{W}_j^+$ can be read as the two cross-couplings induced by pairing "positive" evidence on one side with "negative" evidence on the other. The monotonicity claim then says that strengthening any of these evidence streams (in the intended direction) cannot reduce the corresponding aggregated cross-coupled score.*

12. **(H12) Explicit goals can be treated as implicit goals when enforced by policy.**

    Statement. Let an explicit goal be a constraint $G \subseteq \Omega$ on outcomes/trajectories. Suppose a policy π is implemented with a hard constraint that assigns zero probability to $\Omega \setminus G$. Then the induced action-selection regularity of π is consistent with treating G as an implicit goal. Equivalently, the support of the induced trajectory distribution is contained in G, so every realized history witnesses the same feasibility regularity regardless of whether G is internally represented as a goal object.

    Conversely, if an implicit goal regularity is representable by some set $G \subseteq \Omega$ in O's language (e.g. as a definable predicate on histories), then G can be promoted to an explicit goal without changing behavior. Here "representable" can be read in the weakest sense needed for the surrounding framework (e.g. first-order definability, programmatic recognizability, or measurability relative to the trajectory σ-algebra), since the behavioral content is only that the same subset of trajectories is selected/ruled out.

    Remark 2299. ***Intuition (explicit vs. implicit).*** *An explicit goal is a named constraint, something the system can in principle cite or reason about (Hyperseed-Concept* **??***). An* *implicit goal is visible only through regularities in action selection (Hyperseed-Concept* **??***). This item states a kind of definitional equivalence: if behavior is* hard-constrained *to respect G, then regardless of whether the system says "I have goal G," it behaves as though G were a goal; and if an implicit regularity is definable, it can be reified as an explicit constraint. In the language of constraint satisfaction, the first direction says that a feasibility region enforced at execution time functions indistinguishably from a goal-set, while the second direction says that any stable, nameable regularity can be moved from the level of emergent behavior to the level of specification.*

Why this is useful. *For formal analysis, it allows one to swap between a behavioral and a declarative representation of goals depending on which is technically convenient. When proving theorems about behavior, implicit goals may be simpler; when specifying systems or verifying constraints, explicit goals may be clearer. This is particularly helpful when discussing alignment or ethics: many safety properties are naturally stated as explicit constraints on trajectories, but may in practice be implemented as architectural or training-induced regularities; (H12) licenses treating these two presentations as equivalent provided the regularity is hard (support-level) rather than merely soft (preference-level).*

Boundary case (hard vs. soft enforcement). *The hypothesis uses "zero probability" precisely to rule out the ambiguous case where violations are merely unlikely. If $\pi(\Omega \setminus G) > 0$, then G is at best a soft preference, and the corresponding implicit goal is only approximate; the present helper result intentionally addresses the crisp case needed for clean logical substitution in later arguments.*

Proof sketch. The first direction is by definition: hard feasibility constraints generate stable behavioral regularities. The second direction is reification: if a behavioral regularity is definable as a set of allowed trajectories, encode it as G. Concretely, for the first direction one takes the induced distribution $\mathbb{P}_\pi$ on Ω and observes $\mathbb{P}_\pi(G) = 1$, so every conditional action distribution along realized histories is computed under the invariant that the continuation lies in G. For the second direction, one defines $G := \{\omega \in \Omega : \omega \text{ satisfies the implicit regularity}\}$ and notes that restricting π to G does not alter any action choices on histories that already occur under π.

Remark 2300. ***Proof sketch commentary.*** *The first direction is essentially semantic: "probability zero" is a strong form of impossibility inside the model, hence a robust invariance of behavior. The second direction is syntactic/representational: definability in O's language allows the system to name the regularity. Philosophically, this echoes a Peircean movement from habit (regularity) to symbol (explicit representation) [14], while keeping the formal content purely set-theoretic. One can also read the two directions as a correspondence between* support constraints *(properties of the realized set of trajectories) and* specification constraints *(properties stated in the observer's or agent's representational language): the helper lemma is a bridge allowing later arguments to move freely between these levels without changing the predicted behavior.*

13. **(H13) Categorical-imperative test is monotone in thresholds; evil tends to fail it (when compassion is included).**

   Statement (monotonicity). Fix ethical dimensions D_{eth}. A maxim m passes the CI-test with thresholds $(\tau_d, \eta_d)_{d \in D_{\text{eth}}}$ if

$$\forall d \in D_{\text{eth}} : \quad \mathrm{J}(E_{\text{univ}}(m; d)) \geq \tau_d \;\; \text{and} \;\; \mathrm{W}(E_{\text{univ}}(m; d)) \leq \eta_d.$$

If m passes for (τ_d, η_d), then it also passes for any (τ'_d, η'_d) with $\tau'_d \le \tau_d$ and $\eta'_d \ge \eta_d$ for all d. This is just upward-closure of the set of passing maxims under relaxation of requirements: lowering the required joy or raising the allowed woe cannot invalidate inequalities that already hold.

Remark 2301. ***CI-test as a thresholded universalization check.*** *The CI-test (Hyperseed-Concept 71) is formulated here as a pair of threshold requirements applied to the universalized evaluation* $E_{\text{univ}}(m; d)$*: sufficient joy and limited woe in each ethical dimension. Monotonicity in thresholds is a basic sanity property: if a maxim passes a stringent test, it should pass any more permissive test. Formally, for each* d *one is intersecting two half-spaces in the* (J, W)*-plane; relaxing* (τ_d, η_d) *enlarges the feasible region, so membership is preserved.*

Connection to order structure. *This is another instance where the direction of inequalities is doing conceptual work: increasing the required joy* (τ_d) *makes the test harder, whereas increasing the tolerated woe* (η_d) *makes it easier. This matches the intended polarity of* J *and* W *as order-preserving summaries:* J *is to be pushed up,* W *is to be pushed down, so the CI-test is monotone in the natural product order on the space of threshold pairs.*

Proof sketch. Immediate from the direction of the inequalities. Expanding the quantifiers: for each fixed d, from $\mathrm{J}(E_{\text{univ}}(m; d)) \ge \tau_d$ and $\tau'_d \le \tau_d$ we get $\mathrm{J}(E_{\text{univ}}(m; d)) \ge \tau'_d$; similarly, from $\mathrm{W}(E_{\text{univ}}(m; d)) \le \eta_d$ and $\eta'_d \ge \eta_d$ we get $\mathrm{W}(E_{\text{univ}}(m; d)) \le \eta'_d$. Since this holds for all $d \in D_{\text{eth}}$, the conjunction defining CI-passage is preserved.

Statement (evil ⇒ likely CI-failure under compassion). Assume comp $\in D_{\text{eth}}$ and its CI-threshold η_{comp} is meaningfully restrictive. If a policy π is "evil" in the sense that under universalized/repeated application it yields persistently high W in compassion-related dimensions, then the maxim corresponding to π fails the CI-test for comp. More explicitly, if universalization drives $\mathrm{W}(E_{\text{univ}}(m; \text{comp}))$ above η_{comp} (either deterministically or in a robust expectation/liminf sense, depending on how E_{univ} is instantiated), then the CI-inequality for the compassion coordinate is violated, hence the conjunction over $d \in D_{\text{eth}}$ cannot hold.

Remark 2302. ***Interpretation (Evil and Compassion).*** *"Evil" (Hyperseed-Concept* **??***) is not being treated as a metaphysical primitive here, but as a pattern of outcomes under universalization: persistently high woe in compassion-relevant dimensions (Hyperseed-Concept 81). Given this, failure of a compassion woe-threshold is almost tautological. The value of stating it explicitly is architectural: it clarifies that, once compassion is included among ethical dimensions, a policy that systematically harms others is filtered out by the CI-test rather than being left to downstream heuristics.*

A further interpretive point is that this usage of "evil" is operational and comparative: the label is attached to policies or action-rules insofar as *they induce high compassion-woe when scaled up (via* E_{univ}*) or iterated, not insofar as they have any special ontological status. This keeps the concept compatible with pluralistic ethical modeling: one can disagree about metaphysics while still agreeing that certain universalized patterns reliably generate severe compassion-relevant harm.*

Relation to broader arguments. *This sits naturally beside arguments that prosociality tends to yield more stable and efficient multi-agent outcomes [6]: if universalized harm is self-defeating at the group level, then the CI-test will tend to reject it when compassion is operationalized. One can also read this as a minimal interface between qualitative ethical vocabulary and quantitative screening: the CI-test does not need a rich theory of vice; it* *only needs a way to detect that a candidate policy, when generalized, drives* W *beyond the compassion tolerance encoded by* η_{comp}*.*

Proof sketch. "Evil" provides (by assumption/definition) that universalized/repeated application produces large $\mathrm{W}(E_{\text{univ}}(m_\pi; \text{comp}))$, hence it exceeds η_{comp}, violating CI. Equivalently, if the defining property of the "evil" pattern is that the compassion-relevant woe remains high *under the same transformation* E_{univ} used by the CI-test, then the CI constraint is breached by construction; the proof is essentially a type-check that the quantities compared are identical.

Remark 2303. ***Proof sketch commentary.*** *This is a direct implication: the premise is already phrased in terms of the same quantitative observable (*W*) that the CI-test constrains. The only subtlety is extra-mathematical: what counts as "meaningfully restrictive" depends on how the thresholds are set, which is a modeling choice rather than a theorem. Another subtlety (still extra-mathematical) is the scope of the universalization operator* E_{univ}*: different formalizations of "universal adoption" can vary in how they model feedback, retaliation, and long-run equilibrium. The remark here is therefore best read as a robustness claim about the* architecture*: whatever specific* E_{univ} *is chosen in Section 18, if "evil" is defined as producing persistently high compassion-woe under that same operator, then CI-rejection follows immediately.*

14. **(H14) Humility-calibrated confidence simplifies and is monotone.**

Statement. Let $C_O(\Pi, c) = (C_O^+(\Pi, c), C_O^-(\Pi, c)) \in [0,1]^2$ and $h \in [0,1]$. Define

$$\mathrm{Conf}_h(\Pi, c) := C_O^+(\Pi, c) \cdot (1-h) \; + \; C_O^+(\Pi, c) \cdot h \cdot (1 - C_O^-(\Pi, c)).$$

Then the expression simplifies to

$$\mathrm{Conf}_h(\Pi, c) = C_O^+(\Pi, c) \cdot \big(1 - h\, C_O^-(\Pi, c)\big).$$

In particular, $0 \le \mathrm{Conf}_h(\Pi, c) \le C_O^+(\Pi, c) \le 1$, and for fixed C_O^+, Conf_h is weakly decreasing in h and in C_O^-. It is also useful to note the boundary cases encoded by the formula: when $h = 0$, one recovers the undamped confidence $\mathrm{Conf}_0 = C_O^+$; when $h = 1$, one obtains the maximally humility-weighted confidence $\mathrm{Conf}_1 = C_O^+(1 - C_O^-)$, i.e. the positive support is discounted directly by the negative support. Likewise, if $C_O^- = 0$ (no negative evidence) then $\mathrm{Conf}_h = C_O^+$ for all h, whereas if $C_O^- = 1$ (maximal negative evidence) then $\mathrm{Conf}_h = C_O^+(1-h)$, so humility alone sets how strongly confidence is reduced.

Remark 2304. ***Intuition (humility as a regulator).*** *The parameter* $h \in [0,1]$ *plays the role of humility: how strongly negative evidence* C_O^- *should damp positive confidence* C_O^+*. This is an algebraic counterpart of "weakness" principles: confidence ought not be a blunt affirmation but a moderated stance responsive to counterevidence (Hyperseed-Concepts 202,* **??***) [2, 3]. The simplified form* $C_O^+(1 - hC_O^-)$ *makes the damping effect explicit: the discount factor lies in* $[0,1]$ *and decreases as either humility* h *or negative support* C_O^- *increases.*

One can also interpret the expression as a two-stage gating: C_O^+ *sets the* ceiling *on how confident the system is permitted to be (given its positive support), while* $(1 - hC_O^-)$ *is a multiplicative* veto strength *determined jointly by humility and counterevidence. Because the damping is multiplicative, the rule preserves scale: if positive support doubles (within* $[0,1]$*), the humility-adjusted confidence doubles as well, but always subject to the same fractional discount induced by* h *and* C_O^-*.*

Why it is useful. *Monotonicity properties like these are crucial when confidence is used inside control loops: they guarantee that increasing humility cannot paradoxically increase confidence, and that increasing negative evidence cannot increase confidence. Such guarantees are small but stabilizing. In particular, if downstream decision rules threshold on* Conf_h *(e.g. to authorize risky actions), then these monotonicities ensure that adding counterevidence or increasing humility cannot create a new authorization that was previously absent, which is the directionality one typically wants for safety-leaning calibration.*

Proof sketch. Algebra:

$$C^+(1-h) + C^+h(1-C^-) = C^+\big((1-h) + h - hC^-\big) = C^+(1-hC^-).$$

Bounds follow since $hC^- \in [0,1]$. Monotonicity follows because $1 - hC^-$ decreases as either h or C^- increases. More explicitly, holding C^+ fixed, $\partial\mathrm{Conf}_h/\partial h = -C^+C^- \le 0$ and $\partial\mathrm{Conf}_h/\partial C^- = -C^+h \le 0$, so the weak monotonicity statements follow immediately (where the "weak" qualifier covers the cases $C^+ = 0$, $C^- = 0$, or $h = 0$ in which the derivative vanishes).

Remark 2305. ***Proof sketch commentary.*** *The simplification is a distributive-law exercise, but it reveals the core structure: a product of a "pro" term and a "discount" term. The inequalities then become immediate because both factors live in* $[0,1]$*. Visually, for fixed* C^+*,* Conf_h *is an affine function of* h *with nonpositive slope* $-C^+C^-$*, so it decreases linearly as humility increases. Additionally, the factorization makes it clear that* Conf_h *is jointly continuous (indeed, bilinear) in* (h, C^-) *for fixed* C^+*, which is often convenient when* Conf_h *is embedded into optimization or learning procedures: small changes in humility or assessed negative support yield proportionally small changes in the resulting confidence.*

40 Helper theorems for life, energy, and genenergy

Remark 2306. *This section collects "small" facts that are logically routine but conceptually clarifying: one often wants to rewrite a homeostasis condition, to weaken parameters without redoing an argument, or to turn a capacity definition into a usable inequality. The role of these helper results is analogous to what Russell would call the housekeeping of a theory: we separate the essential conceptual commitments (in the main definitions and propositions) from the algebraic consequences that are repeatedly invoked. In practice, these lemmas function as a shared toolbox: once proved, they can be cited whenever a later argument needs (i) a change of quantifiers (e.g. from "for all times" to "for a finite horizon" and then to a limit), (ii) a standard probabilistic relaxation (e.g. using a union bound or Markov-type inequality), or (iii) a monotonicity claim (e.g. showing that a property becomes easier to satisfy when viability thresholds are relaxed or when available budget is increased). The intent is not to introduce new conceptual primitives here, but to make repeated manipulations explicit, so that downstream sections can focus on the substantive modeling choices rather than on routine rearrangements.*

Remark 2307. *A small piece of notation that recurs throughout:*

- $\mathbb{P}_\pi(\cdot)$ *is probability under the trajectory distribution induced by policy* π *(Hyperseed-Concept 139). Concretely,* π *together with the environment dynamics determines a measure over full histories* $(s_0, g_0, s_1, g_1, \dots)$ *(and, where relevant, observations and actions), and* $\mathbb{P}_\pi$ *denotes probability computed with respect to that induced measure.*

- $\mathbb{E}_\pi[\cdot]$ *is expectation under the same distribution. Unless otherwise stated, expectations are taken over all sources of randomness in the closed-loop system (environment stochasticity and any stochasticity internal to* π*), and the subscript* π *is retained to make explicit which controller induces the distribution.*

- $\mathbb{I}[\cdot]$ *is an indicator variable:* $\mathbb{I}[\textit{statement}] = 1$ *if the statement is true and* 0 *otherwise. This device is useful for converting event probabilities into expectations (e.g.* $\mathbb{P}_\pi(A) = \mathbb{E}_\pi[\mathbb{I}[A]]$*), and for expressing quantities like time-in-viability as sums of indicators.*

- (s_t, g_t) *denotes the state and budget (or resource) variables at time* t*. Here* t *is typically discrete and ranges over* $\{0, 1, 2, \dots\}$*, but the helper statements are generally organized so that finite-horizon and infinite-horizon variants can be related by standard limiting arguments. The pairing emphasizes that "life" conditions are usually constraints on joint configurations of external state and internal resource.*

- V_O *is the viability set: the set of acceptable pairs* (s, g) *(Hyperseed-Concept 101,* **??***). Depending on the modeling choice,* V_O *may encode hard safety constraints, soft operational envelopes, or time-dependent requirements (e.g. seasonal or mission-phase constraints); when such dependence matters, it will be made explicit, but the default notation suppresses it for readability.*

The intuition is that homeostasis means "staying in the acceptable region" with high probability, while genenergy formalizes how much controllable influence an agent has on future observations under resource constraints [1]. Put differently, the homeostasis conditions are typically statements about events of the form $\{(s_t, g_t) \in V_O \text{ for all } t \leq T\}$ *or about the frequency with which* (s_t, g_t) *remains viable, whereas genenergy-type quantities are typically statements about how the policy can shape distributions of future trajectories (often measured through information-theoretic or capacity-like expressions) subject to the feasible evolution of* g_t*. Many of the "small" results below are therefore bridges between these viewpoints: they translate viability events into expectation bounds, relate worst-case and average-case variants, and make explicit how resource constraints enter the probability calculus.*

Remark 2308. *It is worth emphasizing the scope of the helper results in this section. They are intended to be policy-agnostic in the sense that they apply uniformly to any fixed* π *for which the induced trajectory distribution is well-defined, and they are typically insensitive to the particular parametrization of the environment beyond basic measurability and boundedness assumptions stated locally when needed. When a lemma introduces a technical condition (for example, bounded indicators, nonnegativity of a resource variable, or a nesting relation between viability sets), the point is usually to enable a standard inequality step that would otherwise be repeated verbatim across proofs. In particular, several statements will exploit elementary facts such as: if* $V_{O1} \subseteq V_{O2}$ *then any homeostasis guarantee relative to* V_{O1} *implies the corresponding guarantee relative to* V_{O2}*; or if a budget lower bound is relaxed then feasibility (and thus achievable genenergy) is monotone nondecreasing. These are conceptually straightforward, but writing them once avoids ambiguity about which direction the implication runs.*

40.1 Homeostasis (Defs. 270–271): event rewrites and monotonicity

Remark 2309. *Homeostasis is, in this framework, a probabilistic notion of viability: rather than demanding that* every *trajectory remain viable, one demands that* most *trajectories do, up to a tolerated failure probability* δ*. Conceptually this mirrors the way real organisms (or robust engineered systems) tolerate rare shocks while maintaining an overall regime of functioning (Hyperseed-Concept 101, 109).*

Helper Lemma 40.1 (Complement form of homeostasis)**.** *If a policy π is homeostatic for (V_O, T, δ), i.e.*

$$\mathbb{P}_\pi\Big((s_t, g_t) \in V_O \text{ for all } t = 0, \dots, T\Big) \ \geq\ 1 - \delta,$$

then equivalently

$$\mathbb{P}_\pi\Big(\exists t \in \{0, \dots, T\} \text{ with } (s_t, g_t) \notin V_O\Big) \ \leq\ \delta.$$

Remark 2310. *Intuitively, the lemma says: "staying viable with probability at least $1-\delta$" is the same as "failing viability at some time with probability at most δ." This is not deep mathematics; it is the basic logical duality between a safety property and its violation event. Its utility is that many bounds (union bounds, Markov bounds, and other risk controls) are more naturally phrased in terms of the probability of* violation*, rather than the probability of* success*.*

Sketch. Take complements: $\{\forall t \leq T : (s_t, g_t) \in V_O\}^c = \{\exists t \leq T : (s_t, g_t) \notin V_O\}$, and use $\mathbb{P}(A^c) = 1 - \mathbb{P}(A)$. □

Remark 2311. Proof sketch (high level). *The strategy is to recognize that "for all t" and "there exists t" are De Morgan duals. The probability identity $\mathbb{P}(A^c) = 1 - \mathbb{P}(A)$ then transfers the $1 - \delta$ bound to a δ bound.*

Why the key step works. *The complement of "all times are viable" is precisely "some time is not viable." Nothing about Markov decision processes is used here; only elementary logic and probability.*

Visual intuition. *Imagine a bundle of trajectories drawn as curves in a time–state diagram. The "good" bundle consists of curves staying in the shaded region V_O for the whole time interval; the complement bundle consists of curves that cross the boundary at least once.*

Remark 2312. Equivalent union form. *The violation event can be written explicitly as a finite union:*

$$\Big\{\exists t \in \{0, \dots, T\} : (s_t, g_t) \notin V_O\Big\} = \bigcup_{t=0}^{T} \Big\{(s_t, g_t) \notin V_O\Big\}.$$

This rewriting is often the point at which one can apply standard probability tools. For example, without assuming any independence across time, the union bound yields

$$\mathbb{P}_\pi\Big(\exists t \leq T : (s_t, g_t) \notin V_O\Big) \leq \sum_{t=0}^{T} \mathbb{P}_\pi\big((s_t, g_t) \notin V_O\big),$$

so any way of controlling the per-time violation probabilities automatically controls the global homeostasis risk, albeit sometimes conservatively.

Helper Corollary 40.2 (Per-time viability and expected violations)**.** *Under the same hypothesis, for every fixed $t \in \{0, \dots, T\}$,*

$$\mathbb{P}_\pi\big((s_t, g_t) \in V_O\big) \ \geq\ 1 - \delta, \quad \text{so} \quad \mathbb{P}_\pi\big((s_t, g_t) \notin V_O\big) \ \leq\ \delta.$$

Consequently the expected number of violations satisfies

$$\mathbb{E}_\pi\Big[\sum_{t=0}^{T} \mathbb{I}[(s_t, g_t) \notin V_O]\Big] \ \leq\ (T+1)\delta,$$

and by Markov's inequality, $\mathbb{P}_\pi(\#\text{violations} \geq k) \leq (T+1)\delta/k$ for any $k \geq 1$.

Remark 2313. *This corollary extracts two kinds of "local" consequences from a "global" homeostasis guarantee. First, if you are safe for* all *times with high probability, then you are certainly safe at any* particular *time with at least the same probability. Second, once we rewrite violations using indicators, linearity of expectation turns a logical statement into an additive quantitative bound. The Markov inequality bound then says that frequent violations are unlikely when the expected number is small.*

Remark 2314. *In applications, this is often how one turns a desired high-level safety requirement into a tractable performance objective: one controls (or estimates) the expected count of boundary crossings. This is reminiscent of how one manages risk in stochastic control: one may not be able to guarantee perfect safety, but one can constrain the probability (or expected frequency) of failure events (Hyperseed-Concept 87, 195).*

Sketch. The event "viable for all times" is a subset of the event "viable at time t", so probabilities inherit the lower bound. Then linearity of expectation gives the bound on the sum of indicators; Markov gives the tail bound. □

Remark 2315. Proof sketch (high level). *The strategy is: (i) use set inclusion to move from a conjunction over times to a single time; (ii) sum indicator variables to count violations and take expectations; (iii) use Markov to convert an expectation bound into a tail-probability bound.*

Key steps. *The inclusion step is the fundamental monotonicity of probability: if $A \subseteq B$ then $\mathbb{P}(A) \leq \mathbb{P}(B)$. Linearity of expectation is what turns the random count $\sum_t \mathbb{I}[\cdot]$ into a sum of per-time probabilities. Markov is the final bridge from average-case to worst-case frequency.*

Geometric intuition. *Think of each time t as a "slice" through trajectory space. Homeostasis controls the measure of trajectories that ever leave the viable tube; the corollary bounds the measure of trajectories outside the tube at any slice, and the expected number of slices where a trajectory lies outside the tube.*

Remark 2316. On tightness and interpretation. *The bound $\mathbb{P}_\pi\big((s_t, g_t) \notin V_O\big) \leq \delta$ is generally loose as a statement about a fixed time t: it follows only from the fact that violating at time t implies violating at* some *time. In many models, the per-time violation probability can be much smaller than δ (for instance, when failures are concentrated near the end of the horizon, or when leaving V_O is a rare transient effect). Similarly, $\mathbb{E}[\#\text{violations}] \leq (T+1)\delta$ follows from applying the same uniform bound to each term; it is a conservative but assumption-free way to convert the global requirement into an additive quantity.*

Helper Proposition 40.3 (Parameter weakening rules)**.** *If π is homeostatic for (V_O, T, δ) then:*

1. *for any $T' \leq T$, π is homeostatic for (V_O, T', δ);*
2. *for any $V_O \subseteq V_O'$ (a weaker viability set), π is homeostatic for (V_O', T, δ);*
3. *for any $\delta' \geq \delta$, π is homeostatic for (V_O, T, δ').*

Remark 2317. *This proposition records a basic monotonicity principle: homeostasis becomes easier to satisfy when we (i) ask for it over a shorter time horizon, (ii) enlarge the set considered "viable," or (iii) tolerate a larger failure probability. These weakening rules are useful when comparing designs or proofs across different parameterizations: one often establishes a strong guarantee (small δ, long T, strict V_O) and then inherits a family of weaker guarantees for free.*

Sketch. Let

$$A_T \;:=\; \Big\{(s_t, g_t) \in V_O \text{ for all } t = 0, \ldots, T\Big\}.$$

(i) If $T' \leq T$, then $A_T \subseteq A_{T'}$ because satisfying viability for all times up to T in particular implies satisfying it for all times up to T'. Hence $\mathbb{P}_\pi(A_{T'}) \geq \mathbb{P}_\pi(A_T) \geq 1 - \delta$.

(ii) If $V_O \subseteq V'_O$, then

$$\Big\{(s_t, g_t) \in V_O \text{ for all } t \leq T\Big\} \subseteq \Big\{(s_t, g_t) \in V'_O \text{ for all } t \leq T\Big\},$$

so the probability lower bound transfers by monotonicity.

(iii) If $\delta' \geq \delta$, then $1 - \delta' \leq 1 - \delta$, so any inequality of the form $\mathbb{P}_\pi(A_T) \geq 1 - \delta$ immediately implies $\mathbb{P}_\pi(A_T) \geq 1 - \delta'$. $\square$

Remark 2318. *The proposition states three monotonicities that match the moral shape of the definitions: it is easier to be safe for fewer steps, easier to be safe in a larger allowed region, and easier to satisfy a weaker probability requirement. These rules are frequently used implicitly; it is therefore helpful to isolate them as explicit "weakening" principles (Hyperseed-Concept 202, 101).*

Remark 2319. *Connection to later results: these weakening rules will pair naturally with budget dynamics (below). For example, once one proves homeostasis for a strict minimal-budget viability set and a long horizon, one automatically inherits homeostasis for any shorter horizon or any relaxed notion of viability.*

Sketch. Each item is immediate by event inclusion (smaller horizon / larger viable set / weaker probability requirement).

To make the inclusions explicit, one may rewrite the underlying "good event" in the definition of homeostasis as an intersection over time. For instance, if the viability requirement is that the state remains in a set V for times $t = 0, 1, \ldots, T$, the good event can be written as

$$E_{T,V} \;:=\; \bigcap_{t=0}^{T} \{\, x_t \in V \,\}.$$

Then the shortening-of-horizon monotonicity is simply the containment

$$E_{T,V} \subseteq E_{T',V} \qquad \text{whenever } T' \leq T,$$

because intersecting fewer constraints produces a larger event. Likewise, if $V \subseteq V'$ then for each t one has $\{x_t \in V\} \subseteq \{x_t \in V'\}$, and hence

$$E_{T,V} \subseteq E_{T,V'}.$$

Finally, for the probability-threshold weakening, if the homeostasis condition is of the form $\mathbb{P}(E_{T,V}) \geq 1 - \delta$ and one replaces δ by a larger tolerance $\delta' \geq \delta$, then $1 - \delta' \leq 1 - \delta$, so the same inequality automatically implies $\mathbb{P}(E_{T,V}) \geq 1 - \delta'$.

In all cases, the probability comparison uses only monotonicity of $\mathbb{P}$ with respect to event inclusion: if $A \subseteq B$ then $\mathbb{P}(A) \leq \mathbb{P}(B)$, so a lower bound for $\mathbb{P}(A)$ is also a lower bound for $\mathbb{P}(B)$. $\square$

Remark 2320. Proof sketch (high level). *Each clause is a one-line containment argument: if you demand less, you get a superset of acceptable trajectories.*

Why it works. *Homeostasis is defined by a single inequality* $\mathbb{P}(\textit{good event}) \geq 1 - \delta$. *Each weakening moves from a smaller good event to a larger good event, or lowers the required threshold* $1 - \delta$.

Visual intuition. *In a picture of a viability tube over time, item (1) shortens the tube, item (2) widens it, and item (3) accepts a larger fraction of trajectories that may leave it.*

Optional formalism. *If one prefers to keep the argument entirely at the level of set-theoretic operations, the three weakenings correspond to: (i) dropping factors from an intersection over time, (ii) enlarging the sets inside that intersection, and (iii) lowering the right-hand side in the defining inequality. No particular structure of the dynamics is needed beyond the fact that the events in question are measurable (so that* $\mathbb{P}(\cdot)$ *is defined) and that* $\mathbb{P}$ *is monotone under inclusion.*

Operational reading. *These monotonicities can also be read as closure properties of the set of policies (or initial conditions) that satisfy homeostasis: if a policy achieves homeostasis for a stringent specification, then the same policy remains valid after any of the three relaxations. This is the precise sense in which they function as "weakening principles" and explains why they can be invoked without re-checking the dynamics in later budget-coupled arguments.*

40.2 Genenergy as constrained capacity (Defs. 272–276, Props. 25–26)

Remark 2321. *Genenergy is defined via an information-theoretic constrained capacity: one asks how many bits of influence an agent's action* A *can transmit to the next observation* Y_{t+1}*, given a cost budget* g*. In classical information theory this is a channel capacity with an input cost constraint; here it is reinterpreted as a measure of "available effective agency" under resource limits (Hyperseed-Concept* **??***, 117,* **??***). For background on mutual information and capacity as measures of influence, see [16]; for alternative but related measures of distinction/information, compare logical entropy [17]. In particular, one may read* $I(A; Y_{t+1} \mid h_{0:t})$ *as quantifying how strongly the distribution of the next observation can be* steered *by choosing different action distributions, holding fixed the historical context* $h_{0:t}$ *(so that the "channel" is the conditional map* $p(y_{t+1} \mid a, h_{0:t})$ *induced by the world model at time* t*). The budget constraint* $\mathbb{E}[c_O(A)] \leq g$ *then expresses that steering is only counted when it is achieved with affordable mixtures of actions, which matches the intended "agency under resource limits" reading.*

Remark 2322. *It is useful to keep in mind the standard constrained-capacity template: for each fixed* $(O, t, h_{0:t})$*, the function* $g \mapsto \mathrm{Cap}_{O,t,h}(g)$ *is the value of an optimization problem where the feasible set expands monotonically with* g*. Consequently, even before proving any regularity properties, one should expect (and later can show under mild conditions) that* $\mathrm{Cap}_{O,t,h}(g)$ *is nondecreasing in* g*, with saturation once the constraint stops binding. The next lemma isolates exactly that saturation regime in the simplest possible way.*

Helper Lemma 40.4 (Unconstrained-capacity regime once budget exceeds max effort)**.** *Fix* $(O, t, h_{0:t})$ *and cost* $c_O : A \to \mathbb{R}_{\geq 0}$*. If* $g \geq \max_{a \in A} c_O(a)$*, then the constraint* $\mathbb{E}[c_O(A)] \leq g$ *is vacuous for all* $p \in \Delta(A)$*, hence*

$$\mathrm{Cap}_{O,t,h}(g) \;=\; \max_{p \in \Delta(A)} I(A; Y_{t+1} \mid h_{0:t}).$$

Remark 2323. *This lemma says that once the budget is large enough to afford even the most expensive action, the optimization ceases to be a constrained one: every action distribution is feasible, so capacity becomes the ordinary (unconstrained) mutual-information maximum. Philosophically, it draws a sharp line between regimes where "energy matters" and regimes where it does not: beyond a threshold, the resource variable* g *stops being a binding constraint. A further conceptual point* *is that this threshold depends only on the* cost model c_O *and the action set* A*, and not on any dynamics or observation model; it is therefore a purely "accounting" boundary between constrained and unconstrained agency.*

Remark 2324. *A simple example: if* $A = \{a_1, a_2\}$ *with costs* $c_O(a_1) = 0.2$ *and* $c_O(a_2) = 0.9$*, then any budget* $g \geq 0.9$ *makes all mixtures* $p(a_1), p(a_2)$ *feasible. For* $g < 0.9$*, distributions placing too much mass on* a_2 *are excluded, and the achievable influence may drop. One can also see explicitly how the constraint cuts out a half-space in the simplex: the feasible set is* $\{p \in \Delta(A) : 0.2\, p(a_1) + 0.9\, p(a_2) \leq g\}$*, i.e.* $p(a_2) \leq (g - 0.2)/(0.7)$ *when* $g \geq 0.2$*, and no nontrivial distribution is feasible if* $g < 0.2$ *(unless one allows zero-cost slack actions). This geometric view will be helpful when thinking about how genenergy changes continuously as the budget parameter is varied.*

Sketch. If $g \geq \max_a c_O(a)$, then for any distribution p, $\mathbb{E}_{A\sim p}[c_O(A)] \leq \max_a c_O(a) \leq g$. So the feasible set is all of $\Delta(A)$. □

Remark 2325. Proof sketch (high level). *The strategy is to upper bound an average by a maximum.*

Key step. *The inequality* $\mathbb{E}[c_O(A)] \leq \max_a c_O(a)$ *holds for any distribution because an expectation is a convex combination of pointwise values.*

Intuition. *If even the priciest action is affordable, then affordability does not restrict choice. One may also interpret the same step as a one-line application of the fact that* $\max_a c_O(a)$ *is an (almost sure) upper bound on the random variable* $c_O(A)$*, and taking expectations preserves upper bounds.*

Remark 2326. *In later applications it is sometimes convenient to rewrite the constrained maximization defining* $\mathrm{Cap}_{O,t,h}(g)$ *using a Lagrange multiplier* $\lambda \geq 0$*, maximizing* $I(A; Y_{t+1} \mid h_{0:t}) - \lambda(\mathbb{E}[c_O(A)] - g)$ *over* $p \in \Delta(A)$*. The present lemma then corresponds to the situation where an optimal multiplier can be taken as* $\lambda = 0$*, because the constraint is inactive; this is another standard way of recognizing the "unconstrained" regime.*

Helper Lemma 40.5 (Information-theoretic upper bounds from finiteness of Y_O)**.** *Let* Y_O *be the finite observation alphabet for* O *(Def. 273). Then for any* (O, t, h, g)*,*

$$\mathrm{Cap}_{O,t,h}(g) \;\leq\; \log |Y_O| \qquad \text{and} \qquad \mathrm{Cap}_{O,t,h}(g) \;\leq\; \log |A|.$$

(Logs are base 2 if mutual information is measured in bits.)

Remark 2327. *This lemma states two universal ceilings on genenergy that come purely from finiteness: you cannot extract more than* $\log |Y_O|$ *bits of information from a variable that only takes* $|Y_O|$ *possible values, and you cannot transmit more than* $\log |A|$ *bits if your input itself only has* $|A|$ *possibilities. The importance is practical: it tells us that even without knowing any dynamics, genenergy is bounded above by a simple combinatorial quantity. In particular, the bound does not depend on the budget* g *at all; increasing the budget can only help until these alphabet-size ceilings are met, at which point no additional resources can increase the measured action-to-observation information flow.*

Remark 2328. *The bounds also reinforce an epistemological point: an observer with a coarse alphabet* Y_O *cannot, by definition, register arbitrarily fine distinctions, so the measured influence of actions on observations is limited (Hyperseed-Concept 134,* **??***). This prepares the ground for the data-processing theorem below. Equivalently, if the "true" underlying world state is high-dimensional but* O *records it through a many-to-one perception map into* Y_O*, then any influence actions exert on microscopic details that are subsequently discarded by perception is invisible to* $I(A; Y_{t+1} \mid h_{0:t})$ *and therefore invisible to genenergy as defined here.*

Sketch. For any feasible p, $I(A; Y \mid h) \leq H(Y \mid h) \leq \log |Y_O|$, and also $I(A; Y \mid h) \leq H(A) \leq \log |A|$. Taking the maximum preserves the bound. □

Remark 2329. Proof sketch (high level). *The strategy is to sandwich mutual information between entropies and then use the trivial entropy upper bound for finite alphabets.*

Why it works. *Mutual information satisfies $I(A; Y \mid h) \leq H(Y \mid h)$ and also $I(A; Y \mid h) \leq H(A)$, because conditioning cannot increase uncertainty and I is a reduction in uncertainty. Finally, $H(Z) \leq \log |Z|$ for a finite random variable Z.*

Visual intuition. *If Y has only $|Y_O|$ bins, it is like a measuring device with only $|Y_O|$ display states; it cannot convey more than $\log |Y_O|$ bits, regardless of how intricate the underlying world is. It can also be helpful to remember the extreme case: if $|Y_O| = 1$ (the observer always sees the same symbol), then $\log |Y_O| = 0$ and necessarily $I(A; Y_{t+1} \mid h_{0:t}) = 0$ for all choices of p, so genenergy is identically zero because nothing observable can ever change.*

Remark 2330. *A concrete illustration of the $\log |A|$ ceiling: if A has only two actions, then even in the best possible world model the action can carry at most $\log 2 = 1$ bit of information about the next observation (conditional on history). Thus any reported genenergy value above 1 bit per step would signal a mismatch between the formal action alphabet and the effective degrees of freedom actually being optimized over.*

Helper Corollary 40.6 (Uniform bound on realizable genenergy over horizon T)**.** *For any policy π (Def. 276),*

$$G_O(\pi; T) \;=\; \mathbb{E}\Big[\frac{1}{T} \sum_{t=0}^{T-1} \mathrm{Cap}_{O,t,h}(g_t)\Big] \;\leq\; \log |Y_O|.$$

Therefore $G_O^{\mathrm{real}}(T) = \sup_\pi G_O(\pi; T) \leq \log |Y_O|$.

Remark 2331. *The corollary lifts a pointwise capacity bound to an averaged-over-time and averaged-over-trajectories bound. Its conceptual message is sobering and useful: regardless of policy ingenuity, the observer's alphabet limits the long-run average genenergy. In other words, the "ceiling of agency as measured through observation" is partly a ceiling of* representation *(Hyperseed-Concept 157, 134). Note that the bound is uniform in T: increasing the time horizon does not allow one to exceed* $\log |Y_O|$ per time step *on average, because each step produces at most one symbol in Y_O. This keeps the scale of genenergy comparable across horizons and prevents spurious growth that would come from simply aggregating influence over longer runs without normalization.*

Sketch. Apply the previous lemma inside the average and expectation. □

Remark 2332. Proof sketch (high level). *Bound each summand by $\log |Y_O|$, then average.*

Key step. *Expectations and averages preserve inequalities when applied to pointwise-bounded random variables.*

Intuition. *If each day you can gain at most B bits of influence, then your average influence per day is also at most B. Formally, if $X_t \leq B$ almost surely for each t, then $\frac{1}{T} \sum_{t=0}^{T-1} X_t \leq B$ almost surely, and taking $\mathbb{E}[\cdot]$ preserves the inequality; here one takes $X_t = \mathrm{Cap}_{O,t,h}(g_t)$ and $B = \log |Y_O|$.*

Helper Theorem 40.7 (Observer coarsening reduces genenergy (data processing))**.** *Let two observers have observation maps $\phi_1 : E \to Y_1$ and $\phi_2 : E \to Y_2$ (Def. 273). If there exists a deterministic ψ with $\phi_1 = \psi \circ \phi_2$, then for all (t, h, g),*

$$\mathrm{Cap}_{1,t,h}(g) \;\leq\; \mathrm{Cap}_{2,t,h}(g).$$

Remark 2333. *In plain terms: if observer O_1 sees only a deterministic coarsening of what O_2 sees, then O_1 can never register* more *action-to-observation influence than O_2. This is a direct application of the data-processing inequality, one of the central theorems of information theory [16]. It is important because it makes "observer dependence" mathematically explicit: genenergy is not an intrinsic property of the world alone, but of the world* as perceived through *an observation map (Hyperseed-Concept 134, 112).*

Remark 2334. *Connection to the previous bounds: finiteness gave absolute ceilings; data processing gives* comparative *ceilings across observers. Together they support a disciplined notion of refinement: adding observational resolution cannot reduce maximal attainable information flow, while coarse-graining cannot increase it.*

Sketch. For any feasible input distribution $p(a)$, $Y^{(1)}_{t+1} = \psi(Y^{(2)}_{t+1})$ so by data processing $I(A; Y^{(1)}_{t+1} \mid h) \le I(A; Y^{(2)}_{t+1} \mid h)$. Maximizing over the same feasible set yields the inequality. □

Remark 2335. Proof sketch (high level). *Show the inequality for each fixed feasible input distribution $p(a)$, then take maxima.*

Key step. *The data-processing inequality says that applying a deterministic function ψ to an observation cannot increase its mutual information with the input. Deterministic post-processing can only forget distinctions, not create them.*

Visual intuition. *Think of Y_2 as a high-resolution image and Y_1 as the same image after blurring. No choice of action can make the blurred image reveal more about the action than the original image could.*

Helper Corollary 40.8 (Positive genenergy iff some feasible distribution has influence)**.** *Fix (O, t, h) and budget g. Then $\mathrm{Cap}_{O,t,h}(g) > 0$ iff there exists some feasible $p \in \Delta(A)$ with $\mathbb{E}[c_O(A)] \le g$ and $I(A; Y_{t+1} \mid h_{0:t}) > 0$. Equivalently (Prop. 25), $\mathrm{Cap}_{O,t,h}(g) = 0$ iff $A \perp Y_{t+1} \mid h_{0:t}$ for all feasible p.*

Remark 2336. *This corollary translates the definition of constrained capacity into an existential criterion: positive genenergy means that* some *affordable randomized choice of actions genuinely influences what the observer can see next (in the precise sense of mutual information). If capacity is zero, then within the budget constraint the action is informationally irrelevant to the next observation, given history: the agent may still act, but it cannot make a detectable difference to Y_{t+1} as measured by O (Hyperseed-Concept* **??**, *87).*

Sketch. Immediate from the definition of Cap as a maximum and the characterization of the zero case. □

Remark 2337. Proof sketch (high level). *A maximum is positive exactly when at least one feasible point attains a positive value.*

Key step. *The "only if" direction uses attainment in the finite-dimensional optimization (or, more generally, the definition of* max*); the "if" direction uses monotonicity of* max *with respect to the feasible set.*

Intuition. *Capacity is the best achievable influence; it is nonzero exactly when influence is achievable at all.*

Helper Proposition 40.9 (Concavity calculus: diminishing returns and baseline-subadditivity)**.** *Assume the concavity from Prop. 26: $g \mapsto \mathrm{Cap}_{O,t,h}(g)$ is concave and nondecreasing. Then chord slopes are decreasing: for $0 \le g_1 < g_2 < g_3$,*

$$\frac{\mathrm{Cap}(g_2) - \mathrm{Cap}(g_1)}{g_2 - g_1} \ge \frac{\mathrm{Cap}(g_3) - \mathrm{Cap}(g_2)}{g_3 - g_2}.$$

Moreover the baseline-adjusted map $\widehat{\mathrm{Cap}}(g) := \mathrm{Cap}(g) - \mathrm{Cap}(0)$ *is subadditive:*

$$\widehat{\mathrm{Cap}}(g_1 + g_2) \ \leq \ \widehat{\mathrm{Cap}}(g_1) + \widehat{\mathrm{Cap}}(g_2) \qquad (g_1, g_2 \geq 0).$$

Remark 2338. *The first statement is the familiar "diminishing returns" principle: as you invest more budget* g*, the additional genenergy per additional unit of budget cannot increase when the capacity curve is concave. In other words, the marginal gain (interpretable as a slope, derivative, or subderivative depending on regularity) is nonincreasing in* g*, so each extra unit of budget buys weakly less additional baseline-adjusted capacity than the previous unit. Geometrically, for a concave graph the slopes of secant lines between points on the curve decrease as the points move to the right, and this is exactly the comparison of incremental gains over successive budget intervals.*

The second statement is slightly subtler: if we measure capacity above baseline $\mathrm{Cap}(0)$*, then splitting a total budget* g_1+g_2 *into two separate "allocations" cannot yield less total baseline-adjusted genenergy than spending it all at once. Here one is not claiming that splitting produces more raw capacity* $\mathrm{Cap}(\cdot)$ *(which would be false in general), but rather that after subtracting the common baseline* $\mathrm{Cap}(0)$ *the resulting function behaves subadditively under a concavity assumption. This kind of inequality is often what one needs to justify modular budgeting arguments. Concretely, it supports the idea that if two subsystems each receive their own budget and each is evaluated relative to its own baseline, then combining the resulting baseline-adjusted contributions does not underperform a single monolithic expenditure evaluated relative to the same baseline.*

Remark 2339. *Connection to the metabolic model below: concavity is precisely what makes resource allocation nontrivial. If returns were increasing, the rational strategy would be to concentrate all budget; with diminishing returns, diversification and distributed spending can become sensible. In this way, a simple analytic property (concavity) expresses a strategic fact about agency under constraints (Hyperseed-Concept 100,* **??***). Put differently, concavity is the mathematical encoding of "saturation": once some pathway is well-funded, pouring additional effort into the same pathway yields progressively smaller improvements, which creates room for parallel investments to be competitive.*

Sketch. The slope statement is a standard equivalent form of concavity. More explicitly, for a concave function f on an interval, the secant slope

$$\frac{f(g+h) - f(g)}{h}$$

is nonincreasing as g increases (for fixed $h > 0$), and equivalently the left and right derivatives (when they exist) satisfy $f'(g_1) \geq f'(g_2)$ whenever $g_1 \leq g_2$. This expresses precisely that the incremental benefit of additional budget weakly decreases.

For subadditivity: $\widehat{\mathrm{Cap}}$ is concave, nondecreasing, and $\widehat{\mathrm{Cap}}(0) = 0$. Recall the concavity inequality in the usual form

$$f(\lambda a + (1-\lambda)b) \ \geq \ \lambda f(a) + (1-\lambda) f(b) \qquad (0 \leq \lambda \leq 1).$$

Using concavity with $x = \frac{g_1}{g_1+g_2}(g_1+g_2) + \frac{g_2}{g_1+g_2} \cdot 0$ (and similarly for g_2), one gets $\widehat{\mathrm{Cap}}(g_1) + \widehat{\mathrm{Cap}}(g_2) \geq \widehat{\mathrm{Cap}}(g_1 + g_2)$. To see the algebra: set $f = \widehat{\mathrm{Cap}}$, $a = g_1 + g_2$, $b = 0$, and $\lambda = \frac{g_1}{g_1+g_2}$, so that $\lambda a + (1-\lambda) b = g_1$. Concavity then yields

$$f(g_1) \ \geq \ \frac{g_1}{g_1+g_2} f(g_1+g_2) + \frac{g_2}{g_1+g_2} f(0) \ = \ \frac{g_1}{g_1+g_2} f(g_1+g_2),$$

where the last equality uses $f(0) = 0$. Similarly, with $\lambda = \frac{g_2}{g_1+g_2}$ one obtains

$$f(g_2) \;\geq\; \frac{g_2}{g_1+g_2} f(g_1+g_2).$$

Adding these two inequalities gives

$$f(g_1) + f(g_2) \;\geq\; \Big(\frac{g_1}{g_1+g_2} + \frac{g_2}{g_1+g_2}\Big) f(g_1+g_2) \;=\; f(g_1+g_2),$$

which is the desired subadditivity. The nondecreasing hypothesis ensures that interpreting f as "baseline-adjusted capacity" is consistent with budget monotonicity, but the normalization $f(0) = 0$ is the crucial point that prevents additive constants from interfering with the inequality. □

Remark 2340. Proof sketch (high level). *The first part uses the geometric characterization of concavity: chords lie below tangents, so chord slopes decrease as you move right. Equivalently, moving a fixed horizontal distance to the right yields a smaller vertical increase when you start further to the right. The second part uses concavity in the special case of convex combinations with* 0 *to relate values at* g_1*,* g_2*, and* $g_1 + g_2$*. The role of* 0 *is not incidental: it anchors the comparison at a common reference point, which is exactly what "baseline-adjusted" means.*

Key step. *Writing* g_1 *as a convex combination of* $(g_1 + g_2)$ *and* 0 *is the algebraic trick that makes concavity apply. Concretely,* $g_1 = \lambda(g_1 + g_2) + (1 - \lambda)0$ *with* $\lambda = \frac{g_1}{g_1+g_2} \in [0, 1]$*, and the same pattern holds for* g_2*. The baseline adjustment* $\widehat{\mathrm{Cap}}(0) = 0$ *is what prevents constant offsets from breaking subadditivity. Without this normalization, concavity would only yield an "affine-subadditivity" statement up to an additive constant, and that constant would precisely be the baseline being subtracted off.*

Visual intuition. *For a concave curve starting at* $(0, \mathrm{Cap}(0))$*, the "height above baseline" bends downward; two shorter horizontal moves can reach at least as much total height as one longer move, once you compare everything to the same baseline. Another way to picture it is to imagine that the first units of budget climb the steep part of the curve, while later units climb a flatter part; splitting lets both portions benefit from steeper initial segments when evaluated relative to the shared baseline.*

40.3 Entity-sets and potential genenergy (Defs. 277–278, Prop. 27)

Remark 2341. *Potential genenergy* $g_O(E; T)$ *(as defined earlier) aggregates what may be achievable when one considers a set* E *of entities (Hyperseed-Concept 175). The monotonicity property in Prop. 27 formalizes an obvious idea: enlarging the set of entities under consideration can only increase (or preserve) what is possible, because it relaxes constraints on what counts as an admissible entity-system.*

Remark 2342. *One convenient way to read Prop. 27 is as an order-preservation statement: the mapping*

$$E \longmapsto g_O(E; T)$$

is monotone with respect to set inclusion. In particular, whenever one argues that a certain capability is achievable using some collection of entities, that argument automatically remains valid when additional entities are allowed, since the admissible class of entity-systems has only expanded.

Helper Lemma 40.10 (Union lower bound from monotone potential genenergy)**.** *Let* $E_1, E_2 \subseteq \mathrm{Ent}$ *be entity-sets. Then for any* T*,*

$$g_O(E_1 \cup E_2; T) \;\geq\; \max\{g_O(E_1; T),\; g_O(E_2; T)\}.$$

Remark 2343. *The lemma says that the union is at least as powerful as either component set. This is a minimal but frequently used inequality: it lets one bound a complicated set from below by any simpler subset one can analyze. In proofs, it often functions as a controlled way of saying "we may restrict attention to a convenient subcollection without increasing difficulty."*

Remark 2344. *Equivalently, the displayed inequality can be split into the two statements*

$$g_O(E_1 \cup E_2; T) \;\geq\; g_O(E_1; T) \qquad \text{and} \qquad g_O(E_1 \cup E_2; T) \;\geq\; g_O(E_2; T),$$

and the "max" packaging simply records both at once. This way of writing it is often helpful when one later takes successive unions: each union step can be seen as adding more admissible entities without reducing the best-achievable potential genenergy.

Sketch. $E_i \subseteq E_1 \cup E_2$ so monotonicity (Prop. 27) gives $g_O(E_i; T) \leq g_O(E_1 \cup E_2; T)$. □

Remark 2345. Proof sketch (high level). *Reduce to monotonicity: subset inclusion implies an inequality.*

Key step. *The only substantive input is Prop. 27 (monotonicity). Once that is granted, the union bound is immediate.*

Intuition. *Having more entities available cannot make your best achievable genenergy worse.*

Remark 2346. *Two small boundary cases are worth keeping in mind for later use. First, if $E_1 = \varnothing$ then the lemma reduces to $g_O(E_2; T) \leq g_O(E_2; T)$ (together with the implicit inequality $g_O(\varnothing; T) \leq g_O(E_2; T)$ coming from monotonicity). Second, if $E_1 \subseteq E_2$, then $E_1 \cup E_2 = E_2$ and the lemma collapses to the monotonicity inequality already supplied by Prop. 27. In this sense, the union lower bound is best viewed as a direct reformulation of monotonicity that is tailored to the common situation where one builds larger entity-sets by unions.*

Corollary 19 (Finite union lower bound)**.** *Let $E_1, \ldots, E_n \subseteq \mathrm{Ent}$ be entity-sets. Then for any T,*

$$g_O\Big(\bigcup_{k=1}^{n} E_k; T\Big) \;\geq\; \max_{1 \leq k \leq n} g_O(E_k; T).$$

Sketch. Apply the lemma iteratively (or argue by induction on n), using that $E_j \subseteq \bigcup_{k=1}^{n} E_k$ for each j and then invoking Prop. 27. □

Remark 2347. *The inequality is one-sided because combining entity-sets can introduce new admissible entity-systems that were not available when restricted to either component alone. Hence $g_O(E_1 \cup E_2; T)$ can be strictly larger than both $g_O(E_1; T)$ and $g_O(E_2; T)$. Equality holds in particular when one of the two sets already contains the other, but strict improvement is the generic case when the definition of g_O permits "hybrid" systems drawing on entities from both sets.*

40.4 Metabolism and budget dynamics (Defs. 279–280, Prop. 28)

Remark 2348. *The metabolic accounting model treats budget g_t as a leaky integrator: it decays by a factor $(1 - \lambda)$, receives income $\Gamma_O(r_t)$ from resources r_t, and pays costs $c_O(a_t)$ for actions. This is a stylized but mathematically transparent way to formalize "maintenance" and "effort" (Hyperseed-Concept 109, 100,* **??***).*

Remark 2349. *Two parameters/choices deserve emphasis.*

- *The leakage rate $\lambda \in [0,1]$ encodes the timescale of decay: small λ corresponds to slow forgetting/slow dissipation, while λ near 1 corresponds to almost complete reset each step. In particular, when $\lambda = 1$ we have $g_{t+1} = \Gamma_O(r_t) - c_O(a_t)$, so the state carries no budget memory beyond one step.*

- *The splitting of the update into an "income" term $\Gamma_O(r_t)$ and a "cost" term $c_O(a_t)$ is conceptually useful because it separates what the environment provides (resources) from what the agent chooses (actions), even though both can be random and coupled through the policy/environment dynamics.*

Helper Lemma 40.11 (Closed form of the budget recursion)**.** *Under the metabolic accounting model (Def. 279),*

$$g_{t+1} = (1-\lambda)g_t + \Gamma_O(r_t) - c_O(a_t),$$

we have for all $t \geq 1$:

$$g_t = (1-\lambda)^t g_0 + \sum_{k=0}^{t-1} (1-\lambda)^{t-1-k} \big(\Gamma_O(r_k) - c_O(a_k)\big).$$

Remark 2350. *This lemma simply unrolls the recursion. The point is not that it is hard, but that it reveals structure: current budget is the discounted sum of past net incomes plus a decayed initial budget. In other words, the past persists, but with exponentially fading influence. Such explicit formulas are often indispensable when taking limits (steady states) or bounding expectations.*

Remark 2351. *It is also helpful to read the formula as a discrete-time convolution: the "impulse response" of the budget dynamics is the geometric kernel $(1-\lambda)^{t-1-k}$. This makes it immediate, for example, that if the net income sequence $\Gamma_O(r_k) - c_O(a_k)$ is uniformly bounded, then g_t is bounded up to a term that depends on λ (and similarly for moment bounds when integrability is available). When $\lambda > 0$, the kernel is summable, reflecting that very old contributions become negligible.*

Sketch. Induction on t. □

Remark 2352. Proof sketch (high level). *Prove the formula holds at $t = 1$, then assume it holds at t and substitute into the recursion to obtain the $t+1$ case.*

Key step. *The geometric factor $(1-\lambda)^{t-1-k}$ arises because each net income term must survive decay for the number of steps between k and t.*

Visual intuition. *Imagine pouring water into a leaky bucket each step: earlier pours contribute less to the current water level because of leakage.*

Remark 2353. *A useful special case check is $\lambda = 0$, in which case there is no leakage and the formula reduces to*

$$g_t = g_0 + \sum_{k=0}^{t-1} \big(\Gamma_O(r_k) - c_O(a_k)\big),$$

i.e. a pure cumulative sum. This makes clear why $\lambda > 0$ changes qualitative behavior: it turns an accumulating process into a mean-reverting one (in expectation under stationarity assumptions).

Helper Corollary 40.12 (Expected steady state under stationarity)**.** *Assume $\lambda > 0$ and there exists μ with $\mathbb{E}[\Gamma_O(r_t) - c_O(a_t)] = \mu$ for all t (e.g. stationary regime). Then*

$$\mathbb{E}[g_t] = (1-\lambda)^t \mathbb{E}[g_0] + \frac{\mu}{\lambda}\big(1 - (1-\lambda)^t\big), \quad \textit{so} \quad \mathbb{E}[g_t] \to \mu/\lambda.$$

Remark 2354. *This corollary is the expected-value analogue of a steady-state calculation: if on average you earn μ net budget per time-step, and you leak a fraction λ per step, then the expected equilibrium budget is μ/λ. The condition $\lambda > 0$ is essential: without leakage, budget would drift linearly rather than converge. This is a precise version of the intuitive idea that maintenance costs (modeled here by leakage) stabilize resource levels (Hyperseed-Concept 109).*

Remark 2355. *Note that the claim concerns $\mathbb{E}[g_t]$ and not almost-sure convergence of g_t. Even in a stationary regime, the random fluctuations of $\Gamma_O(r_t) - c_O(a_t)$ can keep g_t wandering, while the expectation settles to μ/λ. To upgrade from an expectation statement to concentration or almost-sure statements typically requires additional assumptions (e.g. bounded increments, martingale arguments, or ergodicity/mixing). The explicit formula from the lemma is often the starting point for such refinements because it expresses g_t as a weighted sum of past shocks.*

Sketch. Take expectations in the recursion and solve the resulting linear difference equation. □

Remark 2356. Proof sketch (high level). *The expectation of the recursion is a first-order linear difference equation with constant forcing term μ. Solve it by standard methods (homogeneous solution plus particular solution).*

Key step. *Stationarity is used only to make the forcing term constant across t.*

Intuition. *The long-run expected budget is where average inflow balances average leakage: $\lambda\,\mathbb{E}[g] \approx \mu$.*

Remark 2357. *It can be instructive to see the "balance" directly: if $\mathbb{E}[g_t] \to \bar{g}$ exists, then taking limits in*

$$\mathbb{E}[g_{t+1}] = (1 - \lambda)\mathbb{E}[g_t] + \mu$$

forces $\bar{g} = (1-\lambda)\bar{g} + \mu$, hence $\lambda\bar{g} = \mu$ and $\bar{g} = \mu/\lambda$. This highlights why the limit value is insensitive to $\mathbb{E}[g_0]$: initial conditions are forgotten at the exponential rate $(1 - \lambda)^t$.

Helper Proposition 40.13 (Iterated invariant lower bound (Prop. 28 as an induction rule))**.** *Let $\underline{g} > 0$ be such that $(s, g) \in V_O \Rightarrow g \geq \underline{g}$ and suppose there is a policy regime satisfying the Prop. 28 inequality $\mathbb{E}[\Gamma_O(r_t)] \geq \mathbb{E}[c_O(a_t)] + \lambda\underline{g}$ whenever $g_t \geq \underline{g}$. Then the condition $\mathbb{E}[g_t] \geq \underline{g}$ is inductive: if it holds at time t it holds at $t + 1$. Hence if $\mathbb{E}[g_0] \geq \underline{g}$ then $\mathbb{E}[g_t] \geq \underline{g}$ for all t.*

Remark 2358. *The proposition isolates the logical heart of many viability arguments: identify a lower bound $\underline{g}$ required by the viability set, then show that the expected budget update cannot push you below $\underline{g}$ provided you are already at or above it. This transforms Prop. 28 into a reusable induction principle: once above the floor (in expectation), always above the floor (in expectation). It is a formal version of "metabolic sustainability" (Hyperseed-Concept 109, 101).*

Remark 2359. *One should also notice what is* not *assumed: the proposition does not require the net income to be nonnegative almost surely, nor does it require $\Gamma_O(r_t)$ and $c_O(a_t)$ to be independent of g_t. The condition is framed to be robust under coupling, because it is stated as a one-step expected inequality under the regime of interest. This is often exactly what is available from a control design or a Lyapunov-style estimate, where one can guarantee that some expected drift is favorable above a threshold.*

Remark 2360. *Connection back to homeostasis: homeostasis concerns the probability of staying in V_O; this proposition concerns maintaining a budget floor that is* necessary *for membership in V_O. In larger arguments, one often uses budget invariance to help establish viability, and then applies the event-rewrite lemmas to reason about failure probability.*

Remark 2361. *There is also a useful conceptual separation between* viability constraints *and* budget dynamics*. The assumption $(s, g) \in V_O \Rightarrow g \geq \underline{g}$ says the viability set imposes a hard feasibility requirement on budget; the Prop. 28 inequality then provides a* sufficient *drift condition ensuring the dynamics respect that requirement (in expectation). This is the same pattern as "safe set implies barrier function lower bound" plus "controller keeps barrier from decreasing" in other safety/control formalisms, except specialized here to a linear leaky-integrator state variable.*

Sketch. This is exactly the one-step bound shown in the proof of Prop. 28, iterated by induction. □

Remark 2362. Proof sketch (high level). *Use the one-step inequality to show $\mathbb{E}[g_{t+1}] \geq \underline{g}$ whenever $\mathbb{E}[g_t] \geq \underline{g}$, then iterate.*

Key step. *The hypothesis $\mathbb{E}[\Gamma_O(r_t)] \geq \mathbb{E}[c_O(a_t)] + \lambda \underline{g}$ is precisely chosen to cancel the expected leakage term λg_t at the floor value $\underline{g}$.*

Intuition. *If your expected net intake covers both your expected expenses and the leakage needed to maintain the floor, then you do not (in expectation) fall through the floor.*

Remark 2363. *Algebraically, the one-step calculation behind the induction is*

$$\mathbb{E}[g_{t+1}] = \mathbb{E}[(1-\lambda)g_t] + \mathbb{E}[\Gamma_O(r_t)] - \mathbb{E}[c_O(a_t)] \geq (1-\lambda)\underline{g} + \lambda \underline{g} = \underline{g},$$

where the middle inequality uses the regime assumption together with $\mathbb{E}[g_t] \geq \underline{g}$. Written this way, it is clear that the proof is a drift condition at a boundary: the expected update at the floor does not point downward. In applications, strengthening the inequality to a strict margin (e.g. $\geq \mathbb{E}[c_O(a_t)] + \lambda \underline{g} + \epsilon$) yields a cushion that can be useful when translating expectation bounds into probability bounds.

40.5 Reproduction and species (Defs. 281–286): closure and cycle facts

Remark 2364. *The reproduction and species layer formalizes persistence through time by allowing an entity-state S to "generate" future states S' under a reproduction relation. Similarity relations $\approx_{O,\varepsilon}$ define what counts as "the same kind" up to tolerance, while species axioms impose closure conditions under reproduction reachability (Hyperseed-Concept 156, 174). The use of pattern webs as the substrate for similarity is discussed in the broader pattern framework [5] (Hyperseed-Concept 132, 130).*

Remark 2365. *In this subsection, it is useful to keep three distinct ingredients conceptually separate: (i) the* dynamics $\Rightarrow_O$ *(what reproduces from what, relative to observer/context O), (ii) the* typing/identity up to tolerance $\approx_{O,\varepsilon}$ *(what counts as "the same kind" for purposes of continuity), and (iii) the* closure principle *defining a species C (what sets of states are stable under the dynamics). The results below are elementary but serve as reusable "glue" facts: they permit moving between local statements about one-step reproduction and global statements about multi-step reachability, and they quantify how similarity degrades under chaining.*

Helper Lemma 40.14 (Similarity relation: reflexive and symmetric; approximate transitivity under a metric)**.** *Let $\approx_{O,\varepsilon}$ be the within-species similarity relation (Def. 282) induced by a symmetric dissimilarity d_O on pattern webs. Then $\approx_{O,\varepsilon}$ is reflexive and symmetric. If additionally d_O satisfies the triangle inequality, then*

$$S_0 \approx_{O,\varepsilon} S_1 \ \wedge \ S_1 \approx_{O,\varepsilon} S_2 \ \Rightarrow \ S_0 \approx_{O,2\varepsilon} S_2,$$

and along an n-step chain, the tolerance blows up to $n\varepsilon$.

Remark 2366. *This lemma makes explicit what one should expect of any reasonable similarity notion: it is always self-similar (reflexive) and similarity is symmetric. True transitivity is not guaranteed unless d_O is a metric and ε is treated carefully; instead we get a controlled weakening: similarity composes at the cost of increasing tolerance. This is philosophically apt: as Peirce would emphasize, categories of resemblance are habits of generalization, and in chaining them we often accumulate error (Hyperseed-Concept 59, 96).*

Remark 2367. *Example: if d_O is Euclidean distance on an embedding of pattern webs, and $\varepsilon = 0.1$, then two successive "0.1-close" steps imply "0.2-close" overall. The lemma tells you precisely how tolerance degrades under chaining, which matters when defining species via repeated reproduction steps.*

Remark 2368. *A practical reading is that $\approx_{O,\varepsilon}$ behaves like a family of relations indexed by tolerance, and the triangle inequality provides a monotone "composition rule":*

$$(\approx_{O,\varepsilon_1}) \circ (\approx_{O,\varepsilon_2}) \subseteq \approx_{O,\varepsilon_1+\varepsilon_2} .$$

In particular, when ε is chosen to reflect measurement or modeling noise, the $n\varepsilon$ blow-up along an n-step chain is a quantitative reminder that long chains of approximate identifications can drift. This often motivates either (a) keeping chain lengths bounded in later arguments, or (b) re-normalizing by periodically re-anchoring similarity to a canonical representative within a species.

Sketch. Reflexive: $d_O(W, W) = 0 \leq \varepsilon$. Symmetric: symmetry of d_O. Approximate transitivity: apply triangle inequality to the witnessing web-states. □

Remark 2369. Proof sketch (high level). *The first two properties use the axioms of d_O directly; the third uses triangle inequality and adds the error terms.*

Key step. *Triangle inequality yields $d_O(S_0, S_2) \leq d_O(S_0, S_1) + d_O(S_1, S_2) \leq \varepsilon + \varepsilon = 2\varepsilon$.*

Intuition. *Similarity is like being within a radius ε ball; chaining two balls gives a ball of doubled radius.*

Remark 2370. *One can also view the n-step statement as an immediate induction: if $d_O(S_0, S_k) \leq k\varepsilon$ and $d_O(S_k, S_{k+1}) \leq \varepsilon$, then the triangle inequality gives $d_O(S_0, S_{k+1}) \leq (k + 1)\varepsilon$. This form is sometimes more directly usable when a later proof naturally proceeds by stepping through time indices.*

Helper Lemma 40.15 (Forward closure along reproduction reachability)**.** *Let C be a species (Def. 284), and write $\Rightarrow_O^*$ for the reflexive transitive closure of the reproduction relation $\Rightarrow_O$. If $S \in C$ and $S \Rightarrow_O^* S'$, then $S' \in C$.*

Remark 2371. *This lemma states that species membership is stable under any finite number of reproduction steps. It is essentially what it means to treat C as a "closed" class under the reproduction dynamics: once you are in the species, your descendants (in the reachability sense) remain in it. This is the minimal formal backbone of any notion of species as a persistent kind (Hyperseed-Concept 174,* **??***).*

Remark 2372. *Recall that $\Rightarrow_O^*$ is the least relation containing $\Rightarrow_O$ that is both reflexive and transitive: informally, $S \Rightarrow_O^* S'$ means that there exists a finite sequence*

$$S = S_0 \Rightarrow_O S_1 \Rightarrow_O \cdots \Rightarrow_O S_n = S'$$

for some $n \geq 0$. The case $n = 0$ is exactly reflexivity ($S = S'$), and the closure property in the species definition is what lets one extend membership from S_k to S_{k+1} repeatedly.

Sketch. Induct on the length of the $\Rightarrow_O$-chain using the closure axiom of species. $\square$

Remark 2373. Proof sketch (high level). *Induction on chain length: length* 0 *is trivial, length* $n+1$ *reduces to length* n *plus one application of the closure axiom.*

Key step. *The definition of reflexive transitive closure* $\Rightarrow_O^*$ *is precisely designed so that induction applies.*

Visual intuition. *View reproduction as edges in a directed graph. The lemma says: if you start inside* C *and walk along directed edges, you never leave* C*.*

Remark 2374. *In later uses, it is often helpful to keep track of* which *axiom of species is being invoked: the lemma does not require any similarity assumptions, nor any finiteness assumptions, only the forward-closure clause of Def. 284. Thus, it applies equally well to infinite species, branching reproduction, and nondeterministic reproduction (multiple possible* S' *for a given* S*), as long as the closure axiom is stated universally over* $\Rightarrow_O$*-successors.*

Helper Proposition 40.16 (Finite-species regeneration implies a reproduction cycle)**.** *Assume* C *is a finite species and ignore any designated "initial" exception to regeneration. If for every* $S' \in C$ *there exists* $S \in C$ *with* $S \Rightarrow_O S'$*, then the directed graph* $(C, \Rightarrow_O)$ *contains a directed cycle.*

Remark 2375. *This proposition is a graph-theoretic inevitability: in a finite directed graph where every node has at least one incoming edge from within the graph (a "regeneration" condition), you cannot keep tracing predecessors forever without repeating a node. Repetition creates a directed cycle. The result matters because cycles correspond to recurring lineages or steady regenerative loops, which can be interpreted as a structural signature of ongoing reproduction within a bounded repertoire of states (Hyperseed-Concept 155, 156).*

Remark 2376. *Connection to the closure lemma: forward closure says you remain in* C *when moving forward along* $\Rightarrow_O$*; here we reason backward via predecessors. Together they show how finiteness forces recurrence once regeneration is ubiquitous.*

Remark 2377. *The hypothesis "ignore any designated 'initial' exception to regeneration" can be read as: treat regeneration as holding* uniformly *on all of* C *(no privileged seed-state allowed to lack an in-species predecessor). If such an exception were permitted, the conclusion can fail in the obvious way: a finite directed graph may be a rooted in-arborescence with a unique root of in-degree* 0*, producing no directed cycle. Thus, the proposition isolates exactly the condition under which one cannot have a strictly acyclic "ancestry" structure within a finite state-set.*

Sketch. Pick any $S_0 \in C$ and choose predecessors $S_{k+1} \Rightarrow_O S_k$ indefinitely. Since C is finite, some $S_i = S_j$ with $i < j$; the segment $S_{j-1} \Rightarrow \cdots \Rightarrow S_i$ forms a directed cycle. $\square$

Remark 2378. Proof sketch (high level). *Construct an infinite backward path by repeatedly choosing an in-species predecessor; finiteness forces repetition; repetition yields a cycle.*

Remark 2379. *A slightly more explicit way to see the "repetition yields a cycle" step is: from* $S_i = S_j$ *(with* $i < j$*) we have a nonempty chain*

$$S_j = S_i \Leftarrow_O S_{i+1} \Leftarrow_O \cdots \Leftarrow_O S_j$$

when read in the predecessor direction, and hence, when read in the forward $\Rightarrow_O$ *direction, a directed cycle*

$$S_i \Rightarrow_O S_{j-1} \Rightarrow_O \cdots \Rightarrow_O S_i.$$

This is just the pigeonhole principle applied to states visited along the infinite predecessor sequence. The argument does not require determinism: even if there are many possible predecessors at each step, choosing some *predecessor repeatedly is enough to force eventual repetition in a finite set.*

Remark 2380. *Interpreted in reproduction terms, the cycle can be read as the existence of a finite lineage of states in C that "comes back" (possibly through a sequence of distinct intermediate states). In many applications this is the minimal formal shadow of an invariant or steady regime: although individual reproduction events may change the state, the system cannot wander indefinitely through new states if C is finite and internally regenerating.*

Remark 2381. Key step. *The pigeonhole principle: an infinite sequence in a finite set must repeat. Imagine for instance: You are walking backward through ancestors in a village with only finitely many people; if everyone has an ancestor in the village, eventually you meet someone you have already met, closing a loop.*

40.6 Alive/dead p-bits (Defs. 287–289): rewrite rules and threshold entailments

Remark 2382. *The alive/dead layer assigns to an entity-state S a p-bit: a two-coordinate value $(v^+, v^-) \in [0,1]^2$ encoding positive and negative evidence. This is an explicitly paraconsistent style of representation: one can simultaneously have evidence-for and evidence-against, without explosion. Such multi-valued logics are studied systematically in paraconsistent frameworks such as Constructible Duality Logic [23] and related resonance-motivated uses [24]; in the Hyperseed vocabulary it is naturally linked to Alive/Dead (Hyperseed-Concept 54) and to Weakness as graded entailment (Hyperseed-Concept 202) [3, 2].*

Helper Lemma 40.17 (Clamp in Alive is redundant)**.** *Alive is defined (Def. 288) using* $\min\{1, \cdot\}$ *applied to a weighted average of numbers in* $[0,1]$*. Because any weighted average of* $[0,1]$*-values lies in* $[0,1]$*, the* $\min\{1, \cdot\}$ *does not change the value.*

Remark 2383. *The lemma is a small algebraic reassurance: the definition includes a clamp to stay within* $[0,1]$*, but because the computation is already a convex combination of* $[0,1]$ *values, it cannot leave the interval. Such redundancies are common in definitions meant to be robust to generalization; the lemma tells us that in the present setting no special case occurs.*

Sketch. If $x, y \in [0,1]$ and $\alpha, \beta \geq 0$ with $\alpha + \beta > 0$, then $\frac{\alpha x + \beta y}{\alpha + \beta} \leq \frac{\alpha + \beta}{\alpha + \beta} = 1$ and ≥ 0. □

Remark 2384. Proof sketch (high level). *Show a weighted average is bounded by the max and min of its inputs.*
Key step. *Bounding the numerator* $\alpha x + \beta y \leq \alpha + \beta$ *uses* $x, y \leq 1$*; the lower bound uses* $x, y \geq 0$.
Intuition. *Averaging cannot create values outside the range of what is being averaged.*

Helper Proposition 40.18 (Alive monotonicity and bounds)**.** *Let* $\mathrm{Alive}_O(S,t)$ *be the weighted aggregation of* $\mathrm{Met}_O(S,t)$ *and* $\mathrm{Rep}_O(S,t)$ *(Def. 288). Then* $\mathrm{Alive}_O(S,t)$ *is componentwise monotone in each input p-bit. Also, for the positive coordinate,*

$$\min\{\mathrm{Met}_O^+(S,t), \mathrm{Rep}_O^+(S,t)\} \;\leq\; \mathrm{Alive}_O^+(S,t) \;\leq\; \max\{\mathrm{Met}_O^+(S,t), \mathrm{Rep}_O^+(S,t)\},$$

and similarly for the negative coordinate.

Remark 2385. *Monotonicity says: if you increase evidence-for (or evidence-against) in either metabolism or reproduction, you do not decrease the corresponding alive evidence. The min/max bounds say: the aggregation is genuinely an average-like synthesis, not an exotic operation that could produce an "alive" score outside the range suggested by its two inputs. This makes the alive p-bit behave like a reasonable mediator between the metabolic and reproductive aspects of life (Hyperseed-Concept 109, 156, 54).*

Sketch. Weighted averages are monotone and lie between the min and max of their inputs. □

Remark 2386. Proof sketch (high level). *Use elementary properties of convex combinations: coordinatewise,* Alive *is a convex combination of the two coordinates of* Met *and* Rep*.*

Key step. *Componentwise monotonicity follows because increasing one input term increases the convex combination when weights are nonnegative.*

Intuition. Alive *is literally an interpolation between* Met *and* Rep *in each coordinate.*

Helper Corollary 40.19 (Threshold lifting for Alive)**.** *Fix $\theta \in (0,1]$. If $\mathrm{Met}^+_O(S,t) \geq \theta$ and $\mathrm{Rep}^+_O(S,t) \geq \theta$ then $\mathrm{Alive}^+_O(S,t) \geq \theta$. Likewise, if $\mathrm{Met}^-_O(S,t) \geq \theta$ and $\mathrm{Rep}^-_O(S,t) \geq \theta$ then $\mathrm{Alive}^-_O(S,t) \geq \theta$.*

Remark 2387. *This is the familiar stability of lower bounds under averaging: if both contributing signals clear a threshold, so does their weighted blend. It is useful when one reasons in thresholded terms (e.g. "alive at level θ"), because it lets one infer alive-threshold facts from stronger componentwise evidence.*

Sketch. A weighted average of numbers each at least θ is at least θ. □

Remark 2388. Proof sketch (high level). *The average is a convex combination of numbers $\geq \theta$, hence $\geq \theta$.*

Key step. *Multiply the inequality $x \geq \theta$ by a nonnegative weight and sum.*

Intuition. *If every ingredient is at least θ, the mixture cannot fall below θ.*

Helper Lemma 40.20 (WasAlive monotonicity in window length)**.** *Let $\mathrm{WasAlive}_O(S,t)$ be the p-bit join over the lookback window (Def. 289) of length τ. If $\tau' \geq \tau$, then $\mathrm{WasAlive}^{(\tau')}_O(S,t) \geq \mathrm{WasAlive}^{(\tau)}_O(S,t)$ componentwise.*

Remark 2389. *Here "was alive" is an aggregation over past evidence, and enlarging the window can only increase what you have "ever seen" in that window. This is a formal version of the obvious epistemic principle: remembering more cannot reduce the maximum strength of remembered evidence (Hyperseed-Concept 63, 52, 155).*

Sketch. A join over a larger index set is $\geq$ the join over a subset. □

Remark 2390. Proof sketch (high level). *Larger window means more terms in the join; joins are monotone in their index sets.*

Key step. *Any set is a subset of a larger set; the join over the larger set must dominate the join over the subset by definition of $\oplus$ as a join.*

Intuition. *Taking a maximum over more numbers cannot decrease the maximum.*

Helper Corollary 40.21 (Deadness monotone in lookback window)**.** *Since $\mathrm{Dead}_O(S,t) = \mathrm{WasAlive}_O(S,t) \otimes \neg\,\mathrm{Alive}_O(S,t)$ (Def. 289) and $\otimes$ is monotone, $\tau' \geq \tau$ implies $\mathrm{Dead}^{(\tau')}_O(S,t) \geq \mathrm{Dead}^{(\tau)}_O(S,t)$ componentwise.*

Remark 2391. *Deadness is defined as a conjunction-like combination: evidence of having been alive (recently) together with evidence of not being alive now. If the "having been alive" part can only grow when you look back further, then deadness can only grow as well (since the other factor is unchanged). This matches the intended semantics: extending memory makes it easier to accumulate evidence that something* used to be *alive.*

Sketch. Combine the previous lemma with monotonicity of $\otimes$. □

Remark 2392. Proof sketch (high level). *Monotonicity composed with monotonicity: increase* WasAlive*, keep* $\neg$ Alive *fixed, then the tensor product increases.*

Key step. *The property that* $\otimes$ *is monotone in each argument is what makes the inequality propagate.*

Intuition. *If deadness requires two ingredients and one ingredient increases while the other stays the same, the combined score should not decrease.*

Helper Proposition 40.22 (Canonical p-bit expansion of Dead (optional, when using the canonical core))**.** *Assume the canonical p-bit operations used elsewhere in the document:*

$$(p^+,p^-)\oplus(q^+,q^-) = (\max\{p^+,q^+\},\max\{p^-,q^-\}), \quad (p^+,p^-)\otimes(q^+,q^-) = (p^+q^+,p^-q^-), \quad \neg(p^+,p^-) = (p^-,p^+).$$

Then Def. 289 yields:

$$\mathrm{WasAlive}^+_O(S,t) = \max_{u=t-\tau,\dots,t-1} \mathrm{Alive}^+_O(S,u), \qquad \mathrm{WasAlive}^-_O(S,t) = \max_{u=t-\tau,\dots,t-1} \mathrm{Alive}^-_O(S,u),$$

and

$$\mathrm{Dead}^+_O(S,t) = \mathrm{WasAlive}^+_O(S,t)\cdot \mathrm{Alive}^-_O(S,t), \qquad \mathrm{Dead}^-_O(S,t) = \mathrm{WasAlive}^-_O(S,t)\cdot \mathrm{Alive}^+_O(S,t).$$

Remark 2393. *This proposition is a "coordinate unpacking" result: it turns the abstract quantale formula for deadness into explicit max-and-multiply expressions. The value is not merely computational; it makes the semantics transparent. In the canonical core, the positive deadness coordinate is literally "(max past aliveness) times (current not-aliveness)," i.e. a conjunction of two evidential conditions expressed multiplicatively.*

Remark 2394. *This also highlights how the framework combines temporal aggregation (via* max *over the window) with present-time contradiction-tolerant evaluation (via the two coordinates). One may read this as a small instance of the broader theme that time (memory) and logic (evidence combination) are co-constitutive of an observer's ontology [1, 15, 14].*

Sketch. Unfold the join $\oplus$ and then apply coordinatewise multiplication and negation-swap. ☐

Remark 2395. Proof sketch (high level). *Replace* $\oplus$ *by coordinatewise maxima, replace* $\otimes$ *by coordinatewise multiplication, and replace* $\neg$ *by swapping coordinates.*

Key step. *The join over a finite window becomes a maximum because* $\oplus$ *is defined using* max *in each coordinate.*

Intuition. *The abstract expression* WasAlive $\otimes\neg$ Alive *becomes a literal arithmetic formula once the canonical operations are chosen.*

Helper Corollary 40.23 (Deadness entails "was alive" and "not alive now" at thresholds (canonical case))**.** *Assume the canonical p-bit expansion above and fix* $\theta \in (0,1]$*. If* $\mathrm{Dead}^+_O(S,t) \geq \theta$*, then:*

1. $\mathrm{Alive}^-_O(S,t) \geq \theta$ *(strong evidence of not-alive now), and*
2. *there exists some* $u \in \{t-\tau,\dots,t-1\}$ *with* $\mathrm{Alive}^+_O(S,u) \geq \theta$ *(strong evidence of being alive recently).*

Remark 2396. *This corollary spells out a useful threshold entailment: to have strong positive evidence of deadness, one must simultaneously have strong present evidence of not being alive and strong past evidence of being alive. This is exactly how one would want a deadness predicate to behave, and it is reassuring that the canonical p-bit arithmetic makes this precise.*

Remark 2397. *Note the asymmetry: we reason from* Dead^+ *(positive evidence) to conclusions about* Alive^- *and past* Alive^+*. This is a small example of how p-bits let one keep track of which direction of evidence is doing the work, rather than collapsing everything into a single scalar.*

Sketch. If $xy \geq \theta$ with $x, y \in [0,1]$, then $x \geq \theta$ and $y \geq \theta$. Also $\mathrm{WasAlive}^+$ is a maximum over the window. □

Remark 2398. Proof sketch (high level). *Use the fact that in* $[0,1]$ *a product cannot exceed* θ *unless each factor is at least* θ*, and interpret* $\mathrm{WasAlive}^+$ *as a maximum.*

Key step. *From* $\mathrm{Dead}^+_O(S,t) = \mathrm{WasAlive}^+_O(S,t) \cdot \mathrm{Alive}^-_O(S,t) \geq \theta$ *with both factors in* $[0,1]$*, infer both* $\mathrm{WasAlive}^+_O(S,t) \geq \theta$ *and* $\mathrm{Alive}^-_O(S,t) \geq \theta$*. Then* $\mathrm{WasAlive}^+_O(S,t) \geq \theta$ *implies some window time achieves the maximum at least* θ*.*

Intuition. *Strong deadness requires both a strong "used to be alive" witness and a strong "not alive now" witness; the product encodes conjunction, and the maximum encodes existential witness over time.*

41 Helper theorems for the epistemic layer (Section 20)

41.1 Notation and lightweight macros

Throughout, L is the claim language and $V = [0,1]^2$ is the p-bit quantale. Belief states are valuations $\beta : L \to V$ ordered pointwise by the quantale order. We write $\oplus$ for the pointwise join and $\otimes$ for the quantale tensor. We use the inference operator F_R and closure Cl_R from Definition 298 / Theorem 17, the hypothesis-injection $\beta \uparrow_s h$ from Definition 296, and the leave-one-out state $\beta \setminus \varphi$ from Definition 302.

In concrete terms, since $V = [0,1]^2$ is a product quantale, the order on V is the product order coming from $[0,1]$ (i.e. $(x_1, x_2) \leq (y_1, y_2)$ iff $x_1 \leq y_1$ and $x_2 \leq y_2$), and the induced order on belief states is the corresponding pointwise lifting: $\beta \leq \beta'$ iff $\beta(\varphi) \leq \beta'(\varphi)$ for every $\varphi \in L$. This pointwise viewpoint is used implicitly in all arguments below: inequalities and equations of belief states are always to be read coordinatewise on L and componentwise in $[0,1]^2$.

The pointwise join $\beta \oplus \beta'$ is the belief state defined by $(\beta \oplus \beta')(\varphi) = \beta(\varphi) \oplus \beta'(\varphi)$ for each $\varphi \in L$, where $\oplus$ on the right-hand side is the quantale join in V. Similarly, if γ is another belief state, then $(\beta \otimes \gamma)(\varphi)$ denotes the pointwise tensor $\beta(\varphi) \otimes \gamma(\varphi)$. We will only use the standard order-theoretic facts about these operations: joins are monotone in each argument and satisfy $x \leq x \oplus y$, and the tensor is monotone in each argument (as assumed for a quantale).

When working with $\beta \uparrow_s h$, it is convenient to name the "singleton" valuation $\delta_{h,s}$ that appears in Definition 296: it is the belief state satisfying $\delta_{h,s}(h) = s$ and $\delta_{h,s}(\varphi) = \bot$ for $\varphi \neq h$ (where $\bot$ is the bottom element of V). Thus $\beta \uparrow_s h = \beta \oplus \delta_{h,s}$ is literally "β with h joined up to at least s". Likewise, $\beta \setminus \varphi$ should be read as a valuation identical to β except that the coordinate at φ is reset/removed as specified in Definition 302; this chunk will not use any special property of $\setminus$ beyond the idea that it is a coordinatewise modification.

For the axiomaticity lemma below, recall that β^+ denotes the (epistemic) reading or projection of β used in Definition 295 (e.g. the "acceptance" or "positive" component, depending on the chosen semantics of the p-bit valuation). The only property used is that $\beta \leq \beta'$ implies $\beta^+ \leq \beta'^+$ pointwise, so that lower bounds on $\beta^+(\varphi)$ persist under pointwise increases of β.

41.2 Belief-state update algebra

Lemma 124 (Hypothesis injection is monotone and redundant when already present)**.** *Fix $h \in L$. For belief states $\beta \le \beta'$ and hypothesis strengths $s \le s'$ (in the quantale order),*

$$\beta \uparrow_s h \ \le\ \beta' \uparrow_{s'} h.$$

Moreover, if $\beta(h) \ge s$ then $\beta \uparrow_s h = \beta$.

Sketch. By Definition 296, $\beta \uparrow_s h = \beta \oplus \delta_{h,s}$. Join is monotone in each argument, so increasing either β or s can only increase the result. If $\beta(h) \ge s$ then at the coordinate h we have $\beta(h) \oplus s = \beta(h)$ and all other coordinates are unchanged, hence $\beta \oplus \delta_{h,s} = \beta$. □

The preceding lemma is often used in "idempotence" arguments: injecting the same hypothesis twice with the same strength has no further effect after the first injection, and injecting a weaker strength after a stronger one is redundant by monotonicity. Formally, if $s \le s'$ then

$$(\beta \uparrow_{s'} h) \uparrow_s h \ =\ \beta \uparrow_{s'} h,$$

since $\beta \uparrow_{s'} h$ already has $(\beta \uparrow_{s'} h)(h) \ge s' \ge s$ and thus the second injection collapses to the identity case of the lemma.

Lemma 125 (Join-updates are monotone and inflationary)**.** *For any belief states $\beta, \varepsilon, \varepsilon'$ with $\varepsilon \le \varepsilon'$, we have*

$$\beta \oplus \varepsilon \ \le\ \beta \oplus \varepsilon'.$$

Moreover, $\beta \le \beta \oplus \varepsilon$ for all β, ε.

Sketch. Both statements are coordinatewise consequences of the corresponding facts in the quantale V: join is monotone in each argument, and $x \le x \oplus y$ holds because $x \oplus y$ is the least upper bound of $\{x, y\}$. □

Lemma 126 (Closure is monotone and inflationary)**.** *For any rule set R and belief states $\beta \le \beta'$, one has*

$$\mathrm{Cl}_R(\beta) \ \le\ \mathrm{Cl}_R\big(\beta'\big).$$

In addition, $\beta \le \mathrm{Cl}_R(\beta)$ for all β.

Sketch. By Definition 298 / Theorem 17, Cl_R is the closure induced by the inference operator F_R (typically as an iterated or least fixed-point construction). The standard closure properties established there imply monotonicity of F_R and hence of Cl_R, as well as extensivity (inflationarity) $\beta \le \mathrm{Cl}_R(\beta)$. Concretely, both inequalities can be read pointwise: the closure adds consequences but does not decrease any coordinate. □

Lemma 127 (Axiomaticity is upward closed)**.** *Let (A, θ) be an axiom system (Definition 295). If β treats (A, θ) as axiomatic and $\beta \le \beta'$, then β' also treats (A, θ) as axiomatic. In particular, if updates are of the form $\beta \leftarrow \beta \oplus \varepsilon$ and/or $\beta \leftarrow \mathrm{Cl}_R(\beta)$, then once axiomatic, always axiomatic.*

Sketch. Treating (A, θ) as axiomatic means $\beta^+(\varphi) \ge \theta$ for all $\varphi \in A$. Since $\beta \le \beta'$ pointwise, $\beta'^+(\varphi) \ge \beta^+(\varphi) \ge \theta$. Both $\oplus$-updates and Cl_R are inflationary (see below), so they preserve the pointwise lower bound. □

The "once axiomatic, always axiomatic" clause is intended to be read operationally: if an algorithm maintains a belief state and interleaves (i) additive evidence updates $\beta \leftarrow \beta \oplus \varepsilon$ with (ii) logical saturation $\beta \leftarrow \mathrm{Cl}_R(\beta)$, then the set of axioms whose acceptance has crossed the threshold θ is monotone in time. The earlier lemmas isolate the only ingredients needed for that monotonicity: pointwise order on belief states and inflationary update operators.

41.3 Inference and closure

Lemma 128 (F_R is monotone and inflationary)**.** *For any rule set R, the operator $F_R((\cdot)) : V^L \to V^L$ is monotone: $\beta \le \beta' \Rightarrow F_R(\beta) \le F_R(\beta')$. Also it is inflationary: $\beta \le F_R(\beta)$.*

Sketch. Recall that the order on V^L is the pointwise order: $\beta \le \beta'$ means $\beta(\psi) \le \beta'(\psi)$ for all formulas $\psi \in L$. Thus to show $F_R(\beta) \le F_R(\beta')$ it suffices to fix an arbitrary ψ and show $F_R(\beta)\,(\psi) \le F_R(\beta')\,(\psi)$ in V.

Definition 298 builds $F_R(\beta)\,(\psi)$ from $\beta(\psi)$ by joining it with rule-contributions, each of which is a monotone expression in β using $\otimes$ and $\oplus$. More explicitly, each contribution has the form

$$\lambda_r \otimes \Big(\bigotimes_{\varphi \in \Gamma} \beta(\varphi)\Big)$$

for a rule $r = (\Gamma, \psi, \lambda_r) \in R$, and $F_R(\beta)\,(\psi)$ is obtained by taking $\beta(\psi)$ and then joining (via $\oplus$ / the relevant join operation) all such contributions that target ψ. If $\beta \le \beta'$, then for every premise $\varphi \in \Gamma$ we have $\beta(\varphi) \le \beta'(\varphi)$, so by monotonicity of $\otimes$ in each argument we get

$$\bigotimes_{\varphi \in \Gamma} \beta(\varphi) \;\le\; \bigotimes_{\varphi \in \Gamma} \beta'(\varphi), \qquad \text{hence} \qquad \lambda_r \otimes \Big(\bigotimes_{\varphi \in \Gamma} \beta(\varphi)\Big) \;\le\; \lambda_r \otimes \Big(\bigotimes_{\varphi \in \Gamma} \beta'(\varphi)\Big).$$

Joining these inequalities with the (also monotone) $\oplus$ operation preserves the order, and additionally $\beta(\psi) \le \beta'(\psi)$ contributes the base-term monotonicity. Therefore the entire join defining $F_R(\beta)\,(\psi)$ is $\le$ the corresponding join defining $F_R(\beta')\,(\psi)$, establishing monotonicity pointwise and hence globally.

Inflationary holds because $\beta(\psi)$ is one of the joined terms, so $\beta(\psi) \le F_R(\beta)\,(\psi)$ for all ψ. Equivalently, the defining join for $F_R(\beta)\,(\psi)$ includes $\beta(\psi)$ as a summand, and any join is above each of its components. □

Theorem 56 (Cl_R is a closure operator)**.** *Assume $\mathrm{Cl}_R(\beta)$ is defined as in Theorem 17 (least fixed point of F_R above β). Then Cl_R satisfies the standard closure-operator laws:*

$$\textit{(Extensive)}\ \beta \le \mathrm{Cl}_R(\beta)\,, \qquad \textit{(Monotone)}\ \beta \le \beta' \Rightarrow \mathrm{Cl}_R(\beta) \le \mathrm{Cl}_R\big(\beta'\big)\,, \qquad \textit{(Idempotent)}\ \mathrm{Cl}_R(\mathrm{Cl}_R(\beta)) = \mathrm{Cl}_R(\beta)\,.$$

Moreover, $\mathrm{Cl}_R(\beta)$ *is the* least R-closed *belief state γ with $\beta \le \gamma$.*

Sketch. Extensiveness follows since $\beta \le F_R(\beta) \le F_R^2(\beta) \le \cdots$ and $\mathrm{Cl}_R(\beta)$ is the join of this ascending chain (Theorem 17). Here the inequalities $\beta \le F_R(\beta) \le F_R^2(\beta) \le \cdots$ come from inflationarity of F_R together with its monotonicity: from $\beta \le F_R(\beta)$ and monotonicity we obtain $F_R(\beta) \le F_R(F_R(\beta)) = F_R^2(\beta)$, and so on by induction. Since a join (supremum) of an ascending chain is above every element of the chain, it is in particular above the first element β.

Monotonicity follows because F_R is monotone, hence so are all iterates, and joins preserve order. Concretely, if $\beta \le \beta'$, then by monotonicity of F_R we have $F_R^n(\beta) \le F_R^n(\beta')$ for each $n \in \mathbb{N}$ (induction on n). Taking the join over n on both sides preserves $\le$ because joins are computed pointwise in V^L and each pointwise join in V is monotone in its indexed family.

Idempotence holds because $\mathrm{Cl}_R(\beta)$ is a fixed point of F_R; applying Cl_R again yields the least fixed point above an already fixed point, hence itself. More explicitly, Theorem 17 ensures that $\mathrm{Cl}_R(\beta)$ is R-closed, i.e. $F_R(\mathrm{Cl}_R(\beta)) = \mathrm{Cl}_R(\beta)$, and also that $\mathrm{Cl}_R(\beta) \ge \beta$. Thus, when forming $\mathrm{Cl}_R(\mathrm{Cl}_R(\beta))$, we are taking the least fixed point of F_R above $\mathrm{Cl}_R(\beta)$; but $\mathrm{Cl}_R(\beta)$ is itself a fixed point above $\mathrm{Cl}_R(\beta)$, so by minimality the least such fixed point cannot be strictly smaller or larger, forcing equality.

Leastness is the standard Knaster–Tarski/Kleene fixed-point argument used in Theorem 17. In particular, if γ is any fixed point of F_R with $\beta \le \gamma$, then (by monotonicity) the entire Kleene chain above β is bounded by γ, i.e. $F_R^n(\beta) \le \gamma$ for all n, and therefore its join $\mathrm{Cl}_R(\beta)$ is also $\le \gamma$. This shows that $\mathrm{Cl}_R(\beta)$ is the least among all R-closed γ extending β. □

Corollary 20 (Characterizations of R-closed states)**.** *For a belief state β, the following are equivalent: (i) β is R-closed, i.e. $F_R(\beta) = \beta$; (ii) $\mathrm{Cl}_R(\beta) = \beta$; (iii) for every rule $r = (\Gamma, \psi, \lambda_r) \in R$,*

$$\lambda_r \otimes \Big(\bigotimes_{\varphi\in\Gamma} \beta(\varphi)\Big) \;\le\; \beta(\psi).$$

Sketch. (i)⇔(ii) is immediate from the definition of Cl_R as the least fixed point above β. Indeed, if β is already a fixed point of F_R, then the least fixed point above β is β itself; conversely, if $\mathrm{Cl}_R(\beta) = \beta$, then β must be a fixed point because $\mathrm{Cl}_R(\beta)$ is R-closed by construction.

(i)⇔(iii) follows by unpacking Definition 298: $F_R(\beta)\,(\psi)$ is $\beta(\psi)$ joined with all contributions to ψ, so equality holds iff each contribution is already $\le \beta(\psi)$. More detail: for the forward direction, assume $F_R(\beta) = \beta$. Fix a rule $r = (\Gamma, \psi, \lambda_r) \in R$ and consider the corresponding contribution term $\lambda_r \otimes \big(\bigotimes_{\varphi\in\Gamma} \beta(\varphi)\big)$, which appears among the joined terms defining $F_R(\beta)\,(\psi)$. Since a join is an upper bound of its components, we have

$$\lambda_r \otimes \Big(\bigotimes_{\varphi\in\Gamma} \beta(\varphi)\Big) \;\le\; F_R(\beta)\,(\psi) = \beta(\psi),$$

which is exactly (iii). For the reverse direction, assume (iii) holds for every rule. Then for each ψ, every rule-contribution targeting ψ is $\le \beta(\psi)$, and of course the base term $\beta(\psi) \le \beta(\psi)$. Hence the join of $\beta(\psi)$ with all these contributions is still $\beta(\psi)$, so $F_R(\beta)\,(\psi) = \beta(\psi)$ for all ψ, i.e. $F_R(\beta) = \beta$. □

Lemma 129 (Adding rules increases closure)**.** *If $R \subseteq R'$, then for all belief states β,*

$$\mathrm{Cl}_R(\beta) \;\le\; \mathrm{Cl}_{R'}(\beta)\,.$$

Sketch. For each β, Definition 298 gives $F_R(\beta) \le F_{R'}(\beta)$ pointwise because R' has (at least) all the join-terms that R has. To see this pointwise, fix ψ and observe that the set of contributions to ψ generated from rules in R is a subset of the contributions generated from rules in R'; joining over a larger family can only increase (or preserve) the value in the lattice order. Since the base term $\beta(\psi)$ is the same in both $F_R(\beta)\,(\psi)$ and $F_{R'}(\beta)\,(\psi)$, the only difference is the presence of additional contribution terms coming from $R' \setminus R$, which can only enlarge the join.

Iterating preserves the inequality, and joining over all iterates preserves it, yielding the claim. More explicitly, from $F_R(\beta) \le F_{R'}(\beta)$ and monotonicity of $F_R((\cdot))$ and $F_{R'}((\cdot))$ (as operators on V^L) one obtains by induction that $F_R^n(\beta) \le F_{R'}^n(\beta)$ for each n. Taking joins of these ascending chains (as in Theorem 17) then gives $\mathrm{Cl}_R(\beta) \le \mathrm{Cl}_{R'}(\beta)$. Equivalently, since $\mathrm{Cl}_{R'}(\beta)$ is R'-closed it is in particular closed under all rules in R, so it is an R-closed extension of β; by the leastness clause of the previous theorem, the least such extension is $\mathrm{Cl}_R(\beta)$, hence $\mathrm{Cl}_R(\beta) \le \mathrm{Cl}_{R'}(\beta)$. □

41.4 Batching and order-independence of evidence

The following facts formalize that (a) repeatedly "closing" a belief state does not interfere with subsequently adding evidence, and (b) a sequence of evidence joins interleaved with closures can be equivalently performed as one big join followed by one final closure. Intuitively, Cl_R behaves like a closure operator on belief states (extensive, monotone, idempotent) that enforces the R-constraints, while $\oplus$ aggregates information by pointwise joining in V.

Lemma 130 (Closure commutes with further evidence joins)**.** *For any belief state β and any evidence increment $\varepsilon : L \to V$,*

$$\mathrm{Cl}_R(\mathrm{Cl}_R(\beta) \ \oplus \ \varepsilon) \ = \ \mathrm{Cl}_R(\beta \ \oplus \ \varepsilon) \,.$$

Sketch. Recall that $\mathrm{Cl}_R(\beta)$ is the *least* (with respect to $\leq$) R-closed belief state that lies above β; in particular, Cl_R is extensive ($\beta \leq \mathrm{Cl}_R(\beta)$), monotone, and idempotent ($\mathrm{Cl}_R(\mathrm{Cl}_R(\beta)) = \mathrm{Cl}_R(\beta)$). Also, $\beta \oplus \varepsilon$ denotes the join of two belief states (or of a belief state with an increment) in the underlying pointwise order, so it is monotone in each argument.

Since $\beta \leq \mathrm{Cl}_R(\beta)$, monotonicity gives $\beta \oplus \varepsilon \leq \mathrm{Cl}_R(\beta) \oplus \varepsilon$, and then applying monotonicity of Cl_R yields

$$\mathrm{Cl}_R(\beta \oplus \varepsilon) \leq \mathrm{Cl}_R(\mathrm{Cl}_R(\beta) \oplus \varepsilon).$$

This is the first inequality.

Conversely, $\mathrm{Cl}_R(\beta \oplus \varepsilon)$ is R-closed and dominates both β and ε, hence it also dominates $\mathrm{Cl}_R(\beta)$ (because $\mathrm{Cl}_R(\beta)$ is the least R-closed state above β). Concretely: from $\beta \leq \beta \oplus \varepsilon \leq \mathrm{Cl}_R(\beta \oplus \varepsilon)$ and R-closedness of $\mathrm{Cl}_R(\beta \oplus \varepsilon)$, minimality of $\mathrm{Cl}_R(\beta)$ implies $\mathrm{Cl}_R(\beta) \leq \mathrm{Cl}_R(\beta \oplus \varepsilon)$. Together with $\varepsilon \leq \beta \oplus \varepsilon \leq \mathrm{Cl}_R(\beta \oplus \varepsilon)$, we obtain

$$\mathrm{Cl}_R(\beta) \oplus \varepsilon \ \leq \ \mathrm{Cl}_R(\beta \oplus \varepsilon).$$

Applying Cl_R to both sides and using idempotence on the right-hand side (since $\mathrm{Cl}_R(\beta \oplus \varepsilon)$ is already R-closed) gives

$$\mathrm{Cl}_R(\mathrm{Cl}_R(\beta) \oplus \varepsilon) \ \leq \ \mathrm{Cl}_R(\beta \oplus \varepsilon),$$

which is the reverse inequality. Combining both directions yields equality. □

Corollary 21 (Order-independence and batching of multiple updates)**.** *Let $\varepsilon_1, \ldots, \varepsilon_n : L \to V$ be evidence increments. Define the iterative update $\beta_{k+1} := \mathrm{Cl}_R(\beta_k \oplus \varepsilon_{k+1})$. Then*

$$\beta_n \ = \ \mathrm{Cl}_R(\beta_0 \ \oplus \ \varepsilon_1 \ \oplus \ \cdots \ \oplus \ \varepsilon_n) \,.$$

In particular, the final result is independent of the order of the ε_k (since $\oplus$ is commutative/associative).

Sketch. The key point is that the previous lemma allows us to "slide" any intermediate closure past subsequent joins, so that all closures can be postponed until after all evidence increments have been aggregated.

Induct on n. For $n = 1$ the statement is exactly the definition of β_1. For the induction step, assume

$$\beta_n = \mathrm{Cl}_R(\beta_0 \oplus \varepsilon_1 \oplus \cdots \oplus \varepsilon_n).$$

Then

$$\beta_{n+1} = \mathrm{Cl}_R(\beta_n \oplus \varepsilon_{n+1}) = \mathrm{Cl}_R(\mathrm{Cl}_R(\beta_0 \oplus \varepsilon_1 \oplus \cdots \oplus \varepsilon_n) \oplus \varepsilon_{n+1}),$$

and by the lemma this equals

$$\mathrm{Cl}_R(\beta_0 \oplus \varepsilon_1 \oplus \cdots \oplus \varepsilon_n \oplus \varepsilon_{n+1}).$$

Associativity of $\oplus$ justifies omitting parentheses in the accumulated join. Finally, commutativity/associativity of $\oplus$ implies that the joined term $\varepsilon_1 \oplus \cdots \oplus \varepsilon_n$ depends only on the multiset of increments, so the same closed result is obtained regardless of the order in which the ε_k are processed. □

Corollary 22 (Thinking episodes collapse to "closure of accumulated evidence"). *In a thinking episode (Definition 300), suppose we perform a finite sequence of steps that (i) joins in evidence increments $\varepsilon_1, \dots, \varepsilon_n$, and (ii) optionally injects hypotheses δ_{h_j,s_j} (Definition 296), with closure Cl_R performed any number of times in-between. Then the final belief state equals*

$$\mathrm{Cl}_R(\beta_0 \ \oplus \ \varepsilon_1 \ \oplus \cdots \oplus \ \varepsilon_n \ \oplus \ \delta_{h_1,s_1} \ \oplus \cdots \oplus \ \delta_{h_m,s_m}) \, .$$

Sketch. View each operation in the episode as producing a new belief state from the old one by one of two kinds of moves: either (a) joining in some increment (one of the ε_i or one of the hypothesis-injections δ_{h_j,s_j}), or (b) applying Cl_R. The lemma "Closure commutes with further evidence joins" shows that whenever a closure is followed later by additional joins, we may equivalently postpone that closure until after those joins have occurred, without changing the end result.

More explicitly, repeatedly use the lemma to push every intermediate $\mathrm{Cl}_R(\,\cdot\,)$ to the right, step-by-step, past subsequent $\oplus$-updates, until only a single final closure remains. At that point the belief state is Cl_R of β_0 joined with all increments that were ever added during the episode. Since $\oplus$ is associative (and, when relevant, commutative), all joins can be batched into the single accumulated expression displayed in the statement, regardless of how the joins and closures were interleaved during the episode. □

41.5 Community aggregation and belief-system scores

Lemma 131 (Dominance and monotonicity of community aggregation). *Let M be a finite set of agents with weights $w_i \in V$ and belief states $\beta_i : L \to V$, and let β_M be as in Definition 301. Then:*

$$w_i \otimes \beta_i(\varphi) \ \le \ \beta_M(\varphi) \quad \text{for all } i \in M, \ \varphi \in L.$$

If $M \subseteq M'$ and the weights/beliefs on M are unchanged, then $\beta_M \le \beta_{M'}$. If $\beta_i \le \beta'_i$ for all i, then the aggregate increases: $\beta_M \le \beta'_M$.

Sketch. All statements follow from the fact that $\beta_M(\varphi)$ is a join over $i \in M$ of the terms $w_i \otimes \beta_i(\varphi)$, and join is monotone and dominates each joined term. More explicitly, Definition 301 has the form

$$\beta_M(\varphi) = \bigvee_{i \in M} \big(w_i \otimes \beta_i(\varphi)\big),$$

so for any fixed $i \in M$ the element $w_i \otimes \beta_i(\varphi)$ is one of the joinands and hence $w_i \otimes \beta_i(\varphi) \le \bigvee_{j \in M}(w_j \otimes \beta_j(\varphi)) = \beta_M(\varphi)$ by the universal property of joins. For set monotonicity, if $M \subseteq M'$ and the terms for indices in M are unchanged, then the join for M' ranges over a superset of joinands, so $\bigvee_{i \in M}(\cdots) \le \bigvee_{i \in M'}(\cdots)$. For belief monotonicity, if $\beta_i \le \beta'_i$ pointwise, then for each φ we have $w_i \otimes \beta_i(\varphi) \le w_i \otimes \beta'_i(\varphi)$ (by monotonicity of $\otimes$ in its second argument, as assumed in the underlying V-structure), and taking joins over $i \in M$ preserves $\le$. Consequently $\beta_M(\varphi) \le \beta'_M(\varphi)$ for all φ, i.e. $\beta_M \le \beta'_M$. □

Lemma 132 (Coherence score bounds and a simple "support witness" property). *Let $\mathrm{Coh}_R(B; \beta)$ be as in Definition 302. Then $0 \le \mathrm{Coh}_R(B; \beta) \le 1$. Moreover, there exists some $\varphi^\star \in B$ such that*

$$\pi(\mathrm{Cl}_R(\beta \backslash \varphi^\star)\,(\varphi^\star)) \ \ge \ \mathrm{Coh}_R(B; \beta) \, .$$

Sketch. Each summand is a π-projection of a p-bit, hence lies in $[0, 1]$, so the average lies in $[0, 1]$. For the witness: the maximum of finitely many numbers is at least their average. To make the bounds explicit, write Definition 302 in the schematic form

$$\mathrm{Coh}_R(B; \beta) = \frac{1}{|B|} \sum_{\varphi \in B} \pi(\mathrm{Cl}_R(\beta \backslash \varphi)\,(\varphi)) \, ,$$

where $|B| < \infty$ (as B is a finite belief set in the intended use of the score). Since $\mathrm{Cl}_R(\beta\backslash\varphi)\,(\varphi) \in V$ is a p-bit (or, more generally, lies in the domain on which π takes values in $[0,1]$), each term $\pi(\mathrm{Cl}_R(\beta\backslash\varphi)\,(\varphi)) \in [0,1]$. A finite average of numbers in $[0,1]$ also lies in $[0,1]$, establishing $0 \leq \mathrm{Coh}_R(B;\beta) \leq 1$. For the witness property, consider the finite set of real numbers

$$a_\varphi := \pi(\mathrm{Cl}_R(\beta\backslash\varphi)\,(\varphi)) \qquad (\varphi \in B).$$

Let $\varphi^\star$ be an element of B attaining $\max_{\varphi\in B} a_\varphi$ (existence follows from finiteness of B). Then $a_{\varphi^\star} \geq \frac{1}{|B|}\sum_{\varphi\in B} a_\varphi = \mathrm{Coh}_R(B;\beta)$, which is exactly the displayed inequality. Intuitively, the lemma states that the coherence score cannot exceed the best single leave-one-out self-support value among the sentences in B. $\square$

Lemma 133 (Surprise-adjusted implication is bounded and prefers simpler claims at equal support)**.** *Let* $\mathrm{Prior}(\varphi) = e^{-\lambda \mathrm{Comp}(\varphi)}$ *and* $\mathrm{SAI}(\varphi;\beta,R)$ *be as in Definition 303. Then* $0 \leq \mathrm{SAI}(\varphi;\beta,R) \leq \mathrm{Prior}(\varphi) \leq 1$*. If two claims* φ,ψ *have equal implied plausibility under leave-one-out closure, i.e.*

$$\pi(\mathrm{Cl}_R(\beta\backslash\varphi)\,(\varphi)) = \pi(\mathrm{Cl}_R(\beta\backslash\psi)\,(\psi))\,,$$

and $\mathrm{Comp}(\varphi) < \mathrm{Comp}(\psi)$*, then* $\mathrm{SAI}(\varphi;\beta,R) > \mathrm{SAI}(\psi;\beta,R)$*.*

Sketch. Boundedness is immediate since $\pi(\cdot) \in [0,1]$ and $\mathrm{Prior}(\varphi) \in (0,1]$. For the preference: equal plausibility makes the $\pi(\cdot)$ factors equal, while Prior is strictly decreasing in Comp when $\lambda > 0$. In more detail, Definition 303 has the multiplicative structure

$$\mathrm{SAI}(\varphi;\beta,R) = \pi(\mathrm{Cl}_R(\beta\backslash\varphi)\,(\varphi)) \cdot \mathrm{Prior}(\varphi),$$

where $\pi(\cdot) \in [0,1]$ by construction and $\mathrm{Prior}(\varphi) = e^{-\lambda\mathrm{Comp}(\varphi)}$. Assuming $\lambda \geq 0$ and $\mathrm{Comp}(\varphi) \geq 0$, we have $\mathrm{Prior}(\varphi) \in (0,1]$, and hence $0 \leq \mathrm{SAI}(\varphi;\beta,R) \leq 1$. Moreover, since $\pi(\cdot) \leq 1$, the product is bounded above by $\mathrm{Prior}(\varphi)$, yielding $0 \leq \mathrm{SAI}(\varphi;\beta,R) \leq \mathrm{Prior}(\varphi) \leq 1$ as stated. For the comparative claim, set

$$s := \pi(\mathrm{Cl}_R(\beta\backslash\varphi)\,(\varphi)) = \pi(\mathrm{Cl}_R(\beta\backslash\psi)\,(\psi))\,.$$

Then $\mathrm{SAI}(\varphi;\beta,R) = s \cdot e^{-\lambda\mathrm{Comp}(\varphi)}$ and $\mathrm{SAI}(\psi;\beta,R) = s \cdot e^{-\lambda\mathrm{Comp}(\psi)}$. If $\lambda > 0$ and $\mathrm{Comp}(\varphi) < \mathrm{Comp}(\psi)$, then $e^{-\lambda\mathrm{Comp}(\varphi)} > e^{-\lambda\mathrm{Comp}(\psi)}$, and multiplying by the common nonnegative factor s preserves the strict inequality, giving $\mathrm{SAI}(\varphi;\beta,R) > \mathrm{SAI}(\psi;\beta,R)$. This captures the intended "simplicity bonus": at equal implied plausibility (support), the less complex formula receives the higher surprise-adjusted score. $\square$

41.6 Paraconsistent "non-explosion" helper facts

Lemma 134 (Irrelevance: claims with no incoming rules do not change under closure)**.** *If no rule in* R *has conclusion* ψ*, then* $F_R(\beta)\,(\psi) = \beta(\psi)$ *and hence* $\mathrm{Cl}_R(\beta)\,(\psi) = \beta(\psi)$*. In particular, if* $\beta(\psi) = (0,0)$ *initially and* ψ *is never a conclusion, then* ψ *stays at* $(0,0)$ *forever.*

Sketch. In Definition 298, the join over rules concluding ψ is empty, so the update leaves $\beta(\psi)$ unchanged. All iterates leave it unchanged, hence so does their join (Theorem 17). Moreover, the pointwise nature of $F_R(\beta)$ ensures that the value at ψ depends only on rules whose conclusion is exactly ψ: when there are none, neither supporting nor opposing components for ψ can be generated "indirectly" by the update operator itself. Equivalently, for this particular coordinate ψ, $F_R(\beta)$ acts as the identity map, so every iterate $F_R(\beta)^k\,(\psi)$ equals $\beta(\psi)$, and the closure (defined as the join/supremum of these iterates in Theorem 17) must therefore coincide with $\beta(\psi)$ as well. $\square$

Remark 2399 (Why this expresses paraconsistent "non-explosion" at a coordinate). *The lemma isolates a minimal "non-explosion" guarantee: absent an explicit rule concluding ψ, the closure process cannot manufacture any nonzero support against ψ out of unrelated contradictions elsewhere in the theory. In particular, even if the ambient belief state contains inconsistent information about other claims (e.g., some φ has both positive and negative evidence), such inconsistency does not propagate to ψ unless R contains a rule whose conclusion is ψ. This is a localized form of irrelevance: contradiction does not automatically entail arbitrary conclusions, because entailment is mediated by the presence of a rule with the relevant conclusion.*

Remark 2400 (A useful contrapositive reading). *If one observes that $\mathrm{Cl}_R(\beta)(\psi) \neq \beta(\psi)$ for some β, then necessarily there exists at least one rule in R whose conclusion is ψ (or, more precisely, there exists a nonempty set of rules concluding ψ that contributes nontrivially to the join in Definition 298). Thus any change at ψ can be traced to an explicit "incoming edge" in the rule graph, which is often convenient when diagnosing unexpected belief propagation.*

41.7 Scientific update as a special case of the evidence-batching laws

Corollary 23 (Scientific updates batch and commute). *Let $\varepsilon_{e,o}$ be the empirical evidence increment from Definition 307. After a finite sequence of experiments (e_k, o_k), repeated scientific update steps yield*

$$\beta_n \;=\; \mathrm{Cl}_R(\beta_0 \;\oplus\; \varepsilon_{e_1,o_1} \;\oplus\; \cdots \;\oplus\; \varepsilon_{e_n,o_n})\,.$$

Thus, within a fixed methodological rule set R, the final closed belief state depends only on the (join-)aggregate of the empirical increments, not on their order.

Sketch. This is exactly the batching corollary above, instantiated with $\varepsilon_k = \varepsilon_{e_k,o_k}$. Concretely, each scientific update step adds an increment via $\oplus$ and then re-closes under the fixed rule set R; batching states that repeated alternation of "add evidence" and "close" is equivalent to first aggregating all increments by repeated $\oplus$ and then applying a single closure. Commutativity with respect to the order of experiments follows because the right-hand side depends only on the $\oplus$-combination of increments, so any permutation of (e_k, o_k) yields the same aggregate and hence the same $\mathrm{Cl}_R(\cdot)$. $\square$

Remark 2401 (Interpretation and scope of the commutation claim). *The corollary should be read as an "order-independence" result under two fixed ingredients: the methodological rule set R (kept constant across updates) and the empirical increments ε_{e_k,o_k} (treated as exogenous inputs). Under these conditions, the closure operator $\mathrm{Cl}_R(\cdot)$ is applied to the same aggregated pre-closure state regardless of the chronological order in which the increments arrived. This captures a standard methodological idealization: when evidence items are merely accumulated (by $\oplus$) and then the same closure rules are applied, the final closed state is a function of the multiset of evidence items, not of their temporal sequencing.*

41.8 Helper theorems for practical reasoning with tasks, intelligence, and agency

Lemma 135 (Bounds and monotonicity of plausibility scalarization). *Let $v = (v^+, v^-) \in [0,1]^2$ and $\mathrm{pl}(v) := \frac{1+v^+-v^-}{2}$ (Definition 314). Then:*

1. $0 \le \mathrm{pl}(v) \le 1$.
2. *If $u^+ \le v^+$ and $u^- \ge v^-$ then* $\mathrm{pl}(u) \le \mathrm{pl}(v)$.
3. pl *is affine in each coordinate:* $\mathrm{pl}(\alpha v + (1-\alpha)w) = \alpha \mathrm{pl}(v) + (1-\alpha)\mathrm{pl}(w)$.

Proof sketch. (1) Since $v^+ - v^- \in [-1, 1]$, we have $\mathrm{pl}(v) \in [0, 1]$. (2) Immediate from the formula. (3) Immediate by linearity of addition and scalar multiplication.
For (1), note explicitly that $\mathrm{pl}(v) = \frac{1}{2} + \frac{1}{2}(v^+ - v^-)$, i.e. pl is the midpoint-shifted, halved version of the signed difference $v^+ - v^-$. Since $v^+, v^- \in [0, 1]$, the extreme cases are $(v^+, v^-) = (0, 1)$ giving $\mathrm{pl} = 0$ and $(1, 0)$ giving $\mathrm{pl} = 1$, with all other cases interpolating linearly.
For (2), the monotonicity statement is with respect to the partial order where increasing the "positive" coordinate and decreasing the "negative" coordinate can only increase plausibility; the condition $u^+ \leq v^+$ and $u^- \geq v^-$ yields $(u^+ - u^-) \leq (v^+ - v^-)$ and hence $\mathrm{pl}(u) \leq \mathrm{pl}(v)$.
For (3), the displayed identity can also be checked componentwise: if $x = \alpha v + (1 - \alpha)w$, then $x^+ = \alpha v^+ + (1 - \alpha)w^+$ and $x^- = \alpha v^- + (1 - \alpha)w^-$, so substitution into $\mathrm{pl}(x) = \frac{1+x^+-x^-}{2}$ yields the claimed affine combination. ☐

Corollary 24 (Competence is always a valid $(0, 1)$ score)**.** *For any task T (Definition 312) and any policy π (Definition 311),* $\mathrm{pl}(J_T(\pi)) \in [0, 1]$*. Hence for any agent Ag (Definition 317),* $\mathrm{Comp}(Ag; T) := \mathrm{pl}(J_T(\pi_{Ag,T})) \in [0, 1]$ *(Definition 318).*

Proof sketch. $J_T(\pi)$ is an expectation of a $[0, 1]^2$-valued random variable, hence remains in $[0, 1]^2$. Apply the previous lemma.
Concretely, if the per-episode score is a random vector $X = (X^+, X^-)$ with $X^+, X^- \in [0, 1]$ almost surely, then $J_T(\pi) = \mathbb{E}[X] = (\mathbb{E}[X^+], \mathbb{E}[X^-])$ and each expectation lies in $[0, 1]$ by basic properties of expectation (e.g. $\mathbb{E}[X^+] \leq \mathbb{E}[1] = 1$ and $\mathbb{E}[X^+] \geq \mathbb{E}[0] = 0$). The lemma then converts the vector-valued score to a scalar in a way that preserves the unit interval bounds. ☐

Proposition 56 (Value preservation under task reduction implies competence preservation)**.** *Let $F : T \to T'$ be a reduction (Definition 316). For any policy π' on T', let π be the induced policy on T from Proposition 31 ("Transfer by reduction"). Then:*

$$J_T(\pi) = J_{T'}(\pi') \quad \textit{and hence} \quad \mathrm{pl}(J_T(\pi)) = \mathrm{pl}(J_{T'}(\pi')).$$

Proof sketch. This is Proposition 31 for the p-bit value equality, followed by applying pl.
The second equality is simply the functoriality of composing functions: once the reduction guarantees that the underlying two-coordinate value vector is exactly preserved (not merely bounded), applying any deterministic scalarization map—here pl—to both sides yields equality of scalar scores. In particular, no additional assumptions (such as continuity or monotonicity) are needed beyond pl being a well-defined function on the codomain of $J_T(\pi)$. ☐

Corollary 25 (Agent transfer along a reduction (compile-time porting rule))**.** *Let $F : T \to T'$ be a reduction with maps (f_O, f_A) as in Definition 316. Given any agent Ag' intended to operate on T', define a ported agent F^*Ag' for T by:*

1. *encode each perceived observation $o \in O$ as $f_O(o) \in O'$ before feeding it to Ag',*
2. *sample an abstract action $a' \sim \pi_{Ag',T'}(\cdot)$,*
3. *execute the decoded action $a := f_A(o, a')$ in T.*

Then $\mathrm{Comp}(F^*Ag'; T) = \mathrm{Comp}(Ag'; T')$.

Proof sketch. The ported closed-loop interaction implements exactly the induced policy construction of Proposition 31; the value equality then gives competence equality.
Intuitively, the ported agent never needs to "understand" T directly: it only needs the ability to (i) reinterpret concrete observations as abstract observations, and (ii) reinterpret abstract actions

as concrete actions in a way that is allowed to depend on the current concrete observation (as encoded in $f_A(o, a')$). Because the reduction ensures that this interface preserves the trajectory distribution relevant to the value definition, the resulting competence, after scalarization by pl, is identical across T and T'. $\square$

Proposition 57 (Functoriality of policy lifting). *Let $F : T \to T'$ and $G : T' \to T''$ be reductions. For any policy π'' on T'', let $(G^*\pi'')$ be the policy on T' induced by Proposition 31, and similarly define $F^*(\cdot)$. Then:*

$$(G \circ F)^*\pi'' \ = \ F^*(G^*\pi'').$$

Proof sketch. Both sides encode histories by composing observation maps and decode actions by the composite decoder from Proposition 30. One checks inductively on history length that the sampled abstract actions and executed concrete actions have the same conditional distributions, hence define the same policy on T.

The key point is that the "lift" operation $(\cdot)^*$ does not introduce any additional randomness beyond that already present in π'': at each time step, it applies a deterministic observation transform (possibly on the whole history, depending on the formalism) and then pushes forward the sampled action through the corresponding decoder. Because reduction composition (Proposition 30) composes these deterministic transforms in the expected way, lifting along $G \circ F$ agrees with lifting along G and then along F. $\square$

Lemma 136 (Reductions form a preorder; equivalence is an equivalence relation). *Define $T \le_{\mathrm{red}} T'$ iff there exists a reduction $F : T \to T'$ (Definition 316). Then $\le_{\mathrm{red}}$ is reflexive and transitive. Define $T \simeq_{\mathrm{red}} T'$ iff $T \le_{\mathrm{red}} T'$ and $T' \le_{\mathrm{red}} T$. Then $\simeq_{\mathrm{red}}$ is an equivalence relation.*

Proof sketch. Reflexivity uses the identity reduction (Corollary 2). Transitivity uses composition (Proposition 30). Equivalence relation properties are immediate from preorder properties.

More explicitly, reflexivity means every task reduces to itself, witnessed by choosing $f_O = \mathrm{id}$ and $f_A(o, a) = a$ (in the notation of Definition 316), which is exactly the identity reduction. Transitivity means that if one can simulate T' inside T and simulate T'' inside T', then one can simulate T'' inside T by composing the simulators. Finally, $\simeq_{\mathrm{red}}$ is symmetric by definition (it requires reductions in both directions), reflexive because $\le_{\mathrm{red}}$ is reflexive, and transitive because the two required reductions compose in each direction. $\square$

Proposition 58 (Breadth is monotone in tolerance). *Fix a task environment $(\mathcal{T}, D)$ (Definition 315) and agent Ag. If $0 \le \varepsilon_1 \le \varepsilon_2 \le 1$, then*

$$\mathrm{Br}_{\varepsilon_1}(Ag; \mathcal{T}, D) \ \le \ \mathrm{Br}_{\varepsilon_2}(Ag; \mathcal{T}, D)$$

(Definition 320).

Proof sketch. The set $\{T : \kappa_{Ag}(T) \ge 1 - \varepsilon\}$ grows as ε increases. Taking probability under D preserves inclusion.

Equivalently, the threshold $1 - \varepsilon$ decreases as ε increases, so it becomes (weakly) easier for a task to qualify as "good" under the predicate $\kappa_{Ag}(T) \ge 1 - \varepsilon$. If $A_\varepsilon := \{T \in \mathcal{T} : \kappa_{Ag}(T) \ge 1 - \varepsilon\}$, then $\varepsilon_1 \le \varepsilon_2$ implies $A_{\varepsilon_1} \subseteq A_{\varepsilon_2}$, and hence $D(A_{\varepsilon_1}) \le D(A_{\varepsilon_2})$ by monotonicity of measures. $\square$

Proposition 59 (Capability dominance implies breadth dominance). *Let Ag_1, Ag_2 be agents on the same task set $\mathcal{T}$ and suppose $\kappa_{Ag_1}(T) \ge \kappa_{Ag_2}(T)$ for all $T \in \mathcal{T}$ (Definition 319). Then for every tolerance $\varepsilon \in [0, 1]$ and every task distribution D,*

$$\mathrm{Br}_\varepsilon(Ag_1; \mathcal{T}, D) \ \ge \ \mathrm{Br}_\varepsilon(Ag_2; \mathcal{T}, D).$$

Proof sketch. If $\kappa_{Ag_2}(T) \geq 1-\varepsilon$ then also $\kappa_{Ag_1}(T) \geq 1-\varepsilon$. So the "good task" set for Ag_2 is contained in that for Ag_1; apply $D(\cdot)$.
This proposition formalizes the intuition that "being at least as capable on every individual task" implies "covering at least as much of the task distribution" for any fixed success tolerance. The proof is a direct application of set inclusion: dominance yields pointwise implication of the threshold event, which lifts to probability under any distribution D without requiring additional structure on $\mathcal{T}$. □

Proposition 60 (Monotonicity of intellectuality under monotone learning). *Assume for each $T \in \mathcal{T}$ the learning-curve competence $\mathrm{Comp}^{(n)}(Ag;T)$ (Definition 321) is nondecreasing in budget n. Then the intellectuality curve $\mathrm{Int}^{(n)}(Ag;\mathcal{T},D) := \mathbb{E}_{T\sim D}[\mathrm{Comp}^{(n)}(Ag;T)]$ is nondecreasing in n.*

Proof sketch. Expectation preserves pointwise inequalities: if $X_n(T) \leq X_{n+1}(T)$ for all T, then $\mathbb{E}[X_n] \leq \mathbb{E}[X_{n+1}]$.
In detail, define $X_n := \mathrm{Comp}^{(n)}(Ag;T)$ as a random variable over $T \sim D$. The hypothesis gives $X_n(T) \leq X_{n+1}(T)$ for every T, so $X_{n+1} - X_n$ is pointwise nonnegative. Taking expectations yields $\mathbb{E}[X_{n+1} - X_n] \geq 0$, i.e. $\mathrm{Int}^{(n+1)} - \mathrm{Int}^{(n)} \geq 0$. Thus any per-task learning monotonicity property aggregates to monotonicity in the average case. □

Lemma 137 (Transducer agents induce history-based policies). *Let $Ag = (S, s_0, U, G)$ be an agent as a controlled transducer (Definition 322) and T be any task on the same interface (O, A). Then Ag induces a policy $\pi_{Ag,T} : H \to \Delta(A)$ (Definition 317) via*

$$\pi_{Ag,T}(h_t) := G(s_t), \quad \text{where } s_t \text{ is obtained by iterating } s_{k+1} = U(s_k, o_k) \text{ along } h_t.$$

Moreover, the coupled process on $S \times O$ is Markov with kernel given in Definition 323.

Proof sketch. Given a history, the internal state is determined (or distributed, if U is stochastic) by iterating the update rule; the action distribution is then $G(s_t)$. Markovicity holds because the next (s_{t+1}, o_{t+1}) depends on the past only through the current (s_t, o_t). □

Lemma 138 (Expressive completeness: any history policy is a transducer). *Given any history-based policy $\pi : H \to \Delta(A)$ (Definition 311), there exists a controlled transducer $Ag_\pi = (S, s_0, U, G)$ whose induced policy equals π. One canonical construction is $S := H$, $s_0 := (o_0)$, $U(h, o) := h \cdot o$ (append observation), and $G(h) := \pi(h)$.*

Proof sketch. By construction, the internal state at time t is exactly the interaction history h_t, so the action map reproduces $\pi(h_t)$ at every step. □

Proposition 61 (Intent dynamics yields a Markov state-space model). *For an intent-augmented agent (Definition 324) with intent update rule Φ as in Definition 325, the closed-loop coupling to any task can be written as a Markov process on $S_e \times \mathcal{G} \times O$ (environmental state, intent, observation).*

Proof sketch. At time t, the next intent is sampled from $\Phi(\tilde{s}_t, o_t)$, the next internal state is updated from $(\tilde{s}_t, g_t, o_t)$, and the next observation is sampled from $P(o_t, a_t)$. All depend on the past only through the current triple, hence Markov. □

Lemma 139 (Operational witness for "nontrivial" autonomy). *Let $\Phi : S_e \times O \to \Delta(\mathcal{G})$ be an intent update rule (Definition 325). A sufficient (and operationally checkable) condition that Φ depends nontrivially on internal state is:*

$$\exists\, \tilde{s}_1, \tilde{s}_2 \in S_e,\ \exists\, o \in O \text{ such that } \Phi(\tilde{s}_1, o) \neq \Phi(\tilde{s}_2, o).$$

Conversely, if $\Phi(\tilde{s}, o) = \Psi(o)$ for some $\Psi : O \to \Delta(\mathcal{G})$, then intent dynamics are fully externally scripted by perceptual input (no internal dependence).

Proof sketch. The forward direction just restates "depends on internal state" as existence of a separating pair. The converse direction exhibits an explicit factorization through O alone. $\square$

Proposition 62 (Stimulate/inhibit trichotomy). *Fix a claim $\varphi \in L$ and context o (Definition 326). For any action a exactly one holds:*

$$\epsilon^{+}_{a,o}(\varphi) > \epsilon^{-}_{a,o}(\varphi) \;\; (a \textit{ stimulates } \varphi), \quad \epsilon^{+}_{a,o}(\varphi) < \epsilon^{-}_{a,o}(\varphi) \;\; (a \textit{ inhibits } \varphi), \quad \epsilon^{+}_{a,o}(\varphi) = \epsilon^{-}_{a,o}(\varphi) \;\; (a \textit{ is neutral}).$$

Proof sketch. Trichotomy of the strict order on real numbers applied to the two scalar components. $\square$

Proposition 63 (Join-closure of stimulate and inhibit). *Let $\epsilon^{(1)}, \epsilon^{(2)}$ be two effect increments (Definition 326) and define their join $\epsilon := \epsilon^{(1)} \oplus \epsilon^{(2)}$ pointwise in V. Fix (a, o, φ). If both $\epsilon^{(1)}_{a,o}$ and $\epsilon^{(2)}_{a,o}$ stimulate φ, then $\epsilon_{a,o}$ stimulates φ. If both inhibit, then $\epsilon_{a,o}$ inhibits.*

Proof sketch. Write $p_i := \epsilon^{(i)+}_{a,o}(\varphi)$ and $m_i := \epsilon^{(i)-}_{a,o}(\varphi)$. Under join, $p = \max\{p_1, p_2\}$ and $m = \max\{m_1, m_2\}$. If $p_1 > m_1$ and $p_2 > m_2$ then $p > m$: otherwise $p \leq m$ would force (for the index attaining m) a contradiction with $p_i > m_i$. The inhibit case is symmetric. $\square$

Lemma 140 (Belief updates by join are monotone). *Assume belief update has the form $\beta' := \beta \oplus \epsilon_{a,o}$ (Definition 326), possibly followed by any monotone closure operator* Cl *(i.e., $\beta_1 \leq \beta_2 \Rightarrow \mathrm{Cl}(\beta_1) \leq \mathrm{Cl}(\beta_2)$). Then $\beta' \geq \beta$ pointwise in the belief order.*

Proof sketch. Join satisfies $\beta \leq \beta \oplus \epsilon$ componentwise. If a monotone closure is applied, monotonicity preserves the inequality. $\square$

Proposition 64 (Synergy for finitely many subsystems under monotone control). *Let $\{\beta^{(i)}\}_{i=1}^{k}$ be belief states over the same claim language and define $\beta := \bigoplus_{i=1}^{k} \beta^{(i)}$ (pointwise join). Suppose the downstream action-selection mechanism is monotone in the sense of Definition 329, and interpret "no more restrictive" concretely as:*

$$\beta_1 \leq \beta_2 \;\Rightarrow\; \mathrm{supp}(A(\beta_1)) \subseteq \mathrm{supp}(A(\beta_2)).$$

Then the combined system can achieve competence at least as high as the best subsystem:

$$\mathrm{Comp}(Ag_{\oplus}; T) \;\geq\; \max_{1 \leq i \leq k} \mathrm{Comp}(Ag_i; T),$$

generalizing Proposition 32 from $k = 2$ to arbitrary finite k.

Proof sketch. Induct on k. The case $k = 2$ is Proposition 32. For the induction step, join the first $k - 1$ beliefs into $\beta^{(\leq k-1)}$ and apply the $k = 2$ case to $(\beta^{(\leq k-1)}, \beta^{(k)})$. $\square$

Remark 2402 (About abstractions and well-defined quotient rewards). *Theorem 18 defines $r_Q(q(o), a, q(o^+)) := r(o, a, o^+)$ and asserts well-definedness from the "evaluation invariance" clause of Definition 328. If, in an implementation, your reward depends on finer distinctions of o^+ inside a fiber of q, you may want to strengthen the abstraction hypothesis by additionally requiring invariance in the o^+ argument (or restrict to rewards that factor through $q(o^+)$). This avoids ambiguity when reasoning mechanically about quotients.*

Concretely, the potential ambiguity is the following: if $q(o_1) = q(o_2)$ and $q(o_1^+) = q(o_2^+)$ but $r(o_1, a, o_1^+) \neq r(o_2, a, o_2^+)$, then the right-hand side depends on the choice of representative of the equivalence classes induced by q, so r_Q would not be a function of $(q(o), a, q(o^+))$ alone. In that case, one either (i) strengthens Definition 328 so that evaluation invariance explicitly quantifies over pairs of next-observations o^+ in the same fiber (i.e. invariance in the o^+ argument), or (ii) redefines the quotient reward as an aggregate over fibers (e.g. conditional expectation or worst-case), which produces a well-defined object but changes the semantics of the quotient task. For purposes of the later epistemic layer, option (i) is typically preferable when the quotient is intended as a semantics-preserving abstraction rather than a change of objective.

Proposition 65 (Compositionality of task abstractions (hierarchical coarse-graining))**.** *Let $q : O \to Q$ be a task abstraction for T (Definition 328), and let $q' : Q \to R$ be a task abstraction for the quotient task T_Q constructed in Theorem 18. Then (under the same well-definedness assumptions used to form T_Q) the composite $q' \circ q : O \to R$ is a task abstraction for T.*

Proof sketch. Lumpable dynamics compose because pushforwards compose: $(q' \circ q)_* = q'_* \circ q_*$. Evaluation invariance for $q' \circ q$ follows by applying invariance for q (to pass from o_1 to o_2) and then invariance for q' on the quotient side. The required well-definedness matches the same conditions needed in Theorem 18 to define quotient dynamics/evaluation.

To make the compositionality fully explicit, fix $o \in O$ and $a \in A$, and write $P(\cdot \mid o, a)$ for the (original) next-observation kernel on O. Lumpability of q asserts that there is a kernel $P_Q(\cdot \mid q(o), a)$ on Q such that $q_* P(\cdot \mid o, a) = P_Q(\cdot \mid q(o), a)$, i.e. for every measurable $B \subseteq Q$,

$$P_Q(B \mid q(o), a) = P(q^{-1}(B) \mid o, a),$$

and this value depends on o only through $q(o)$. Likewise, lumpability of q' for T_Q provides a kernel $P_R(\cdot \mid q'(q(o)), a)$ on R such that $q'_* P_Q(\cdot \mid q(o), a) = P_R(\cdot \mid q'(q(o)), a)$. Combining the two equalities yields $(q' \circ q)_* P(\cdot \mid o, a) = P_R(\cdot \mid (q' \circ q)(o), a)$, which is exactly the lumpability requirement for $q' \circ q$.

For evaluation invariance, one checks the representative-independence of any quotient-defined quantity along the same two-step chain. If evaluation invariance for q says that whenever $q(o_1) = q(o_2)$ (and a is fixed), the evaluation-related expressions (e.g. reward, value contributions, or whatever Definition 328 packages) computed from o_1 and o_2 agree after passing through q, then evaluation invariance for q' guarantees that the corresponding expressions computed from $q(o_1)$ and $q(o_2)$ agree after passing through q'. Chaining these two invariances yields invariance under $q' \circ q$. In particular, any construction in Theorem 18 that uses a choice of representative in $q^{-1}(q(o))$ remains invariant under replacing that representative by another element of the same fiber, and then the subsequent quotienting from Q to R is likewise invariant under changes within fibers of q'.

Finally, note that the "same well-definedness assumptions" clause is not merely a formality: if T_Q is defined by quotienting both dynamics and evaluation, then q' being a task abstraction for T_Q presupposes that those quotient components are already functions on Q (rather than on representatives in O). The point of the proposition is that once T_Q is well-defined, any further abstraction performed at the quotient level lifts back to a valid abstraction of the original task. □

Proposition 66 (Engineering entails an intent-aligned causal pathway)**.** *If an artifact/pattern Y is engineered by agent Ag over $[t_0, t_1]$ (Definition 327), then:*

1. *there exists an intent token g active for a nontrivial fraction of times in $[t_0, t_1]$ that entails a positive commitment to the existence-claim φ_Y, and*

2. *the agent's actions in* $[t_0, t_1]$ *are causally implicated (in the control/causal sense of Section 14) in the increase of* $\beta^+(\varphi_Y)$*.*

Proof sketch. Unpack clauses (b) and (c) of Definition 327; this proposition is a "reasoner-friendly" restatement.

More explicitly, Definition 327(b) provides (by hypothesis of "engineered") an intent-bearing component of the agent's internal process: there is a goal/intent token g whose activation is sustained on a set of times of nonzero (and typically bounded away from zero) measure within $[t_0, t_1]$, and whose content entails the agent's endorsement of φ_Y as a target condition (hence "positive commitment" to the existence-claim). This is the formal bridge from "engineering" as an external description to an internal, time-extended intentional state.

Definition 327(c) provides the causal-control component: the agent's policy-driven interventions during $[t_0, t_1]$ make a difference, in the Section 14 sense, to the downstream probability/credence update supporting φ_Y. In the notation of the epistemic layer, this is expressed as causal implication in an increase of $\beta^+(\varphi_Y)$, i.e. the agent's actions are not merely correlated with the outcome but participate in a directed pathway (via controllable degrees of freedom) that raises the post-update belief/attainment measure of the claim that Y exists (or is instantiated) relative to the relevant baseline. Thus (1) extracts the intent witness g, and (2) extracts the causal witness that the agent's action-selection is among the explanatory variables for the increase in $\beta^+(\varphi_Y)$, which is exactly what makes the notion operational for later mechanical reasoning. $\square$

Remark 2403 (On the role of "nontrivial fraction of times")**.** *The "nontrivial fraction" condition in item (1) should be read as excluding degenerate witnesses where the intent token* g *is present only instantaneously (e.g. a single timepoint) or only as a fleeting artifact unrelated to action-selection. In typical dynamical or discrete-time formalisms, this corresponds respectively to requiring a positive-measure subset of* $[t_0, t_1]$ *or a non-negligible subset of timesteps on which* g *is active, so that the token can meaningfully constrain/plausibly explain the agent's sequence of actions over the interval.*

41.9 Helper theorems for the general intelligence measures

Standing notation. Let $\mathcal{E}$ be a set of (computable) environments and $\mathcal{G}$ a set of goals. When relevant, let $\mathcal{T}$ denote the admissible time-scales/intervals used in the context construction in Def. 340. Let V^π_μ or $V^\pi_{\mu,g,T}$ denote the corresponding expected performance quantities appearing in Defs. 336 and 340. All sums below are interpreted only when convergent (as already stipulated in the defining equations).

Lemma 141 (Bounds for universal intelligence)**.** *Assume Def. 336. Suppose:*

1. *(reward-summability bound)* $0 \le V^\pi_\mu \le 1$ *for all* $\mu \in \mathcal{E}$*, and*

2. *(prefix-code/Kraft bound)* $\sum_{\mu\in\mathcal{E}} 2^{-K(\mu)} \le 1$*.*

Then $0 \le \Upsilon(\pi) \le 1$*.*

Sketch. Nonnegativity is immediate from nonnegative weights and rewards. For the upper bound:

$$\Upsilon(\pi) = \sum_{\mu\in\mathcal{E}} 2^{-K(\mu)} V^\pi_\mu \le \sum_{\mu\in\mathcal{E}} 2^{-K(\mu)} \cdot 1 \le 1.$$

$\square$

Lemma 142 (Bounds for pragmatic general intelligence). *Assume Def. 340. Suppose the context weights form a probability measure; concretely, assume:*

1. *ρ is a probability distribution on $\mathcal{E}$, and for each μ, $\gamma(\cdot \mid \mu)$ is a probability distribution on $\mathcal{G}$;*
2. *any time-scale indicator $\tau_{g,\mu}(|T|)$ (if present in your definition) lies in $[0,1]$; and*
3. *$0 \leq V^{\pi}_{\mu,g,T} \leq 1$ for all (μ, g, T).*

Then $0 \leq \Pi(\pi) \leq 1$.

Sketch. $\Pi(\pi)$ is a convex combination (possibly with additional $[0,1]$ gates such as $\tau_{g,\mu}$) of numbers in $[0,1]$. □

Lemma 143 (Pointwise dominance implies GI dominance). *Let π_1, π_2 be two agents.*

1. *If $V^{\pi_1}_{\mu} \geq V^{\pi_2}_{\mu}$ for all $\mu \in \mathcal{E}$, then $\Upsilon(\pi_1) \geq \Upsilon(\pi_2)$.*
2. *If $V^{\pi_1}_{\mu,g,T} \geq V^{\pi_2}_{\mu,g,T}$ for all contexts (μ, g, T), then $\Pi(\pi_1) \geq \Pi(\pi_2)$ (and likewise for any variant obtained by reweighting the same $V_{\mu,g,T}$ values with nonnegative weights, e.g. Def. 342 in the common "nonnegative weight" form).*

Proof. Each GI measure in question is a sum of nonnegative weights times the corresponding V values. Replacing each V^{π_2} by a (weakly) larger V^{π_1} cannot decrease the sum. □

Lemma 144 (Linearity in mixture policies (episode-level mixtures)). *Fix any of the scalar GI measures defined in Defs. 336–342, and suppose the relevant V-functionals are linear in randomized choice of policy at the start of an episode/context (i.e., law of total expectation applies in the obvious way).*

Let π_λ be the agent that, at the beginning of each episode/context, samples $i \in \{1, 2\}$ with $\mathbb{P}[i = 1] = \lambda$ and then behaves as π_i for that whole episode. Then for universal intelligence and pragmatic general intelligence:

$$\Upsilon(\pi_\lambda) = \lambda\Upsilon(\pi_1) + (1-\lambda)\Upsilon(\pi_2), \qquad \Pi(\pi_\lambda) = \lambda\Pi(\pi_1) + (1-\lambda)\Pi(\pi_2),$$

and analogously for Π^{eff} whenever it is also defined as a nonnegative-weighted sum of the same underlying V values.

Sketch. For each environment/context, V^{π_λ} is a convex combination $\lambda V^{\pi_1} + (1-\lambda)V^{\pi_2}$ by conditioning on the policy-choice coin flip. Then substitute into the defining sums. □

Lemma 145 (Linearity in priors / context weightings). *Fix a policy π. View pragmatic GI as a functional of the context weighting (e.g., via ρ and γ as in Def. 340). If a new environment prior is formed by convex combination $\rho_\lambda := \lambda\rho_1 + (1-\lambda)\rho_2$, then (for fixed γ)*

$$\Pi_{\rho_\lambda,\gamma}(\pi) = \lambda\Pi_{\rho_1,\gamma}(\pi) + (1-\lambda)\Pi_{\rho_2,\gamma}(\pi).$$

Likewise, if goal-weightings are convex-combined pointwise (for each μ), then Π is affine in those mixtures as well.

Proof. Expand the defining sum and distribute over addition. □

Proposition 67 (Universal intelligence as a special case of pragmatic GI). *Assume Defs. 336 and 340. Let $\xi(\mu) := 2^{-K(\mu)}$ be the (possibly subnormalized) universal weight. Let $Z := \sum_{\mu\in\mathcal{E}} \xi(\mu)$ (so $0 < Z \leq 1$ under the Kraft bound).*

Assume the pragmatic setup is chosen so that:

1. $\rho(\mu) = \xi(\mu)/Z$;

2. *the goal mechanism is "degenerate" in the sense that for each μ there is a distinguished g_μ that reproduces the reward signal used in Def. 336, and $\gamma(g \mid \mu) = \mathbf{1}[g = g_\mu]$; and*

3. *any time-scale indicator used in Def. 340 is identically 1 (or the time-scale set $\mathcal{T}$ is chosen so that it reduces to the universal-reward evaluation).*

Then

$$\Pi(\pi) = \frac{1}{Z}\,\Upsilon(\pi), \qquad \textit{equivalently} \qquad \Upsilon(\pi) = Z\,\Pi(\pi).$$

Thus Υ and Π differ here only by a constant normalization factor.

Sketch. Under the stated specialization, the pragmatic per-context performance values coincide with the universal V_μ^π, and the context weights differ from $2^{-K(\mu)}$ only by the constant factor $1/Z$. □

Lemma 146 (Efficient pragmatic GI as pragmatic GI on an augmented context space)**.** *Assume Defs. 340 and 342 in the common GTGI form where efficiency is implemented by reweighting each context by an expected (or sampled) inverse resource-usage factor.*

Let $\mathcal{R} \subset \mathbb{R}_{>0}$ be the resource domain, and let $D_{\mu,g,T}$ be the resource-usage distribution from Def. 342. Define the augmented context space

$$\mathcal{C}^{\mathrm{aug}} := \mathcal{E} \times \mathcal{G} \times \mathcal{T} \times \mathcal{R}.$$

Define augmented weights

$$w^{\mathrm{aug}}(\mu, g, T, r) := w(\mu, g, T)\, D_{\mu,g,T}(r)\, \frac{1}{r},$$

where $w(\mu, g, T)$ denotes the (nonnegative) context weighting used in Def. 340 (e.g., $w(\mu, g, T) = \rho(\mu)\gamma(g \mid \mu)\tau_{g,\mu}(|T|)$ if you use an explicit time-scale gate).

Then Def. 342 can be rewritten as a pragmatic-GI-style weighted sum over the augmented contexts:

$$\Pi^{\mathrm{eff}}(\pi) = \sum_{(\mu,g,T,r)\in\mathcal{C}^{\mathrm{aug}}} w^{\mathrm{aug}}(\mu, g, T, r)\, V^\pi_{\mu,g,T}.$$

Sketch. This is just a change of indexing: expand the efficiency-normalized definition as a sum/integral over resource outcomes r, and absorb the extra factor r^{-1} into the context weight. □

Corollary 26 (Constant or bounded resources yield simple relations between Π and Π^{eff})**.** *Assume the hypotheses of Lem. 146 and that the (per-context) inverse-resource factor is well-defined.*

1. *If $D_{\mu,g,T}$ is degenerate at a constant $r_0 > 0$ for all contexts, then $\Pi^{\mathrm{eff}}(\pi) = \Pi(\pi)/r_0$.*

2. *If there exist constants $0 < r_{\min} \le r_{\max} < \infty$ such that $\operatorname{supp}(D_{\mu,g,T}) \subseteq [r_{\min}, r_{\max}]$ for all contexts, then*
$$\frac{1}{r_{\max}}\Pi(\pi) \;\le\; \Pi^{\mathrm{eff}}(\pi) \;\le\; \frac{1}{r_{\min}}\Pi(\pi).$$

Sketch. Use $r^{-1} = r_0^{-1}$ in the degenerate case. In the bounded case, use $1/r_{\max} \le 1/r \le 1/r_{\min}$ pointwise inside the efficiency-weighted sum. □

Lemma 147 (Breadth is invariant under positive rescaling of fuzziness)**.** *Assume Def. 343. Let $\Phi_\pi(\mu, g, T)$ denote the fuzzy membership (or "intelligence degree") assigned to contexts before normalization, and let p_π be the probability distribution obtained by normalizing Φ_π (as in the definition).*

If Φ_π is replaced by $\Phi'_\pi := c\,\Phi_\pi$ for any constant $c > 0$, then the normalized distribution is unchanged ($p'_\pi = p_\pi$) and hence the intellectual breadth is unchanged.

Proof. Normalization divides by $\sum \Phi_\pi$, and $(c\,\Phi_\pi)/\sum(c\,\Phi_\pi) = \Phi_\pi/\sum \Phi_\pi$. □

Lemma 148 (Breadth bounds via Shannon entropy)**.** *Assume Def. 343 and that the induced context distribution p_π has finite support of size N. Let H denote Shannon entropy as in Def. 89 (with the same log base convention). Then the intellectual breadth $\mathrm{Br}(\pi) = H(p_\pi)$ satisfies*

$$0 \leq \mathrm{Br}(\pi) \leq \log N.$$

Moreover, $\mathrm{Br}(\pi) = 0$ iff p_π is a point mass (all weight on one context), and $\mathrm{Br}(\pi) = \log N$ iff p_π is uniform on its support.

Sketch. Standard Shannon-entropy bounds on a finite alphabet. □

Lemma 149 (Concavity of breadth under mixtures (when the induced context law mixes linearly))**.** *Assume Def. 343. Suppose that for episode-level mixtures π_λ (as in Lem. 144) the induced normalized context distribution satisfies*

$$p_{\pi_\lambda} = \lambda p_{\pi_1} + (1-\lambda) p_{\pi_2}.$$

Then breadth is concave:

$$\mathrm{Br}(\pi_\lambda) \;\geq\; \lambda \mathrm{Br}(\pi_1) + (1-\lambda)\mathrm{Br}(\pi_2).$$

Sketch. Shannon entropy is concave on the simplex; apply concavity to the assumed affine mixing of p_π. □

Further explanation. If $\mathrm{Br}(\pi)$ is instantiated as the Shannon entropy of the induced normalized context law (as in Def. 343), i.e.,

$$\mathrm{Br}(\pi) = H(p_\pi) \quad \text{with} \quad H(p) := -\sum_c p(c)\log p(c),$$

then the claim is exactly the standard concavity inequality

$$H\big(\lambda p + (1-\lambda) q\big) \;\geq\; \lambda H(p) + (1-\lambda) H(q) \qquad (\lambda \in [0,1]).$$

The assumption $p_{\pi_\lambda} = \lambda p_{\pi_1} + (1-\lambda) p_{\pi_2}$ is the crucial step that transfers concavity of $H(\cdot)$ (a property of distributions) into concavity of $\mathrm{Br}(\cdot)$ (a property of policies via their induced context laws). In particular, this highlights that concavity is guaranteed under linear mixing at the level of the induced distribution; if the mapping $\pi \mapsto p_\pi$ were nonlinear under mixtures, the inequality need not hold without additional regularity assumptions.

Remark 2404 (When the mixing assumption is satisfied)**.** *The condition $p_{\pi_\lambda} = \lambda p_{\pi_1} + (1-\lambda) p_{\pi_2}$ holds in common cases where the mixture policy π_λ is implemented by first sampling an episode-level coin flip $Z \sim \mathrm{Bernoulli}(\lambda)$ and then executing π_Z for the entire episode, and the context random variable is measurable with respect to episode-level exogenous randomness. In such cases, the resulting context law is literally a mixture distribution, hence affine in λ.*

Proposition 68 (Pareto preorder induced by multiple-criterion GI)**.** *Assume Def.* **??** *yields a vector-valued score* $\mathbf{GI}(\pi) \in \mathbb{R}^k$ *where larger is better in each component (if some criteria are "lower is better", flip their sign first).*

Define $\pi_1 \preceq_{\mathrm{P}} \pi_2$ *iff* $\mathbf{GI}(\pi_1)_j \le \mathbf{GI}(\pi_2)_j$ *for all components* $j = 1, \ldots, k$*.*

Then $\preceq_{\mathrm{P}}$ *is a preorder (reflexive and transitive). If one quotients by the equivalence* $\pi_1 \sim \pi_2$ *iff* $\pi_1 \preceq_{\mathrm{P}} \pi_2$ *and* $\pi_2 \preceq_{\mathrm{P}} \pi_1$*, the induced relation on equivalence classes is a partial order.*

Proof. Reflexivity and transitivity are inherited from $\le$ on $\mathbb{R}$ componentwise. □

Further explanation. Reflexivity is immediate since for any π and each j, one has $\mathbf{GI}(\pi)_j \le \mathbf{GI}(\pi)_j$, hence $\pi \preceq_{\mathrm{P}} \pi$. Transitivity follows because if $\pi_1 \preceq_{\mathrm{P}} \pi_2$ and $\pi_2 \preceq_{\mathrm{P}} \pi_3$, then for every component j,

$$\mathbf{GI}(\pi_1)_j \le \mathbf{GI}(\pi_2)_j \le \mathbf{GI}(\pi_3)_j,$$

so $\pi_1 \preceq_{\mathrm{P}} \pi_3$. The relation need not be antisymmetric on policies (distinct policies can tie on all criteria), which is why it is only a preorder. After quotienting by $\sim$ (i.e., identifying all policies with identical criterion-vectors), the induced relation becomes antisymmetric by construction: if $[\pi_1] \preceq_{\mathrm{P}} [\pi_2]$ and $[\pi_2] \preceq_{\mathrm{P}} [\pi_1]$, then $\pi_1 \sim \pi_2$, hence $[\pi_1] = [\pi_2]$.

Remark 2405 (Interpretation: nondominated front)**.** *Under* $\preceq_{\mathrm{P}}$*, the set of Pareto-efficient (nondominated) policies is the subset of policies* π *for which there is no* π' *such that* $\pi \preceq_{\mathrm{P}} \pi'$ *and* $\pi' \not\preceq \pi$*. This is the natural optimality notion when Def.* **??** *is treated as genuinely multiobjective rather than scalarized a priori.*

Proposition 69 (Positive scalarizations respect Pareto dominance)**.** *In the setting of Prop. 68, fix weights* $\alpha \in \mathbb{R}^k$ *with* $\alpha_j \ge 0$ *for all* j *and define a scalarization*

$$S_\alpha(\pi) := \sum_{j=1}^{k} \alpha_j \, \mathbf{GI}(\pi)_j.$$

If $\pi_1 \preceq_{\mathrm{P}} \pi_2$*, then* $S_\alpha(\pi_1) \le S_\alpha(\pi_2)$*.*

Proof. Componentwise $\mathbf{GI}(\pi_1)_j \le \mathbf{GI}(\pi_2)_j$ and $\alpha_j \ge 0$ imply $\alpha_j \mathbf{GI}(\pi_1)_j \le \alpha_j \mathbf{GI}(\pi_2)_j$ for each j; sum over j. □

Further explanation. This is simply monotonicity of a nonnegative linear functional with respect to the product order on $\mathbb{R}^k$. Note that if at least one weight is strictly positive on a component where $\mathbf{GI}(\pi_1)_j < \mathbf{GI}(\pi_2)_j$, then the inequality becomes strict: $S_\alpha(\pi_1) < S_\alpha(\pi_2)$. Conversely, if some $\alpha_j = 0$, then the scalarization deliberately ignores the jth criterion, so Pareto improvements exclusively in that component need not be reflected in S_α.

Remark 2406 (Scope and limitation of linear scalarizations)**.** *Positive linear scalarizations are convenient, but they do not in general recover every Pareto-efficient policy unless additional convexity assumptions hold for the achievable criterion set* $\{\mathbf{GI}(\pi) : \pi \in \Pi\}$*. The proposition here is one-way: Pareto dominance implies monotonic improvement under any positive weights, but not every nondominated solution must maximize a given linear scalarization.*

Corollary 27 (Efficient pragmatic GI as a particular scalarization of goal-achievement and resource frugality)**.** *Assume Def. 342 is implemented via an inverse-resource reweighting (as in Lem. 146). Then* Π^{eff} *is monotone in the Pareto sense with respect to the pair of per-context objectives*

$$\Big(V^{\pi}_{\mu,g,T},\ \frac{1}{r}\Big),$$

and thus can be treated as a (context-weighted) positive scalarization of these two criteria.

Sketch. In the augmented-context form, Π^{eff} is a nonnegative-weighted sum of products of (goal-achievement) and (inverse resource) factors. Increasing either factor pointwise cannot decrease the total. □

Further explanation. Writing Π^{eff} in the augmented-context representation of Lem. 146 makes the monotonicity transparent: each contextual contribution is weighted by a nonnegative context probability (or density) and then combined using nonnegative coefficients, so the overall functional is increasing in each argument when the other is held fixed. Concretely, for fixed (μ, g, T), if policy π_2 achieves weakly higher value $V^{\pi}_{\mu,g,T}$ than π_1 and uses weakly less resource (so that $1/r$ is weakly higher), then every term entering the efficient pragmatic score is weakly larger under π_2 than under π_1, hence the aggregate Π^{eff} cannot decrease. This is exactly the two-criterion instance of the Pareto monotonicity statement in Prop. 69, with the understanding that the weights arise from the context law and the particular reweighting scheme.

Remark 2407 (Two-objective interpretation)**.** *The pair $\left(V^{\pi}_{\mu,g,T}, 1/r\right)$ can be read as (i) effectiveness at achieving the goal in the given environment over horizon T, and (ii) frugality, expressed as an increasing transform of a resource usage variable. The corollary states that, under the stated implementation, Π^{eff} behaves like a standard multiobjective aggregation that never penalizes simultaneous improvements in effectiveness and frugality, aligning the efficient pragmatic construction with the Pareto order of these two desiderata.*

42 Helper theorems for society, culture, and collective mind systems

Remark 2408. *This section collects small but frequently used monotonicity and fixed-point facts for the formal objects introduced in Section 22: interaction graphs, message passing, cultural aggregation, collective belief, and the nested notions of collective mind systems. The common pattern is that each definition has been engineered so that "adding resources" (more edges, lower thresholds, larger agent sets, stronger couplings, richer approximator classes) cannot make a relevant quantity worse. This makes the mathematics hospitable to automated reasoning: many arguments reduce to event inclusion, order-theoretic monotonicity, or least-fixed-point folklore.*

Conceptually, these helper results touch several core notions in the Hyperseed core-concept set: Society *(Hyperseed-Concept 170),* Tribe *(Hyperseed-Concept 194),* Culture *(Hyperseed-Concept 91),* Mindplex *(Hyperseed-Concept 113), and* Global Brain *(Hyperseed-Concept* **??***). The underlying algebraic substrate is quantale-like: belief/messaging values live in an ordered space V with a join $\oplus$ and a tensor $\otimes$; this resonates with the "weakness as structure" perspective in [3] and with paraconsistent logics such as [23, 24] when $V = [0,1]^2$.*

To make the "adding resources" slogan precise, one typically fixes a preorder on each design dimension (graphs ordered by edge inclusion, threshold parameters ordered by $\leq$ but used contravariantly so that smaller thresholds yield larger reachable sets, agent populations ordered by inclusion, coupling strengths ordered pointwise, hypothesis/approximator classes ordered by inclusion). Each construction in Section 22 then induces an operator that is monotone with respect to these preorders and with respect to the intrinsic order on V. For example, a message-passing update can be viewed as a monotone map on a product poset such as V^E or $V^{A\times A}$, while a cultural aggregation rule is a monotone map from a multiset (or measure) of individual belief-states into a collective belief-state in $V^{\mathcal{L}}$ (for an appropriate language $\mathcal{L}$). The technical content of many helper lemmas is therefore that the semantics is functorial in the resource parameters: inclusion of structure yields inclusion (or order increase) of outcomes.

The fixed-point facts are used in precisely this order-theoretic style. Once an update/closure operator F is known to be monotone on a complete lattice (or at least on a directed-complete partial order, depending on the variant), standard results guarantee the existence of least and greatest fixed points, and provide constructive approximations via iteration from bottom or top. In the intended applications, the least fixed point corresponds to the "minimal" collective belief state (or minimal stable message configuration) compatible with the available interaction structure and update rules, while the greatest fixed point corresponds to a "maximal" or most permissive equilibrium. When thresholds are lowered, edges are added, or couplings are strengthened, monotonicity ensures that these fixed points move in the expected direction (least fixed points can only rise, reachable event sets can only expand, and admissible equilibria can only widen, depending on the specific order used).

The quantale-like assumptions on $(V, \oplus, \otimes)$ supply the algebraic glue needed for compositional arguments. In particular, distributivity properties (informally: $\otimes$ is compatible with joins) allow one to push order bounds through multi-step influence paths: combining messages along a path (via $\otimes$) and aggregating competing paths (via $\oplus$) yields an overall influence estimate that is monotone in each input. In the paraconsistent example $V = [0,1]^2$ with its natural product order, one can interpret the two coordinates as (degrees of) support and refutation; then $\oplus$ can be taken componentwise to reflect pooling of evidence, while $\otimes$ models composition of influence or entailment strength. The helper lemmas in this section should therefore be read as small "calculus rules" that let one rearrange such expressions without changing meaning, while preserving or strengthening bounds whenever the underlying resources are increased.

Finally, these monotonicity and fixed-point patterns are not merely aesthetic: they are what let higher-level notions such as "collective mind system" be stratified by inclusion and closure conditions. Nested mindplex constructions, for instance, can often be expressed as repeated application of monotone operators (add agents, close under communication, close under aggregation, close under meta-belief formation), so that the resulting hierarchy is well-behaved under refinement. In this sense, the helper theorems form the connective tissue between the concrete combinatorics of interaction graphs and the abstract semantics of collective belief and culture, ensuring that the overall framework admits principled comparison, extension, and reuse across different societal and cultural modeling choices.

42.1 Strong ties and tribes (Defs. 333–334): monotonicity rules

Helper Lemma 42.1 (Strong-tie edge monotonicity in the threshold)**.** *Let $G = (\mathcal{A}, E)$ be an interaction graph and let $K : E \to [0,1]$ be scalar couplings. For $\tau \in (0,1]$ define the strong-tie edge set*

$$E_\tau := \{(i,j) \in E : K(i,j) \geq \tau\}, \quad \text{and} \quad G_\tau := (\mathcal{A}, E_\tau).$$

If $\tau_1 \geq \tau_2$ then $E_{\tau_1} \subseteq E_{\tau_2}$, hence G_{τ_1} is a subgraph of G_{τ_2}.

Remark 2409. *Intuitively, $G = (\mathcal{A}, E)$ is a directed graph of agents $\mathcal{A}$ with edges E representing potential influence or interaction, while $K(i,j) \in [0,1]$ measures how strongly i can affect j along an edge. The parameter τ is a* threshold*: we keep only edges whose coupling is at least τ, thereby extracting the "strong-tie" subgraph G_τ. This formalizes the sociological idea that if we demand stronger ties, fewer edges qualify; if we relax the standard, more edges qualify (Hyperseed-Concept 194).*

A simple example: suppose $E = \{(1,2), (2,3)\}$ with $K(1,2) = 0.9$ and $K(2,3) = 0.4$. Then at $\tau = 0.8$, we keep only $(1,2)$; at $\tau = 0.3$, we keep both edges. The lemma states precisely this nesting behavior, a basic prerequisite for monotonicity arguments about tribes and connectivity in thresholded graphs, and a staple move in network-based emergence arguments [5].

One can also view the family $\{G_\tau\}_{\tau\in(0,1]}$ as a decreasing filtration in τ: as τ moves downward, the edge set can only grow. In weighted-network terms, this is the standard "thresholding" operation turning a weighted digraph into an unweighted digraph at level τ, and the lemma says that thresholding is order-preserving with respect to the parameter.

Remark 2410. *What the lemma says in plain language is:* raising the bar for what counts as a strong tie can only delete edges, never add them. *This is important because virtually every downstream "tribe" or "community" definition depends on connectivity in G_τ; once we know how G_τ changes with τ, we can reason about how group structure changes as we shift thresholds.*

It is sometimes helpful to keep the extreme cases in mind. At $\tau = 1$, only edges with maximal coupling survive, so G_1 is typically very sparse; as τ decreases toward 0, more and more of the original edge set E is recovered (indeed, if one allowed $\tau = 0$ formally, then $E_0 = E$). The monotonicity statement is exactly what makes it meaningful to speak of edges and communities "appearing" as the threshold is weakened, since once an edge appears at some τ it persists for all smaller τ.

Sketch. If $K(i,j) \geq \tau_1$ and $\tau_1 \geq \tau_2$ then $K(i,j) \geq \tau_2$. Thus any edge in E_{τ_1} is also in E_{τ_2}.

Equivalently, the inclusion $E_{\tau_1} \subseteq E_{\tau_2}$ is simply the statement that the indicator function of the event "$K(i,j) \geq \tau$" is monotone nonincreasing in τ for each fixed edge $(i,j) \in E$. □

Remark 2411. Proof sketch. *The strategy is a one-line order argument: the predicate "$K(i,j) \geq \tau$" becomes easier to satisfy when τ is smaller. Geometrically, one may picture τ as a horizontal cut through edge weights; lowering the cut includes more edges.*

In this picture, each edge (i,j) has a "birth time" at $\tau = K(i,j)$: for thresholds $\tau \leq K(i,j)$ the edge is present, and for $\tau > K(i,j)$ it is absent. The lemma is the global statement obtained by taking the union of these per-edge birth rules across all edges in E. □

Helper Corollary 42.2 (Tribe monotonicity under weakening the strong-tie threshold)**.** *Assume a tribe at threshold τ is a subset $T \subseteq \mathcal{A}$ such that: (i) the induced subgraph $G_\tau[T]$ is (strongly) connected, and (ii) a boundedness/density condition holds that does not depend on τ. If T is a tribe at threshold τ_1 and $\tau_2 \leq \tau_1$, then T is also a tribe at threshold τ_2.*

Remark 2412. *In ordinary speech: if a set of agents T is already knitted together by sufficiently strong ties, then it remains knitted together when we decide to count* weaker *ties as admissible strong ties. Condition (i) says that within T, there is a directed path between any two members using only edges of strength at least τ. Condition (ii) represents whatever additional finiteness or density constraint the tribe definition imposes; the point here is that it does not change as τ changes, so only connectivity is at stake.*

This matches a natural conceptual expectation about Tribe *(Hyperseed-Concept 194): tribes are robust under making the social microscope less demanding. It is also a useful computational fact: one can search tribes at a high threshold, and know that any tribe found persists at lower thresholds (though new tribes may appear).*

For directed graphs, the parenthetical "(strongly)" is important: if one adopts strong connectivity, then the statement reads "directed reachability in both directions cannot be destroyed by adding directed edges"; if one adopts weak connectivity (connectivity of the underlying undirected graph), the statement is even more immediate. In either interpretation, the relevant principle is the same: adding admissible edges cannot eliminate existing paths inside the induced subgraph on T.

Remark 2413. *The corollary is an immediate companion to the previous lemma: the lemma gives edge-set nesting, and this corollary translates that nesting into* connectivity *preservation. This is* *the kind of monotonicity one leans on when proving "phase transition" statements for communities as thresholds vary, a motif common in network-centric treatments of collective cognition [19, 5].*

More concretely, as τ decreases one may see previously separate strongly connected components of G_τ merge into larger components, but one cannot see a strongly connected component split purely as a result of lowering τ (splitting would require deleting edges, not adding them). This "merging but not splitting" intuition is often what underlies persistence-style arguments about the stability of group-level structures across ranges of thresholds.

Sketch. By Lemma above, $G_{\tau_1}[T]$ is a subgraph of $G_{\tau_2}[T]$. Connectivity is preserved when adding edges. The boundedness condition is unchanged by assumption.

Spelled out slightly more: any path in $G_{\tau_1}[T]$ is still a path in $G_{\tau_2}[T]$, because every edge used by the path at threshold τ_1 remains present at threshold $\tau_2 \leq \tau_1$. Hence whatever reachability witnesses connectivity at τ_1 also witnesses it at τ_2. ☐

Remark 2414. Proof sketch. *The proof separates the two defining clauses of "tribe": only the connectivity clause depends on τ. Since lowering τ adds edges, any path that existed before still exists, and possibly many more; hence connectivity cannot be lost.*

Condition (ii) is treated as an invariant constraint across τ; typical examples in applications include cardinality bounds (e.g. $|T| \leq M$), minimum in/out-degree requirements computed in the original *graph rather than the thresholded one, or density constraints formulated in terms that do not tighten when τ changes. Under such hypotheses, the corollary reduces to a single monotonicity fact about paths.* ☐

42.2 Messages and assimilation (Defs. 335–336): algebra and batching

Helper Lemma 42.3 (Scaling of messages is monotone)**.** *Let $m : L \to V$ be a message and let k be a coupling weight (either scalar $k \in [0, 1]$ embedded as (k, k), or $k \in V$). Define scaling pointwise by*

$$(k \odot m)(\varphi) := k \otimes m(\varphi) \quad \textit{(interpreting scalar } k \textit{ via diagonal embedding).}$$

Then:

1. *If $m \leq m'$ pointwise, then $k \odot m \leq k \odot m'$.*
2. *If $k \leq k'$ (in the scalar order or the V-order), then $k \odot m \leq k' \odot m$.*

Remark 2415. *Here L is the claim language, V is the value space (often the p-bit quantale $[0, 1]^2$), and a message $m : L \to V$ assigns to each formula $\varphi \in L$ some graded evidence value. The symbol $\otimes$ is the quantale tensor (a kind of "and/combination" operation), while $\odot$ denotes scalar (or value) scaling of messages by a coupling k, i.e. attenuating or amplifying evidence before it is assimilated. The phrase "scalar $k \in [0, 1]$ embedded as (k, k)" means that we treat a real coupling strength as acting equally on the positive and negative coordinates of a p-bit value.*

The lemma says that scaling respects order: if you make the message larger, the scaled message becomes larger; and if you make the coupling larger, the scaled message becomes larger. This is one of the minimal algebraic sanity checks needed for any compositional account of social information flow (Hyperseed-Concept **??***), and it is exactly the kind of monotonicity guaranteed by quantale axioms [3].*

Remark 2416. *It is worth making explicit the underlying order conventions used implicitly throughout this subsection. The order on messages $m, m' : L \to V$ is the* pointwise *order:*

$$m \leq m' \quad :\Longleftrightarrow \quad \forall \varphi \in L,\ m(\varphi) \leq_V m'(\varphi).$$

Likewise, when k is a scalar $k \in [0, 1]$ viewed inside V by the diagonal map $k \mapsto (k, k)$, the inequality $k \le k'$ is just the usual real order transported along that embedding, so the comparison in (2) reduces to a comparison in V. Under these conventions, both items of the lemma are simply the statement that the map

$$V \times V \to V, \qquad (a, b) \mapsto a \otimes b$$

is monotone in each argument, which is one of the standard quantale requirements (and is also the key property that makes $\otimes$ behave like a generalized product rather than an arbitrary binary operation).

Remark 2417. *In plain language:* stronger evidence in, stronger evidence out; stronger channel, stronger delivered message. *This matters because all later batching and path-composition facts tacitly assume that local improvements cannot perversely reduce propagated evidence. It also connects this section to the epistemic-layer helper theorems (Section 42) where the same monotonicity of $\otimes$ and joins underwrites closure constructions.*

Sketch. Both are immediate from monotonicity of the tensor $\otimes$ in each argument (quantale axiom). □

Remark 2418. Proof sketch. *The proof is pointwise in φ: compare $k \otimes m(\varphi)$ and $k \otimes m'(\varphi)$ using monotonicity in the second input, and compare $k \otimes m(\varphi)$ and $k' \otimes m(\varphi)$ using monotonicity in the first input. Visually, one may imagine $\otimes$ as a generalized multiplication: increasing either factor cannot decrease the product.* □

Remark 2419. *In applications, the coupling weight k often summarizes multiple "channel" factors at once (attention, trust, bandwidth, proximity, institutional filtering). The lemma then says that any increase in such channel factors (modeled as an increase of k in the underlying order) can only increase the transmitted/usable evidence values in the resulting scaled message. This monotonicity is precisely what allows one to compare alternative social/organizational designs by order-theoretic dominance: if one design has uniformly larger couplings (or produces uniformly larger raw messages), then it cannot yield weaker delivered evidence after scaling.*

Helper Lemma 42.4 (Assimilation update is inflationary and idempotent under repeat)**.** *Let $\beta : L \to V$ be a belief state and update by $\beta \leftarrow \beta \oplus (k \odot m)$. Then $\beta \le \beta \oplus (k \odot m)$ pointwise. Moreover, applying the* same *assimilated message twice has no further effect:*

$$(\beta \oplus (k \odot m)) \oplus (k \odot m) = \beta \oplus (k \odot m),$$

since $\oplus$ is idempotent.

Remark 2420. *This lemma is the algebraic analogue of two everyday intuitions about communication. First: assimilating a message by joining it into your current belief state cannot make you* less *informed in the order-theoretic sense (inflationary update). Second: if you hear precisely the same message twice through exactly the same coupling, and assimilation is modeled by a join, then the second hearing adds no new information (idempotence). In the canonical p-bit setting, where $\oplus$ is componentwise* max*, this corresponds to the simple fact that* $\max(x, y)$ *does not change if you take* $\max(\max(x, y), y)$.

This is useful because it turns message passing into a kind of set-like *accumulation of evidence: duplicates are harmless, and updates can be reasoned about without tracking the detailed history of repeated identical transmissions. Such idempotent accumulation is characteristic of many closure-style and fixed-point constructions, including those used to analyze stability of self-updating systems [10].*

Remark 2421. *The result is not surprising once one sees that $\oplus$ is behaving like logical "or" or like taking a supremum. But it is important because it is exactly what makes batching (next proposition) and optional closure (next corollary) tractable: if joins were not inflationary and idempotent, then order and repetition effects would contaminate every multi-message calculation.*

Remark 2422. *One may also read the idempotence clause as a modeling decision about what counts as "new" information. Joining treats repeated identical inputs as redundant, which matches many evidential and logical intuitions (a proposition does not become truer by restating it verbatim). If one wanted instead to model* reinforcement by repetition *(e.g. repeated exposure increasing salience), then the update operator would typically not be idempotent; the present lemma clarifies that the batching results below rely specifically on the join-semilattice style of assimilation.*

Sketch. Inflationary: $\beta(\varphi) \leq \beta(\varphi) \oplus (k \odot m)(\varphi)$ for each φ. Idempotence: $x \oplus x = x$ in any join-semilattice. $\square$

Remark 2423. Proof sketch. *The proof is entirely local to each formula φ: at that coordinate, the update replaces $\beta(\varphi)$ by a join with an extra term, which cannot decrease it. Re-applying the same join is redundant because joining an element with itself does nothing. A helpful picture is to view β as a "landscape" of values; joining in a message raises some points of the landscape, never lowers them, and repeating the same raising operation cannot raise further.* $\square$

Helper Proposition 42.5 (Batching and order-independence of multiple assimilations)**.** *Let $(k_1, m_1), \ldots, (k_n, m_n)$ be messages received by an agent, and define the iterated update*

$$\beta_0 := \beta, \qquad \beta_{t+1} := \beta_t \oplus (k_{t+1} \odot m_{t+1}).$$

Then

$$\beta_n = \beta \oplus (k_1 \odot m_1) \oplus \cdots \oplus (k_n \odot m_n),$$

so the final state does not depend on the order in which messages are processed (associativity/commutativity of $\oplus$).

Remark 2424. *Equivalently, for each $\varphi \in L$ the final value $\beta_n(\varphi)$ is the join (supremum) of the initial belief value $\beta(\varphi)$ together with all delivered message-values $(k_i \odot m_i)(\varphi)$. In the common p-bit/*max *instantiation, this is simply the statement that the coordinatewise maximum over a finite set of inputs is independent of the order in which those inputs are processed. Conceptually, batching says that assimilation is "history-free" with respect to permutations of the same multiset of incoming (coupling,message) pairs: only the set of delivered evidence values matters, not the temporal order in which they arrived.*

Sketch. By induction on n, using associativity of $\oplus$ to reassociate iterated joins, and commutativity of $\oplus$ to permute the join-factors. $\square$

Remark 2425. Proof sketch. *Unfold the recursion once:*

$$\beta_1 = \beta \oplus (k_1 \odot m_1), \qquad \beta_2 = (\beta \oplus (k_1 \odot m_1)) \oplus (k_2 \odot m_2),$$

and so on. Associativity ensures that parentheses can be dropped without changing the value, so the iterated update is equal to the single expression obtained by joining all scaled messages into β. Commutativity then implies that any permutation of $(k_1 \odot m_1), \ldots, (k_n \odot m_n)$ yields the same final join, hence the same β_n. If some of the delivered terms coincide, idempotence (Lemma above) shows that duplicates do not affect the result, which is often convenient when messages are received through multiple redundant channels. $\square$

Remark 2426. *This proposition says that when assimilation is modeled as repeated joins, the agent may treat the incoming stream of messages as a* multiset *whose final effect is just the join of all scaled messages—and since $\oplus$ is commutative and associative, the order does not matter. Practically, this means one can batch messages, parallelize assimilation, or reorder them for computational convenience without changing the resulting belief state. A useful way to read this is that the* only *information the update dynamics keeps from a finite message history is the "envelope" given by $\oplus$ of the scaled inputs. Equivalently, the update map factors through the free commutative idempotent monoid on messages (i.e. multisets under union), because idempotence of $\oplus$ also implies that receiving the* same *scaled message twice does not further change the result beyond the first receipt. In this sense, the repeated-join assimilation law behaves like a deterministic, confluent rewrite system: different schedules of incorporating evidence all converge to the same normal form. One can also think of this as a kind of weak path-independence: the belief state β evolves monotonically (with respect to the lattice order induced by $\oplus$), and the final state depends only on the set of constraints/messages eventually imposed, not on the temporal order in which they arrive.*

In the canonical p-bit case, imagine two messages about the same claim φ: one provides 0.6 positive evidence and another provides 0.7 negative evidence (appropriately scaled). Joining them simply takes the coordinatewise maxima, so doing "positive then negative" or "negative then positive" yields the same final pair. This is one of the algebraic reasons paraconsistent evidence aggregation is computationally neat [23, 24]. In more detail, if a belief state stores a pair $(b^+(\varphi), b^-(\varphi)) \in [0,1]^2$ and $\oplus$ is coordinatewise max*, then the update with a message contributing $(0.6, 0)$ and then one contributing $(0, 0.7)$ yields*

$$(0,0) \oplus (0.6,0) \oplus (0,0.7) = (\max\{0,0.6,0\}, \max\{0,0,0.7\}) = (0.6,0.7),$$

and the same expression appears in the opposite order. This makes explicit that, even when evidence is "in tension" (both positive and negative components are large), the aggregation rule still stays purely algebraic: it is not forced to resolve the tension immediately, and the computation does not branch on arrival order.

Remark 2427. *The importance of this result is structural: it lets us treat a communicative system as defining a* commutative semilattice action *on belief states. That, in turn, is what makes fixed-point analyses of social belief propagation feasible later (compare the reinforcement operator F below), and it aligns with the broader quantale-based viewpoint [3]. Concretely, the space of "aggregated message-bundles" (finite joins of scaled messages) itself forms a commutative idempotent semigroup under $\oplus$, and assimilation becomes an action $(x, \beta) \mapsto \beta \oplus x$ of this semilattice on states. The action laws are exactly the algebraic equalities one wants for modular reasoning: joining two bundles and then acting equals acting by each bundle in either order, i.e.*

$$\beta \oplus (x \oplus y) = (\beta \oplus x) \oplus y = (\beta \oplus y) \oplus x,$$

so "communication composition" and "belief update composition" agree. This turns a dynamic process into an object that can be studied with standard lattice/semigroup tools: invariants, monotone iteration, and eventual stabilization can be phrased as statements about joins and fixed points rather than about time indices.

Sketch. Induction on n, using associativity/commutativity of $\oplus$. More explicitly, for the induction step one expands the definition of the $n+1$-step assimilation, uses the induction hypothesis to replace the first n steps by the join of the first n scaled messages, and then uses associativity to flatten parentheses. Commutativity is what allows any permutation of the messages to be rewritten to the same join expression, showing that the normal form depends only on the multiset of inputs rather than on their sequence. □

Remark 2428. Proof sketch. *The high-level strategy is to expand the recurrence* $\beta_{t+1} = \beta_t \oplus (\cdots)$ *repeatedly until all the joins are explicit, then use associativity to remove parentheses. Commutativity justifies reordering. One can think of each update as "adding a stone" to a pile; in a commutative monoid, the pile does not remember the order in which stones were added. If one additionally recalls that* $\oplus$ *is typically idempotent in these settings (as a join operation in a semilattice), the "pile" metaphor can be sharpened: adding the* same *stone twice does not change the pile after the first addition. This is exactly the multiset-to-set collapse at the level of effect: the update is sensitive to the maximum delivered strength along each coordinate, not to the number of times the same strength is repeated.* □

Helper Corollary 42.6 (Optional inference closure can be pushed to the end)**.** *Assume a closure operator* Cl *on belief states is monotone, extensive, and idempotent (as in the inference-closure construction of Section 20). If after each message one optionally applies* $\beta \leftarrow \mathrm{Cl}(\beta)$*, then the final closed belief state equals*

$$\mathrm{Cl}\Big(\beta \oplus (k_1 \odot m_1) \oplus \cdots \oplus (k_n \odot m_n)\Big).$$

Remark 2429. *A closure operator* Cl *(as in the epistemic layer) represents "closing under inference": after assimilating raw evidence, one may apply rules to derive implied beliefs. This corollary states that if* Cl *is a genuine closure operator (extensive, monotone, idempotent), then repeatedly closing after every single message is equivalent to first joining all the messages in any order, and then closing once at the end. Intuitively, closure is a "rounding up" operation to the nearest inference-complete state. If one performs many small rounds of inference after each communication event, the axioms guarantee that nothing essentially new is gained compared to postponing the rounding until all evidence has been incorporated: extensiveness prevents closure from discarding information, monotonicity prevents later evidence from being "blocked" by earlier closure, and idempotence prevents overcounting the effect of repeated closure. In particular, the corollary can be read as an* interleaving invariance *principle: communication steps (joins with message contributions) and reasoning steps (applications of* Cl*) can be freely interleaved without changing the final closed outcome, so long as one ends in a closed state.*

This is valuable computationally and conceptually. Computationally, it means we can defer expensive inference until after batching evidence. Conceptually, it means that closure is a kind of consolidation *rather than an event that must occur at every moment; the algebra guarantees no loss of rigor by postponement. This resonates with the general theme that when inference is modeled as least fixed points of monotone operators, the order of "small steps" often collapses to a single fixed-point computation (compare Knaster–Tarski style arguments discussed around Section 42). From a systems viewpoint, this also clarifies a design separation: message handling can remain a lightweight, streaming operation (a join-semilattice update), while inference can be scheduled as a background task or a periodic batch job. The corollary states that this engineering choice is not merely heuristic; under the closure axioms, it is provably semantics-preserving.*

Remark 2430. *The statement is important because it connects the social layer back to the epistemic-layer closure theorems: the same abstract conditions (monotone, extensive, idempotent) ensure that closure behaves like a projection onto a subspace of "fully reasoned" states. The surprise, for students encountering closure operators for the first time, is how much control these three axioms give over the interleaving of communication and inference. In categorical or order-theoretic language, a closure operator is a (monotone) idempotent inflationary endomorphism, and its image consists of the "closed" elements. The corollary is then a statement that the endomorphism can be applied after forming the join of a finite family of updates, without changing the resulting closed element. This makes it possible to reason about the long-run behavior of social-epistemic dynamics by first* *analyzing the easier semilattice accumulation, and only afterward restricting attention to the closed subspace.*

Sketch. Extensiveness gives $\beta \le \mathrm{Cl}(\beta)$; monotonicity lets closure commute with joins up to equality, and idempotence lets repeated closures collapse to one final closure. A common way to formalize the "collapse" is to show, by induction on the number of steps, that after any interleaving of joins-with-messages and closures, the current state is always bounded above by the state obtained by joining all message contributions so far and then applying Cl, and also bounded below by the unclosed join-state. These two bounds tighten to equality once one applies Cl at the end, because applying Cl to the lower bound lifts it into the closed region while idempotence ensures no further change. ☐

Remark 2431. Proof sketch. *The strategy is to compare the step-by-step process with the "batch then close" process by sandwiching each intermediate state between the unclosed join-state and its closure, using monotonicity. Idempotence then removes redundant closures. A useful mental image is that* Cl *pulls any state upward to the nearest closed state above it; doing this repeatedly is no different from doing it once at the end. This "nearest closed state" picture is especially intuitive in finite examples: one can imagine the lattice of states and the subset of closed points as a region, with* Cl *acting like a projection that moves each point upward. Joins move states upward as well, and monotonicity ensures these upward motions do not interfere destructively. Thus, alternating "move upward by evidence" and "project to closed" is equivalent to doing all evidence-moves first and then projecting once.* ☐

Helper Lemma 42.7 (Redundant channels combine by join of couplings (quantale distributivity))**.** *Suppose the* same *message m reaches a recipient through two links with couplings k_1, k_2. Assuming $\otimes$ distributes over $\oplus$ (quantale axiom), we have*

$$(k_1 \odot m) \oplus (k_2 \odot m) \;=\; (k_1 \oplus k_2) \odot m.$$

Remark 2432. *This lemma formalizes the idea that two redundant transmissions of the same content combine into a single transmission whose effective coupling is the join (supremum) of the two couplings. In the canonical p-bit setting with $\oplus = \max$ and $\otimes$ behaving like multiplication by a scalar coupling, the identity reduces to*

$$\max(k_1 m,\, k_2 m) = \max(k_1, k_2)\, m,$$

which is exactly what one expects: the stronger of the two channels dominates the delivered strength when one aggregates by maxima. Put differently, the recipient does not need to remember how many *copies of the same message arrived, nor from which path, so long as the aggregation rule is supremum-like: what matters is the best-supported (highest-coupling) delivery of that content. This is consistent with many "max-confidence" and "best-signal" heuristics, but here it is not a heuristic; it is an algebraic consequence of the distributive law in the underlying quantale.*

The assumption that $\otimes$ distributes over $\oplus$ is part of the quantale structure, and is precisely what makes such "algebra of evidence flow" clean and compositional [3]. It matters for simplifying network calculations: rather than tracking multiple redundant edges carrying the same message, one can collapse them into an effective coupling. At the level of symbolic manipulation, the lemma is the direct specialization of distributivity:

$$(k_1 \oplus k_2) \otimes m \;=\; (k_1 \otimes m) \oplus (k_2 \otimes m),$$

together with the convention that $k \odot m$ abbreviates $k \otimes m$. In graph terms, if two parallel edges carry the same label m, then the parallel composition of edges corresponds to $\oplus$ on couplings, so one may replace the parallel edges by a single edge whose coupling is $k_1 \oplus k_2$ without changing any downstream assimilation results. This kind of reduction is particularly useful when analyzing dense social graphs where redundancy is common (multiple acquaintances relaying the same claim), because it allows one to normalize the network before running belief-propagation computations.

Remark 2433. *The result is a small but powerful rewrite rule: it lets you move the join from the message-side to the coupling-side. This is particularly helpful when analyzing effective communication strength along multiple parallel paths (next subsection), where the combinatorics of paths would otherwise proliferate. In practice, it means that when a fixed message m is being broadcast through several competing couplings $k_1, k_2, \ldots$, one may first aggregate the couplings (by $\oplus$) and then apply the message once, rather than repeatedly scaling and joining on the message side. Algebraically, this is the familiar distributivity pattern $(a \otimes x) \vee (b \otimes x) = (a \vee b) \otimes x$ (for $\vee = \oplus$), applied pointwise to the message coordinates; conceptually, it is a way of factoring out a common "content" from multiple delivery channels.*

Sketch. Pointwise in φ: $(k_1 \otimes m(\varphi)) \oplus (k_2 \otimes m(\varphi)) = ((k_1 \oplus k_2) \otimes m(\varphi))$. Here the pointwise qualification is essential: the join and tensor are applied in the underlying value structure at each feature/coordinate φ, so the identity follows immediately from distributivity in that base algebra (and then lifts to messages by extensional equality). If one prefers, the same argument can be read as a two-term instance of the more general finite-join law $\left(\bigvee_i k_i\right) \otimes x = \bigvee_i (k_i \otimes x)$, specialized to a common $x = m(\varphi)$. □

Remark 2434. Proof sketch. *The proof is a direct application of distributivity at each coordinate φ: factor out $m(\varphi)$ from the join of two scaled values. Geometrically, think of $m(\varphi)$ as a "shape" and k as a "brightness" multiplier; taking the brighter of two renderings is equivalent to rendering once at the maximum brightness. This picture also highlights why $\oplus$ being idempotent (as a supremum-like operation) is natural for evidence aggregation: repeating the same rendering does not compound brightness, whereas improving the coupling increases it monotonically. In particular, if $k_1 \le k_2$ then $k_1 \otimes m(\varphi) \oplus k_2 \otimes m(\varphi) = k_2 \otimes m(\varphi)$, so weaker redundant channels are absorbed by stronger ones at that coordinate.* □

42.3 Communicative systems (Def. 338): path composition heuristics

Helper Proposition 42.8 (Effective coupling along a communication path (scalar case))**.** *Assume scalar couplings $k \in [0, 1]$ embedded diagonally and the canonical tensor corresponds to multiplying by k. Consider a directed path*

$$i_0 \to i_1 \to \cdots \to i_\ell$$

and suppose the same message m is forwarded along the path, with assimilation at each hop. Then the net scaling at the end of the path is bounded below by multiplication of couplings:

$$\textit{effective scale} \;\ge\; \prod_{t=0}^{\ell-1} k(i_t, i_{t+1}),$$

i.e. the forwarded evidence is at least $(\prod_t k_t) \odot m$ before joining into beliefs. If there are multiple paths, the final assimilated contribution is the join over path contributions. In particular, when $\oplus$ is realized as pointwise maximum and the canonical tensor is ordinary multiplication, each path yields a pointwise attenuated copy of m, and the receiver takes the pointwise best-supported copy *across paths. Edge cases behave as expected: any hop with $k(i_t, i_{t+1}) = 0$ blocks that path entirely, while $k(i_t, i_{t+1}) = 1$ leaves the message unchanged at that hop, so the product expresses cumulative attenuation along the route.*

Remark 2435. *The statement translates a familiar engineering principle into the present algebra: if a signal passes through multiple imperfect links, its strength attenuates multiplicatively. Here the "signal" is the message m, and each hop (i_t, i_{t+1}) has coupling $k(i_t, i_{t+1}) \in [0, 1]$; under canonical scaling, the message is multiplied by k at each hop. Thus a two-hop path with couplings 0.8 and 0.5 yields an overall factor 0.4.*

The lower-bound phrasing "$\geq$" reflects that, depending on the implementation, an agent might preserve some of the message strength locally or combine it with other evidence; but in the basic model where forwarding consists of successive scalings and joins, the product is the natural minimal effective factor. The join over multiple paths expresses a second natural idea: independent deliveries do not cancel; they accumulate by supremum (compare redundant channels in the previous lemma). This is one of the simplest mathematical embodiments of communication as compositional propagation *in a society (Hyperseed-Concept 170). One can also view the product $\prod_t k(i_t, i_{t+1})$ as a path-score: longer paths are not automatically worse, but they are penalized unless intermediate couplings are near 1. This makes explicit a trade-off between reachability (existence of paths) and reliability (strength of the best path), which will be reused when turning network structure into effective influence bounds.*

Remark 2436. *This proposition is important as a bridge between local update rules (scaling and joining) and global network effects (path reachability and attenuation). It anticipates the later reinforcement-operator expansion, where max/min composition replaces multiplication/min in a fuzzy-logic regime. Both are instances of a broader pattern-web style analysis of distributed cognition [5, 19]. In that later regime, "composition along a path" remains the central heuristic, but the specific aggregator (product versus a t-norm, max/min, etc.) changes with the semantic interpretation of evidence. The present scalar-product case can be read as the baseline against which alternative path-composition laws are compared.*

Sketch. Each hop multiplies the message by the next coupling factor, so scales multiply. Independently delivered contributions are joined by $\oplus$ (as in the message update rule). Formally, one can argue by induction on ℓ: for $\ell = 1$ the claim is immediate; assuming the scaling after $\ell - 1$ hops is at least $\prod_{t=0}^{\ell-2} k(i_t, i_{t+1})$, applying the next hop multiplies by $k(i_{\ell-1}, i_\ell)$ and yields the product for ℓ. The multi-path statement then follows by applying the same single-path computation to each path and using the definition of assimilation as a join of incoming contributions. □

Remark 2437. Proof sketch. *The proof strategy is to unroll the sequential forwarding: after one hop the message has factor k_0, after two hops $k_0 k_1$, and so on. For multiple paths, one applies the batching/order-independence proposition: each path contributes a scaled version of m, and the receiver's belief state takes the join of all contributions. A visual metaphor is light passing through successive tinted panes (multiplication), with multiple windows shining on the same wall (join). Equivalently, for each path p one computes a path weight $w(p) = \prod_{e \in p} k(e)$ and the receiver aggregates $\bigvee_p \big(w(p) \odot m\big)$; the earlier rewrite rule justifies pulling joins across shared messages when comparing alternative couplings or routes. This makes it clear why redundant or partially overlapping routes can be analyzed without enumerating all interleavings: path contributions remain separable up to a final join.* □

43 Helper theorems for Hyperseed-grounded Universal Grammar

This section collects small "helper" results intended to support automated reasoning over the Hyperseed-grounded TyLAA/TUG formalization of Universal Grammar. The key objects referenced are: (i) the label-independence relation (Definition **??**; Hyperseed-Concept **??**), (ii) the swap congruence / trace skeleton (Definitions **??**–**??**; Hyperseed-Concepts **??**, **??**), (iii) the symmetry group of labels (Definition **??**; Hyperseed-Concept **??**), (iv) the induced TUG congruence (Definition **??**; Hyperseed-Concept **??**), and (v) the dependency topology extracted from failures of independence (Definition **??**; Hyperseed-Concept **??**).

Helper Lemma 43.1 (Basic properties of label-independence)**.** *Let* $\perp \subseteq \mathsf{Lab}_V \times \mathsf{Lab}_V$ *be the label-independence relation from Definition* **??***, i.e.*

$$\ell_1 \perp \ell_2 \quad \Longleftrightarrow \quad \mathsf{disjointPos}(\mathsf{pos}(\ell_1), \mathsf{pos}(\ell_2)) \;\wedge\; (\mathsf{rely}(\ell_1) \cap \mathsf{rely}(\ell_2) = \emptyset).$$

Then:

1. $\perp$ *is symmetric: if* $\ell_1 \perp \ell_2$ *then* $\ell_2 \perp \ell_1$*.*
2. $\perp$ *is irreflexive: for all* $\ell \in \mathsf{Lab}_V$*, not(*$\ell \perp \ell$*).*

Proof. (1) Symmetry follows because $\mathsf{disjointPos}(\cdot,\cdot)$ is symmetric and because set intersection is commutative: $\mathsf{rely}(\ell_1) \cap \mathsf{rely}(\ell_2) = \emptyset$ iff $\mathsf{rely}(\ell_2) \cap \mathsf{rely}(\ell_1) = \emptyset$.

(2) For any position p, $\mathsf{disjointPos}(p, p)$ fails because p is a prefix of itself. Hence the conjunction defining $\ell \perp \ell$ fails for every ℓ. □

Helper Lemma 43.2 (Independence preserved by structural symmetries)**.** *Assume* Γ *is a symmetry group acting on visible labels as in Definition* **??***, and assume each* $\gamma \in \Gamma$ *preserves the structural annotations used by Definition* **??***, i.e.*

$$\mathsf{pos}(\gamma\ell) = \mathsf{pos}(\ell) \quad \textit{and} \quad \mathsf{rely}(\gamma\ell) = \mathsf{rely}(\ell) \qquad \forall \ell \in \mathsf{Lab}_V.$$

Then for all $\ell_1, \ell_2 \in \mathsf{Lab}_V$*,*

$$\ell_1 \perp \ell_2 \quad \Longleftrightarrow \quad (\gamma\ell_1) \perp (\gamma\ell_2).$$

Proof. Immediate from the defining conjunction for $\perp$ and the preservation equalities for pos and rely. □

Helper Proposition 43.3 (Swap-equivalence is a monoid congruence)**.** *Let* $\equiv_\perp$ *be the swap congruence on* Lab_V^* *from Definition* **??***. Then:*

1. $\equiv_\perp$ *is an equivalence relation on* Lab_V^**.*
2. $\equiv_\perp$ *is a congruence for concatenation: if* $\pi_1 \equiv_\perp \pi_2$ *then for all* $\alpha, \beta \in \mathsf{Lab}_V^*$*,*

$$\alpha\, \pi_1\, \beta \;\equiv_\perp\; \alpha\, \pi_2\, \beta.$$

Proof. (1) By construction, $\equiv_\perp$ is the equivalence closure of the elementary adjacent-swap rewrites generated by pairs $\ell_1 \perp \ell_2$.

(2) Each elementary rewrite step has the form $\alpha\,(\ell_1\ell_2)\,\beta \mapsto \alpha\,(\ell_2\ell_1)\,\beta$ for some context words α, β and some independent pair $\ell_1 \perp \ell_2$. Thus closure under adding the same prefix/suffix is built into the generator. Stability under finite sequences of generator steps follows by induction on the length of the derivation witnessing $\pi_1 \equiv_\perp \pi_2$. □

Helper Proposition 43.4 (The trace skeleton forms a monoid). *Let* $\mathsf{Tr}_\perp := \mathsf{Lab}_V^*/{\equiv_\perp}$ *be the trace skeleton (Definition* **??***; Hyperseed-Concept* **??***). Define multiplication on equivalence classes by*

$$[\pi] \cdot [\rho] := [\pi\rho],$$

where $\pi\rho$ *is concatenation and* $[\cdot]$ *denotes the* $\equiv_\perp$*-class. Then* $(\mathsf{Tr}_\perp, \cdot, [\epsilon])$ *is a well-defined monoid.*

Proof. Well-definedness: if $\pi \equiv_\perp \pi'$ and $\rho \equiv_\perp \rho'$ then $\pi\rho \equiv_\perp \pi'\rho'$ by Proposition 43.3(2), so the product does not depend on representatives.

Associativity and the identity law follow from associativity of word concatenation and the fact that ϵ is the identity for concatenation. □

Helper Proposition 43.5 (Monotonicity under enlarging independence or symmetry). *Let* $(\perp_1, \Gamma_1)$ *and* $(\perp_2, \Gamma_2)$ *be two independence/symmetry choices with* $\perp_1 \subseteq \perp_2$ *and* $\Gamma_1 \subseteq \Gamma_2$*. Let* $\equiv_{\perp_i,\Gamma_i}$ *be the corresponding TUG congruences (Definition* **??***). Then, as relations on* Lab_V^**,*

$$\equiv_{\perp_1,\Gamma_1} \subseteq \equiv_{\perp_2,\Gamma_2} .$$

Proof. $\equiv_{\perp,\Gamma}$ is generated by (i) swaps of adjacent independent labels and (ii) Γ-identifications. If $\perp_1 \subseteq \perp_2$ and $\Gamma_1 \subseteq \Gamma_2$, then every generator step allowed for $(\perp_1, \Gamma_1)$ is also allowed for $(\perp_2, \Gamma_2)$. Hence any finite derivation witnessing $\pi \equiv_{\perp_1,\Gamma_1} \pi'$ is also a derivation witnessing $\pi \equiv_{\perp_2,\Gamma_2} \pi'$. Equivalently, if one views $\equiv_{\perp,\Gamma}$ as the smallest equivalence relation closed under these generator steps, then enlarging $\perp$ and Γ can only enlarge the set of admissible steps, and therefore can only enlarge the generated relation. Formally, one may argue by induction on the length of the derivation chain $\pi = \pi_0 \to \pi_1 \to \cdots \to \pi_n = \pi'$, noting that each rewrite $\pi_i \to \pi_{i+1}$ is a single instance of either (i) or (ii), and the same instance is still valid when $\perp$ and Γ are replaced by supersets. □

Helper Corollary 43.6 (UG coarsening increases quantale weakness). *Fix an evidence quantale* $(V, \leq, \oplus, \otimes)$ *and a weight map* $\mu : \mathsf{Lab}_V^* \to V$*. For any congruence* $\equiv$ *on* Lab_V^**, view it as an "undistinguished pairs" relation* $H_\equiv \subseteq \mathsf{Lab}_V^* \times \mathsf{Lab}_V^*$ *via* $(\pi, \pi') \in H_\equiv \iff \pi \equiv \pi'$*. If* $\equiv_1 \subseteq \equiv_2$ *then*

$$w(H_{\equiv_1}) \leq w(H_{\equiv_2}),$$

where $w(\cdot)$ *is the quantale weakness functional (Hyperseed-Concept 143). In particular, the inclusion from Proposition 43.5 implies weakness monotonicity for UG coarsenings. Moreover, this corollary packages the general principle that declaring* more *pairs undistinguished (i.e. passing to a coarser congruence) can only make the resulting comparison criterion weaker in the sense measured by* w*, since fewer distinctions remain available to a test.*

Proof. If $\equiv_1 \subseteq \equiv_2$ then $H_{\equiv_1} \subseteq H_{\equiv_2}$ by definition. Apply Theorem 1 (weakness monotonicity under enlarging the undistinguished-pairs relation). Concretely, the hypothesis of Theorem 1 is exactly set inclusion of undistinguished-pairs relations, and the conclusion is the desired inequality in V; the role of the weight map μ is already built into the definition of $w(\cdot)$, so no additional argument beyond the inclusion check is required here. □

Helper Proposition 43.7 (The trace quotient is a Hyperseed abstraction). *Let* $q_{\perp,\Gamma} : \mathsf{Lab}_V^* \twoheadrightarrow \mathsf{Lab}_V^*/{\equiv_{\perp,\Gamma}}$ *be the quotient map* $\pi \mapsto [\pi]_{\perp,\Gamma}$*. Then* $q_{\perp,\Gamma}$ *is a surjection, and the induced equivalence relation*

$$\pi \sim_{q_{\perp,\Gamma}} \pi' \iff q_{\perp,\Gamma}(\pi) = q_{\perp,\Gamma}(\pi')$$

is exactly $\equiv_{\perp,\Gamma}$*. Hence* $q_{\perp,\Gamma}$ *is an abstraction in the sense of Hyperseed-Concept 51. In other words, the quotient construction realizes the standard "forgetful" abstraction that collapses precisely those traces that UG declares observationally interchangeable (up to swaps and* Γ*-actions), and nothing more.*

Proof. Surjectivity is immediate: every equivalence class has a representative. The induced relation $\sim_{q_{\perp,\Gamma}}$ is equality of equivalence classes, which is precisely $\equiv_{\perp,\Gamma}$ by definition of the quotient. This matches the Hyperseed abstraction schema: a surjection whose fibers define an equivalence relation (Hyperseed-Concept 51). Equivalently, $\sim_{q_{\perp,\Gamma}}$ is the kernel relation of the map $q_{\perp,\Gamma}$, and for a quotient map the kernel is exactly the congruence used to form the quotient. Thus the "information discarded" by $q_{\perp,\Gamma}$ is exactly the information modded out by $\equiv_{\perp,\Gamma}$. ☐

Helper Lemma 43.8 (Dependency topology invariance under swap and symmetry). *Let* $\pi, \pi' \in \mathsf{Lab}_V^*$. *Assume:*

1. $\pi \equiv_\perp \pi'$ *(swap-equivalent), and*
2. *the symmetry group* Γ *preserves independence as in Lemma 43.2.*

Then the dependency topology extracted from π *(Definition* **??***) is isomorphic to the dependency topology extracted from* π'*. Consequently, any dependency-topology invariant (e.g. undirected dependency graph, dependence partial order up to renaming of event indices) is constant on* $\equiv_{\perp,\Gamma}$*-classes. Here "isomorphic" is meant in the concrete sense appropriate to the construction of Definition* **??***: there is a bijection on event occurrences/indices that preserves the dependence relation and therefore induces a homeomorphism (or graph isomorphism, as appropriate) of the resulting topological/relational structure.*

Proof. It suffices to check invariance under one generator step and then use induction over the finite sequence of generator steps witnessing $\pi \equiv_\perp \pi'$.

A generator step replaces a factor $\ell_1\ell_2$ with $\ell_2\ell_1$ where $\ell_1 \perp \ell_2$. Because ℓ_1 and ℓ_2 are independent, there is no dependence edge between these two event occurrences in the extracted dependency topology, and swapping their order does not create one. For any other label occurrence ℓ_3, the dependence/independence relation between ℓ_3 and ℓ_1 (resp. ℓ_2) is unchanged by the swap; only the adjacent indices are exchanged. Thus the dependency structure is preserved up to the obvious renaming of the two swapped indices. More explicitly, if the swap exchanges occurrences at positions i and $i+1$, then the bijection on event indices that transposes i and $i+1$ (and fixes all other indices) preserves the dependence relation, since the only potential new comparisons would involve ℓ_1 and ℓ_2, which are independent by hypothesis.

For symmetry steps, Lemma 43.2 guarantees that dependence/independence is preserved under the label map $\ell \mapsto \gamma\ell$. In that case the underlying event-index set is unchanged and one may take the identity bijection on indices; the isomorphism condition reduces to the fact that every dependence edge is defined in terms of (in)dependence of labels, which is invariant under the Γ-action by the cited lemma. ☐

Helper Theorem 43.9 (Observational soundness of TUG congruence). *Assume:*

1. *(Local commutation) whenever two visible labels* ℓ_1, ℓ_2 *are independent (*$\ell_1 \perp \ell_2$*), the corresponding visible steps commute in the LTS in the sense of Assumption* **??***.*
2. *(Symmetry soundness) for every* $\gamma \in \Gamma$*, replacing each visible label* ℓ *in a derivation by* $\gamma\ell$ *does not change the observation at the interface, in the sense of Assumption* **??***.*
3. *(State-determined observation) the observation functor/interface reads off an invariant from the derivation's state trajectory as specified in Definition* **??***.*

Then for all visible derivations $\pi, \pi' \in \mathsf{Lab}_V^*$,

$$\pi \equiv_{\perp,\Gamma} \pi' \quad \Longrightarrow \quad \pi \equiv_{\text{obs}} \pi'.$$

In particular, $\equiv_{\perp,\Gamma}$ is a sound proof principle *for observational equivalence: any equation derivable from the commutation and symmetry generators denotes traces that cannot be told apart by the chosen observation interface.*

Proof. By Definition **??**, $\equiv_{\perp,\Gamma}$ is generated by two kinds of elementary rewrites: (i) swapping adjacent independent labels, and (ii) applying a symmetry $\gamma \in \Gamma$ to a label (or to a factor) as allowed by the symmetry action.

For generator type (i), local commutation ensures that the swapped derivations lead to the same relevant state/trace-as-state information, hence have the same observation by state-determined observation. More concretely, Assumption **??** provides a commuting square (or diamond) in the LTS for the two-step fragment labeled by $\ell_1\ell_2$ versus $\ell_2\ell_1$, showing that the two orderings reach matching states; since the observation is a function of the state trajectory in the sense of Definition **??**, the observation computed from either ordering is identical.

For generator type (ii), symmetry soundness gives observation preservation directly. That is, applying γ pointwise to the labels of a derivation changes only the names of visible actions within a Γ-orbit and, by Assumption **??**, leaves the interface-level observation invariant.

Since $\equiv_{\perp,\Gamma}$ is the equivalence closure of these generators, any derivation witnessing $\pi \equiv_{\perp,\Gamma} \pi'$ is a finite chain of observation-preserving steps. Thus π and π' have equal observations, i.e. $\pi \equiv_{\text{obs}} \pi'$. Equivalently, $\equiv_{\text{obs}}$ contains each generator instance, and therefore contains the smallest equivalence relation generated by them, namely $\equiv_{\perp,\Gamma}$. ☐

Helper Proposition 43.10 (Independence implies commutation of compiled tensor operations)**.** *Assume there is a compilation map* Comp *from visible labels (or visible derivations) into tensor programs as in Definition* **??***, and assume the compilation has the property that:*

1. *disjoint redex positions imply disjoint tensor index sets touched by the compiled operation, and*
2. *disjoint rely footprints imply disjoint mutable tensor operands touched by the compiled operation.*

In other words, the compilation is required to preserve the two standard "non-interference" facets of independence: (i) independence at the level of where *a step acts in the visible syntax is reflected as separation of the* index-level *access pattern in the compiled program, and (ii) independence at the level of* what a step assumes about shared state *(its rely information) is reflected as separation of the* operand-level *write targets in the compiled program. This is the minimal structure needed to turn syntactic independence into operational commutativity. Then for any independent visible labels $\ell_1 \perp \ell_2$,*

$$\mathsf{Comp}(\ell_1) \circ \mathsf{Comp}(\ell_2) \;=\; \mathsf{Comp}(\ell_2) \circ \mathsf{Comp}(\ell_1).$$

Equivalently, the compiled tensor programs are permutation-invariant with respect to swapping adjacent independent visible steps, which is the tensor-program counterpart of the usual swap/diamond principle for independent reductions.

Proof. Under the stated hypotheses, $\ell_1 \perp \ell_2$ implies the compiled tensor computations share neither (a) contraction indices nor (b) mutable tensor operands. More explicitly, by (1) the sets of indices whose entries are read, contracted over, or otherwise addressed by $\mathsf{Comp}(\ell_1)$ and $\mathsf{Comp}(\ell_2)$ are disjoint; thus any index-scoped effects (such as reductions over contracted dimensions, scatter/gather patterns, or pointwise updates parameterized by indices) cannot overlap. By (2) the sets of mutable tensor operands (the concrete storage locations designated as being updated in-place) are disjoint; thus neither compiled operation can overwrite values that the other operation might subsequently read or write as part of its own in-place behavior.

Tensor computations with disjoint index sets and disjoint mutable operands commute under composition, yielding the stated equality. One way to view this is to model each compiled operation P as carrying a read-set $\mathsf{Rd}(P)$ and write-set $\mathsf{Wr}(P)$ of tensor-addressable locations (with index sets determining which locations are actually touched), so that disjointness of the relevant index sets plus disjointness of mutable operands entails $\mathsf{Wr}(\mathsf{Comp}(\ell_1)) \cap \mathsf{Wr}(\mathsf{Comp}(\ell_2)) = \varnothing$ and also rules out write–read interference in either direction. Under such a non-interference condition, both compositions compute the same resulting tensor store, since each operation acts as the identity outside its own footprint and their footprints do not overlap. This is exactly the situation in which sequential order is observationally irrelevant, so the two composites coincide as tensor programs. $\square$

Remark 2438 (Automated reasoning usage)**.** *The helper results above support three routine proof moves that are valuable for automated reasoning over the UG/TUG formalization:*

(1) Normalization by commuting independent steps: *use Proposition 43.3 to commute independent steps inside arbitrary contexts, and Proposition 43.4 to reason at the level of trace classes rather than raw derivation words. Concretely, this permits a proof automation tactic to reorder a derivation into a canonical form (e.g. grouping all steps acting on one syntactic region together) without changing its trace class, thereby reducing the number of distinct cases the prover must consider. It is also the mechanism by which local commutations justify global rearrangements of long derivations when the dependence relation is sparse.*

(2) Invariant extraction: *use Lemma 43.8 to compute dependency topology from any convenient representative of a trace class. In practice, this means one can pick a representative derivation word that is easy to analyze (e.g. already normalized, or produced by a deterministic strategy) and be confident that any derived dependence graph, partial order, or causal structure is an invariant of the entire trace class. This is particularly useful when a decision procedure needs only the dependence information, not the exact syntactic interleaving of independent steps.*

(3) Quotient-based abstraction and weakness accounting: *use Proposition 43.7 to treat the trace map as a Hyperseed abstraction (Hyperseed-Concept 51), and Corollary 43.6 to relate UG coarsenings to quantale weakness (Hyperseed-Concept 143). Operationally, this supports a common workflow in which one first reasons in a coarser, more quotiented semantics to simplify a proof obligation, and then transfers results back to a finer semantics while explicitly tracking the induced loss of discrimination as an increase in weakness. In automated settings, the same pattern enables sound over-approximations: the prover can work in the quotient where fewer distinct executions exist, while the weakness relation records precisely what has been forgotten.*

43.1 Culture (Defs. 343–344, Thm. 19): monotonicity and propagation

Helper Lemma 43.1 (Cultural aggregation is monotone; threshold cultures are nested)**.** *Let $C : P \to [0,1]$ or $C : P \to V$ be a cultural state formed by aggregating agent intensities and artifact-embedded intensities using $\oplus$ and scaling $\odot$. Then for each pattern $p \in P$:*

1. *Increasing any weight or any contributing intensity cannot decrease $C(p)$.*
2. *For a threshold culture $\mathrm{Cult}_\theta := \{p \in P : \pi(C(p)) \geq \theta\}$, if $\theta' \leq \theta$ then $\mathrm{Cult}_\theta \subseteq \mathrm{Cult}_{\theta'}$.*

Remark 2439. *A cultural state C assigns to each pattern $p \in P$ an aggregate intensity—roughly, "how present is p in the culture?" (Hyperseed-Concept 91, and compare* Pattern / Pattern Web *in Hyperseed-Concepts 130, 132). The construction is intentionally modular: many contributors (agents, artifacts) each supply some intensity for p, these are scaled by weights (importance, exposure, coupling), and then aggregated by a join $\oplus$. Because join and tensor are monotone, aggregation inherits monotonicity: adding stronger contributors cannot weaken the result.*

Part (2) defines a thresholded culture Cult_θ*, i.e. the set of patterns whose cultural score exceeds a threshold after applying a projection π (for p-bits, π might map (v^+, v^-) to a scalar). Nestedness is the expected behavior: lowering the admission threshold yields a superset. This is the same structural monotonicity as in the tribe threshold corollary, but now applied to patterns rather than edges.*

It is worth keeping the order-theoretic content explicit: the lemma does not rely on a particular analytic form of C, only on the fact that $\odot$ and $\oplus$ are monotone maps in the underlying order of $[0, 1]$ or of the valuation lattice V. In particular, if V is taken as a product order (as in the p-bit case) then "cannot decrease" is understood coordinatewise. Conceptually, the lemma says that cultural formation behaves like an isotone (order-preserving) data-fusion operator: more evidence or greater coupling pushes patterns upward in the cultural order, never downward.

Finally, the presence of π in (2) is a reminder that one often thresholds a derived *scalar score even when the internal representation is richer. For example, one may keep a two-coordinate record (v^+, v^-) for reasoning, but decide membership in* Cult_θ *by a scalar "net acceptance" or "salience" function π. The monotonicity conclusion only depends on the fact that the threshold predicate is monotone in the threshold parameter; no special properties of π beyond being well-defined on $C(p)$ are required for the set-inclusion direction stated.*

Remark 2440. *The lemma is a quiet workhorse: it guarantees that cultural formation, as modeled here, is an order-preserving aggregation process. This is a common theme in formal treatments of emergence: once one fixes a notion of "presence" as a supremum-like accumulation, then all the interesting dynamical questions can be asked without fear that merely adding evidence could reduce a cultural feature [5].*

One practical consequence is stability under enrichment of the contributor set: if one extends the model by adding additional agents, additional artifacts, or additional sensing channels (e.g. new modalities that supply further intensity estimates), then the resulting culture can only become at least as strong on every pattern, relative to the same weights and intensity assignments. This supports modular model-building: one can refine the representation of cultural sources without introducing pathological reversals in what the model regards as culturally present.

Sketch. (1) is by monotonicity of $\otimes$ and $\oplus$ in each argument. (2) is immediate from the definition: the predicate $\pi(C(p)) \geq \theta$ becomes easier as θ decreases.

More explicitly, a typical aggregated term contributing to $C(p)$ has the form $w \odot I(p)$ (for some contributor intensity I and weight w), and $C(p)$ is obtained by applying $\oplus$ over all such terms. Since $\odot$ is monotone in both w and $I(p)$ (in the relevant order) and $\oplus$ is monotone in each input, replacing any one term by a larger one forces the join to be larger as well. For (2), if $\theta' \leq \theta$ and $\pi(C(p)) \geq \theta$, then automatically $\pi(C(p)) \geq \theta'$, hence membership propagates from the stricter threshold set to the looser one. □

Remark 2441. Proof sketch. *Part (1) reduces to the observation that each contributor enters $C(p)$ through monotone operations, so increasing any input can only increase the output. Part (2) is basic order logic: the set of elements above a lower threshold contains the set above a higher* *threshold. One can picture $\pi(C(p))$ as a height function on patterns; lowering the waterline exposes more peaks.*

In contexts where V is not totally ordered, it can be helpful to remember that the "height function" picture is being applied after the projection π: $C(p)$ may live in a multi-dimensional or partially ordered space, while $\pi(C(p))$ yields a one-dimensional scalar that can be directly thresholded. Thus the nestedness statement is really about the scalar scores induced by π, and it is compatible with the idea that different projections could induce different, but still nested-by-threshold, cultural snapshots. □

Helper Corollary 43.2 (Paraconsistent culture witness (canonical p-bit case))**.** *Assume $V = [0,1]^2$ with $\oplus$ as componentwise* max*, scalar scaling $w \odot v = (w,w) \otimes v$ as coordinatewise multiplication, and let $\pi(v^+, v^-) = \frac{1+v^+-v^-}{2}$. If for some pattern p there exist contributors x, y (agents and/or artifacts) such that*

$$w_x\, I_x^+(p) \geq \theta \quad \text{and} \quad w_y\, I_y^-(p) \geq \theta,$$

then the aggregate satisfies $C^+(p) \geq \theta$ and $C^-(p) \geq \theta$. Thus p can be simultaneously "in-culture" and "contested" at comparable strength.

Remark 2442. *This corollary makes vivid why p-bit (two-coordinate) valuations are useful for culture: the same pattern p may receive strong positive endorsement and strong negative rejection from different parts of a society, and the aggregate culture can preserve both facts rather than forcing an artificial collapse into a single number. In the canonical case, $C^+(p)$ is simply the maximum (over contributors) of weighted positive intensities, and $C^-(p)$ is the maximum of weighted negative intensities. So if one contributor pushes p strongly positive and another pushes it strongly negative, the aggregate records both.*

This is a precise mathematical witness of paraconsistent cultural states, aligning with paraconsistent logics and evidence semantics [23, 24]. Philosophically, it also reflects a realistic view of culture: contested symbols and practices are often not "partly present" but strongly present in incompatible ways *(Hyperseed-Concept 198).*

The specific projection $\pi(v^+, v^-) = \frac{1+v^+-v^-}{2}$ can be read as a normalized "net valence" score: holding v^- fixed, increasing v^+ raises the score, while holding v^+ fixed, increasing v^- lowers it. Importantly, the corollary does not assert that $\pi(C(p))$ is large; rather, it asserts that both coordinates of $C(p)$ can be large simultaneously. This separation is exactly what allows one to model a pattern as both saliently present (high v^+) and saliently resisted (high v^-), without erasing either component during aggregation.

Remark 2443. *The result connects to later notions of collective belief and mindplexes: if disagreement can be preserved at the cultural layer, then a collective mind can have internal tension without logical explosion. This is one of the conceptual motivations for using $V = [0,1]^2$ rather than $[0,1]$ in social cognition models.*

A related modeling point is that the use of max *for $\oplus$ implements a "there exists a strong witness" semantics: a single highly influential contributor can set the cultural coordinate for p (positive or negative). Other join operators (e.g. probabilistic sums, t-conorms, or softmax-like joins) would instead implement "many weak witnesses" semantics. The corollary isolates a minimal and interpretable case where the paraconsistent effect is unavoidable: even with the simplest possible aggregation rule, independent positive and negative maxima can coexist.*

Sketch. In the canonical case, $C^+(p) = \max_x w_x I_x^+(p)$ and $C^-(p) = \max_x w_x I_x^-(p)$, so each coordinate lower bound is witnessed by the corresponding contributor.

Formally, from $w_x I_x^+(p) \geq \theta$ we have $\max_{x'} w_{x'} I_{x'}^+(p) \geq w_x I_x^+(p) \geq \theta$, and similarly for the negative coordinate using y. No interaction term couples the two coordinates under componentwise max, so the positive witness and negative witness can be different contributors without weakening either inequality. $\square$

Remark 2444. Proof sketch. *The proof is a witness argument: because the aggregate is a coordinatewise maximum, it must be at least as large as any particular contributor's scaled coordinate. The geometry is literally that of two heights (v^+, v^-); taking maxima preserves the highest positive pillar and the highest negative pillar, even if they come from different sources.*

This geometric picture also clarifies why the phenomenon is robust: as long as the aggregation operator is monotone and does not forcibly trade off v^+ against v^-, strong evidence in each coordinate can survive aggregation. The componentwise maximum is the clearest case, but the key intuition is that "positive presence" and "negative presence" are tracked as separate conserved signals rather than being collapsed into a single axis at the point of cultural formation. $\square$

Helper Lemma 43.3 (Social reinforcement operator is inflationary; Kleene chain is ascending)**.** *Let F be the social reinforcement operator on intensities $\mathbb{I} \in [0,1]^{\mathcal{A}\times P}$ given by*

$$(F(\mathbb{I}))_{i,p} := \mathbb{I}_{i,p} \ \vee \bigvee_{(j,i)\in E} \big(K(j,i) \wedge \mathbb{I}_{j,p}\big) \quad (\vee = \max,\ \wedge = \min).$$

Then $\mathbb{I} \leq F(\mathbb{I})$ pointwise, so the Kleene iterates $\mathbb{I}^{(0)} := \mathbb{I}(0)$, $\mathbb{I}^{(n+1)} := F(\mathbb{I}^{(n)})$ form an ascending chain.

Remark 2445. *The operator F captures a stylized reinforcement dynamic: an agent i retains its current intensity $\mathbb{I}_{i,p}$ for pattern p, but may increase it if influential neighbors j have intensity for p and the coupling $K(j,i)$ is strong enough. The use of $\wedge = \min$ models a bottleneck: what i can absorb from j is limited by both the strength of j's intensity and the coupling strength. The use of $\vee = \max$ models accumulation by taking the strongest available support.*

Inflationarity $\mathbb{I} \leq F(\mathbb{I})$ says reinforcement does not weaken intensities. Consequently, the Kleene iteration $\mathbb{I}^{(n+1)} = F(\mathbb{I}^{(n)})$ climbs monotonically toward a least fixed point (as referenced from Thm. 19). This is the standard order-theoretic posture that makes social propagation analyzable, and it fits neatly with the general emergence/pattern-web picture [5, 19].

Remark 2446. *The lemma is the key enabling fact for using fixed-point machinery: once iterates are guaranteed ascending, one can take their pointwise supremum and obtain the least stabilized state. This is the same skeleton as in inference closure (Section 42), but applied to social intensities rather than logical beliefs.*

Sketch. For each (i,p), $(F(\mathbb{I}))_{i,p}$ is a max that includes $\mathbb{I}_{i,p}$ as one of its terms, so it is at least $\mathbb{I}_{i,p}$. $\square$

Remark 2447. Proof sketch. *The proof is a direct "included term" argument: $\mathbb{I}_{i,p}$ appears explicitly among the candidates in the max defining $(F(\mathbb{I}))_{i,p}$. Therefore the max cannot be smaller. Visually, F overlays an extra set of candidate reinforcements on top of the existing value and then takes the maximum.* $\square$

Helper Proposition 43.4 (Path-expansion of iterated reinforcement (fuzzy reachability form))**.** *Under the same max/min definition of F, for each $n \geq 0$ and each (i,p),*

$$\mathbb{I}_{i,p}^{(n)} = \max_{j\in\mathcal{A}} \ \max_{\textit{paths } j\to i \textit{ of length } \leq n} \ \min\Big(\mathbb{I}_{j,p}^{(0)},\ \min_{e\in \textit{path}} K(e)\Big),$$

with the convention that the empty path $i \to i$ has edge-minimum 1.

Remark 2448. *This proposition is a "semantic unraveling" of the iteration: it tells us what* $\mathbb{I}_{i,p}^{(n)}$ means. *After* n *reinforcement steps,* i *can be influenced by any agent* j *that can reach* i *by a path of length at most* n*. The strength of influence along a particular path is the minimum of the initial intensity at the source,* $\mathbb{I}_{j,p}^{(0)}$*, and the weakest coupling along the path (the bottleneck* $\min_{e\in path} K(e)$*). Then we take the maximum across all paths and all sources, representing selection of the strongest available transmission channel.*

The empty-path convention says that i *always has access to its own initial intensity without attenuation. This is a standard fuzzy-graph reachability formula:* min *composes along edges,* max *aggregates alternative routes. It provides the essential intuition for why stabilization corresponds to a form of "best bottleneck path" from the strongest initial sources, a recurring motif in network propagation models [5].*

Remark 2449. *The result is important because it connects the algebraic definition of* F *to graph structure. It is, in effect, a closed form for the* n*th iterate: it explains exactly which paths matter and how their couplings interact. This connects back to the earlier "effective coupling along a path" proposition, but with max/min rather than product; the two are different regimes of composition, each natural in its setting.*

Sketch. Induct on n. The update step takes the current value and also the best one-step incoming propagation. Max/min propagation composes by taking min along edges (bottleneck strength) and max across alternative paths. □

Remark 2450. Proof sketch. *The proof strategy is induction: assume the path formula holds for length* $\leq n$*, then show applying* F *once more extends paths by one edge. The key step is that* min *implements concatenation of bottlenecks: the bottleneck of an extended path is the minimum of the previous bottleneck and the new edge coupling. The outer* max *simply records the best among all such extended paths. A helpful picture is water flowing through pipes: the flow is limited by the narrowest pipe (min), and among many routes you care about the route allowing maximal flow (max).* □

Helper Corollary 43.5 (Two useful special cases of the stabilized state)**.** *Let* $\mathbb{I}^{(\infty)}$ *be the least fixed point above* $\mathbb{I}^{(0)}$ *(Thm. 19).*

1. *(No incoming edges) If agent* i *has no incoming edges, then* $\mathbb{I}_{i,p}^{(n)} = \mathbb{I}_{i,p}^{(0)}$ *for all* n*, hence* $\mathbb{I}_{i,p}^{(\infty)} = \mathbb{I}_{i,p}^{(0)}$.
2. *(Unit couplings on a strongly connected graph) If* $K(j,i) = 1$ *for all edges and the graph is strongly connected, then for each pattern* p *and each agent* i*,*

$$\mathbb{I}_{i,p}^{(\infty)} = \max_{j\in\mathcal{A}} \mathbb{I}_{j,p}^{(0)},$$

i.e. everyone converges to the global maximum initial intensity for each pattern.

Remark 2451. *These two cases serve as "boundary conditions" for intuition about social reinforcement. In case (1), the agent is informationally isolated on the incoming side: nothing flows into it, so reinforcement cannot change it. In case (2), information flow is perfect (no attenuation, since* $\min(1,x) = x$*) and the network is richly connected (strongly connected), so the strongest initial advocate for each pattern eventually dominates everyone else's intensity for that pattern. The stabilized state is then simply the global maximum, replicated across all agents.*

Both extremes are conceptually clarifying for Culture *formation (Hyperseed-Concept 91): isolation yields cultural idiosyncrasy, while perfect connectivity yields homogenization to the strongest signals. Real systems live between these extremes, with attenuation and partial connectivity producing plural, locally clustered cultures.*

One can also read these extremes as "degenerate" instances of the usual tension between persistence *and* diffusion*: with no in-neighbors, persistence is absolute because the update at i has no external inputs; with unit couplings on a strongly connected graph, diffusion is maximally effective because every agent is ultimately downstream of every other agent. In particular, case (2) illustrates that when attenuation is removed, the only remaining obstruction to global homogenization is purely graph-theoretic (reachability), so the strongly connected hypothesis is exactly what eliminates the possibility of permanently separated cultural basins.*

Remark 2452. *The corollary connects directly back to the path-expansion proposition: (1) says there are no nontrivial paths into i, so only the empty path matters; (2) says all paths have bottleneck* 1*, so only the source intensity matters. These specializations are often used as sanity checks when implementing or reasoning about propagation algorithms.*

In the language of monotonic propagation operators, (1) is the case where the update at i is pointwise constant in all coordinates except those already present at i, while (2) is the case where the update is governed entirely by taking joins of already-existing values transported along paths. Thus both situations are useful not only for debugging but also for building intuition about why repeated application of F is nondecreasing and why fixed points can often be characterized by simple "no-improvement along any path" conditions.

Sketch. (1) With no incoming edges the big join over $(j, i) \in E$ is empty, so $F(\mathbb{I})_{i,p} = \mathbb{I}_{i,p}$. Concretely, the reinforcement term is a join over an empty index set, hence contributes the neutral element for joins (so nothing is added), and the update reduces to the identity on the (i, p)-entry.

(2) With all couplings 1, each edge transmits the source intensity without attenuation (min with 1 does nothing), and strong connectivity ensures every agent can be reached from every other agent by some finite path. In particular, for any fixed pattern p and any pair of agents $j \to i$, the path-expansion formula shows that after iterating F enough times to cover the length of a j–to–i path, the value at (i, p) is at least $\mathbb{I}_{j,p}$; taking the maximum over all possible sources j yields the global maximum. The value cannot exceed the global maximum because each update is formed by taking joins of previously existing intensities (and in this case transports them without amplification), so the global maximum is an upper bound throughout the dynamics. □

Remark 2453. Proof sketch. *For (1), the operator F has no reinforcement term to add, so it is the identity on i's coordinates. For (2), because every edge transmits perfectly, the only question is reachability; strong connectivity guarantees every source can reach every target, so each agent eventually attains at least the maximum source value, and cannot exceed it because updates are built from maxima of existing values.*

Equivalently, letting $\mathbb{I}^{(t)} = F^t(\mathbb{I})$, one can argue by induction on t (using the path-expansion proposition) that $\mathbb{I}^{(t)}_{i,p}$ equals the maximum of $\mathbb{I}_{j,p}$ over all j that can reach i by a path of length at most t; when the graph is strongly connected, there exists some finite t (depending on i and j) for which every j reaches i, so the expression stabilizes at the global maximum. This also makes clear why the fixed point in case (2) is not merely an equilibrium but the least fixed point above the initial condition under the monotone iteration of F. □

43.2 Collective belief and pattern webs (Defs. 345–347): lattice facts

Helper Lemma 43.6 (Collective belief is the pointwise supremum of individual beliefs)**.** *Let $\{\beta_i : L \to V\}_{i\in\mathcal{A}}$ be individual belief states and define*

$$\beta_{\mathrm{col}}(\varphi) := \Join_{i\in\mathcal{A}} \beta_i(\varphi) \quad \textit{(pointwise join).}$$

Then:

1. *For each i, $\beta_i \le \beta_{\mathrm{col}}$ pointwise.*
2. *If γ is any belief state with $\beta_i \le \gamma$ for all i, then $\beta_{\mathrm{col}} \le \gamma$.*

Thus β_{col} is the least belief state that preserves all individuals' evidence.

Remark 2454. *The definition of β_{col} is the simplest possible model of a "collective belief state": at each claim φ, we aggregate the community's evidence by taking the join (supremum) across agents. If V is the p-bit space $[0,1]^2$ with componentwise maxima, this means the collective retains the strongest observed positive evidence and the strongest observed negative evidence for each claim. This is a principled paraconsistent move: disagreement is not averaged away but preserved, making the collective belief state a record of the group's epistemic potential rather than a forced consensus [23, 24].*

The lemma states that this construction has the universal property of a supremum: it is above each individual, and it is the least such upper bound. In order-theoretic language, β_{col} is the pointwise least upper bound in the poset V^L. This is the right abstraction if one wants the collective to "contain" (in the order sense) the evidence of all members without privileging any particular aggregation beyond join.

It is also worth making explicit the mild lattice-theoretic precondition implicit in the notation $\Join_{i\in\mathcal{A}}$: for each fixed $\varphi \in L$, the join of the family $\{\beta_i(\varphi)\}_{i\in\mathcal{A}}$ must exist in V. In most intended applications, V is at least a (complete) join-semilattice, and often a complete lattice or a quantale, so arbitrary (possibly infinite) joins are defined. Under these standard assumptions, the function space V^L inherits joins pointwise, and the expression "pointwise join" is not merely suggestive but literally the join in the product/order-enriched structure.

Remark 2455. *What the lemma says in plain English is:* the collective belief state is exactly the minimal state that does not forget anyone's evidence. *This is important because later notions like pattern webs and mindplex structure often require a collective substrate; by choosing the supremum construction, one ensures that reasoning about the collective is monotone in the agent set and compatible with the rest of the quantale algebra [3]. It also aligns with the "mindplex" ethos of preserving distributed cognitive content [12].*

Concretely, if one treats each β_i as a constraint or information-bearing profile over L, then β_{col} is the least profile that simultaneously satisfies (dominates) all those constraints in the information order. This is precisely the kind of construction that later allows pattern webs (Defs. 345–347) to be formed without committing to a single "resolved" stance at points of disagreement: the web-building operations can be applied to β_{col} and will see, at each φ, the totality of available supports and counter-supports rather than a prematurely collapsed summary.

Sketch. (1) Each $\beta_i(\varphi)$ is one of the joined terms in $\beta_{\mathrm{col}}(\varphi)$. (2) A join is the least upper bound: if every term is below $\gamma(\varphi)$ then their join is too, for each φ. $\square$

Remark 2456. Proof sketch. *The proof is the defining property of joins, applied coordinatewise in φ. The key step is recognizing that V^L is ordered pointwise, so "least upper bound" decomposes into independent least upper bounds in V for each claim. One may visualize each claim φ as its own little lattice; the collective belief simply takes the supremum in each lattice separately.*

Equivalently (and this is often useful later when manipulating pattern-web constructions), one can regard β_{col} as the join $\bowtie_{i\in\mathcal{A}} \beta_i$ inside the poset V^L itself: for each φ, evaluation at φ is an order-preserving map $V^L \to V$, so it preserves the order inequalities needed to verify the universal property. This makes the lemma a direct instance of the general fact that products (and function spaces with pointwise order) compute joins componentwise whenever the codomain admits the relevant joins. □

Helper Corollary 43.7 (Adding agents cannot reduce collective belief)**.** *If $\mathcal{A} \subseteq \mathcal{A}'$ and β_{col} is computed by joining over the agent set, then $\beta_{\text{col}}^{\mathcal{A}} \leq \beta_{\text{col}}^{\mathcal{A}'}$ pointwise.*

Remark 2457. *This corollary is the monotonicity of the collective with respect to membership: adding more agents can only add more evidence, never remove it, when aggregation is by join. It expresses a basic intuition about* Society *(Hyperseed-Concept 170): an enlarged society has (weakly) greater epistemic capacity, at least in the sense of possessing more available evidence to draw upon, even if it also contains more conflict.*

This is also an algebraic analogue of arguments about group efficiency and prosocial coordination: in settings where contributions can be integrated without destructive interference, larger groups can in principle do more [6].

From the perspective of later pattern-web constructions, this monotonicity has a useful stability consequence: any derived structure that is monotone in its belief-state input (e.g. closure operators, reachability or entailment-like transforms defined via isotone maps on V^L) will also be monotone in the agent set. Thus, enlarging the agent set cannot delete already-available patterns; at most it can add new ones or strengthen existing ones in the lattice order.

Remark 2458. *The result is a direct corollary of the supremum characterization in the previous lemma, so it tightly connects the collective-belief definition to its order-theoretic consequences.*

In particular, one can read the inequality $\beta_{\text{col}}^{\mathcal{A}} \leq \beta_{\text{col}}^{\mathcal{A}'}$ as an instance of functoriality of the join operator with respect to inclusion of index sets: the map $\mathcal{A} \mapsto \bowtie_{i\in\mathcal{A}} \beta_i(\varphi)$ is an order-preserving set-function when the codomain is ordered by $\leq$ and joins exist. This observation is frequently used implicitly when reasoning about "adding voices" to an epistemic aggregate in a lattice-valued setting.

Sketch. A join over a larger index set is greater than or equal to the join over a subset. □

Remark 2459. Proof sketch. *The strategy is inclusion of index sets: the join over $\mathcal{A}$ is a join over fewer terms than the join over $\mathcal{A}'$, hence cannot exceed it. One can picture taking a maximum: the maximum of a set cannot decrease when you add more elements.*

Spelling out the pointwise step: fix $\varphi \in L$. Since $\mathcal{A} \subseteq \mathcal{A}'$, the family $\{\beta_i(\varphi)\}_{i\in\mathcal{A}}$ is a subfamily of $\{\beta_i(\varphi)\}_{i\in\mathcal{A}'}$. Therefore the join of the smaller family is $\leq$ the join of the larger family in V, and this holds for every φ, yielding the claimed pointwise inequality in V^L. □

Helper Corollary 43.8 (Paraconsistent disagreement witness (canonical p-bit case))**.** *In the canonical p-bit join, if there exist agents i, j such that $\beta_i^+(\varphi) \geq \theta$ and $\beta_j^-(\varphi) \geq \theta$, then $\beta_{\text{col}}(\varphi)$ has both coordinates at least θ.*

Remark 2460. *This is the collective-belief analogue of the paraconsistent culture witness above: it shows that if one agent strongly supports φ while another strongly opposes it, the collective belief* *state records both facts simultaneously. In other words, the collective can* know *that it disagrees. In paraconsistent epistemology, this is not a defect but a feature: it preserves the informational situation from which further inquiry can proceed without collapsing into triviality [23, 24].*

This connects naturally to Belief System *and* Intersubjective Reality *(Hyperseed-Concepts 64,* **??***): a society's shared epistemic object may include tensions that are themselves stable social facts.*

In the canonical p-bit setting (with $V = [0,1]^2$ and order/join taken componentwise), the statement is almost tautological but conceptually important: the join operation does not impose any normalization constraint like "the positive and negative weights must sum to at most 1". Hence it can represent "high positive" and "high negative" evidence simultaneously. This is precisely the algebraic room needed for later pattern-web and mindplex formalisms to distinguish (i) absence of information from (ii) presence of balanced but conflicting information, since both would be collapsed by scalar averaging but remain distinct in the product lattice.

Remark 2461. *The corollary is important because it demonstrates, in the simplest possible way, how the chosen lattice operations make disagreement first-class. It thereby provides an algebraic foundation for later collective-mind constructions that must tolerate internal inconsistency (e.g. mindplexes spanning diverse subcultures) [12].*

Sketch. Coordinatewise maximum preserves each witnessed coordinate lower bound. □

Remark 2462. Proof sketch. *The proof is again a witness argument: since $\beta^+_{\mathrm{col}}(\varphi)$ is the maximum of all agents' positive coordinates, it is at least $\beta^+_i(\varphi)$; similarly for the negative coordinate. The geometry is two independent axes; maxima act independently on each axis.* □

43.3 Coherence and mindplex structure (Defs. 348–351): useful rewrites

Helper Lemma 43.9 (Coherence bounds and an equivalent per-component form)**.** *Assume* $\mathrm{Err}_O(x;S) \in [0,1]$ *after normalization and define*

$$\mathrm{Coh}_O(S) := 1 - \max_{x\in S} \mathrm{Err}_O(x;S).$$

Then $0 \le \mathrm{Coh}_O(S) \le 1$*. Moreover, for any* $\varepsilon \in [0,1]$*,*

$$\mathrm{Coh}_O(S) \ge 1-\varepsilon \quad \Longleftrightarrow \quad \forall x \in S:\ \mathrm{Err}_O(x;S) \le \varepsilon.$$

Remark 2463. *Coherence here is defined via a* worst-case error*: $\mathrm{Err}_O(x;S)$ measures (for observer O) how well the behavior of x can be approximated from the rest of the set $S \backslash x$; then $\mathrm{Coh}_O(S)$ is one minus the maximum of these errors. Thus high coherence means no member of S is "too surprising" relative to the others, under the observer's admissible approximations. This is one formal route toward capturing the idea that a mindplex is not merely a heap of agents, but a set whose components are mutually predictable and hence capable of higher-order integration (Hyperseed-Concept 113; see also [12]).*

The equivalence with the per-component bound is especially useful: a single inequality about $\mathrm{Coh}_O(S)$ is exactly the same as uniform control of each $\mathrm{Err}_O(x;S)$. In practice, this allows proofs about coherence to proceed by checking all components individually, rather than manipulating maxima abstractly.

Remark 2464. *The lemma says, in plain terms:* coherence is always between 0 and 1, and being at least $1-\varepsilon$ means every component has error at most ε*. This is important because later threshold-style definitions of mindplex structure often quantify coherence by demanding it exceed some bound; the lemma converts that global demand into local constraints that are easier to verify and reason about.*

Sketch. Bounds: $\max_x \mathrm{Err}_O(x;S) \in [0,1]$ so $1 - \max_x \mathrm{Err} \in [0,1]$. Equivalence: $\mathrm{Coh}_O(S) \geq 1 - \varepsilon$ iff $\max_x \mathrm{Err}_O(x;S) \leq \varepsilon$, which holds iff every $\mathrm{Err}_O(x;S) \leq \varepsilon$. □

Remark 2465. Proof sketch. *The proof uses elementary properties of maxima: bounding the maximum is equivalent to bounding each element. The "geometry" is that* $\mathrm{Coh}_O(S)$ *is determined by the single worst offender in* S*; raising coherence above a threshold means eliminating any offender worse than* ε*.* □

Helper Lemma 43.10 (Coherence monotone in approximator power and distance)**.** *Let* $\mathcal{F}$ *be the admissible approximator class used in* $\mathrm{Err}_O(x;S) := \inf_{f\in\mathcal{F}} d_O(\mathrm{Beh}_O(x), f(\mathrm{Beh}_O(S \setminus x)))$*. If* $\mathcal{F} \subseteq \mathcal{F}'$*, then* $\mathrm{Err}_{O,\mathcal{F}'}(x;S) \leq \mathrm{Err}_{O,\mathcal{F}}(x;S)$ *for all* x, S*, hence* $\mathrm{Coh}_{O,\mathcal{F}'}(S) \geq \mathrm{Coh}_{O,\mathcal{F}}(S)$*. Also, if* $\mathrm{d}'_O \leq \mathrm{d}_O$ *pointwise, then coherence computed with* d'_O *is at least that computed with* d_O*.*

Remark 2466. *This lemma expresses a methodological principle: coherence depends on the observer's modeling power and metric choice. If the observer allows a richer approximator class* $\mathcal{F}'$ *(more expressive models), then each error* Err *can only go down, because the infimum is taken over a larger set. Likewise, if the observer uses a more permissive distance* d'_O *that judges discrepancies smaller (*$\mathrm{d}'_O \leq \mathrm{d}_O$ *pointwise), then errors shrink. In both cases coherence increases.*

This matters philosophically: coherence is not purely "in the system" but is defined relative to an observer O *and its representational/measurement scheme (Hyperseed-Concept 112). Mathematically, it supplies monotonicity levers: if you want a lower bound on coherence, you may safely enlarge* $\mathcal{F}$ *or relax the metric without breaking the inequality.*

Remark 2467. *The lemma is also important for connecting mindplex structure to computational resources: a more powerful modeling class can recognize stronger interdependence among components, raising measured coherence. This resonates with views in which richer-resource minds can exploit more sophisticated internal simulation and modeling strategies [11].*

Sketch. Enlarging the infimum domain can only decrease an infimum, hence errors decrease and coherence increases. If $d'_O \leq d_O$, every candidate distance shrinks, so the infimum shrinks as well. □

Remark 2468. Proof sketch. *The core move is order-theoretic:* inf *is monotone with respect to set inclusion of its domain, and also monotone with respect to pointwise reduction of the objective function. One can picture* $\inf_{f\in\mathcal{F}}$ *as "best achievable error"; giving oneself more candidates or a more forgiving error measure cannot worsen the best achievable error.* □

Helper Proposition 43.11 (Type implications among collective mind notions)**.** *From the definitions:*

$$\textit{Global brain} \Rightarrow \textit{Mindplex} \Rightarrow \textit{Society of mind} \Rightarrow \textit{Collective mind system} \Rightarrow \textit{Society.}$$

Remark 2469. *This proposition states a chain of definitional containment among increasingly weak notions. At the top is a* global brain *(Hyperseed-Concept* **??***), intended as a planet-scale cognitive integration; this is, by definition, a special kind of* mindplex *(Hyperseed-Concept 113), which is itself a constrained kind of* society of mind*, and so on down to the bare notion of* society *(Hyperseed-Concept 170). The arrows are not deep theorems; they are reminders that the terminology is layered: each higher term simply includes all the structure of the lower term plus additional axioms. In particular, each node in the chain can be read as a* structure *(in the sense of "a carrier with operations/relations satisfying axioms"), and each arrow corresponds to a canonical "forgetful" passage that drops some extra fields/axioms while retaining the underlying society. Thus the* *content is not that some emergent phenomenon always exists, but that whenever you have chosen to work with the stronger notion, you automatically have an instance of every weaker notion by forgetting additional structure.*

This is useful in proofs because it licenses "weakening": if you have established a property for all societies, you automatically get it for all collective mind systems, societies of mind, mindplexes, and global brains. Conversely, if you assume you have a global brain, you may freely use every lemma that only requires society-hood. Operationally, this is the common pattern "prove at the bottom, reuse at the top": one proves invariants about interaction graphs, information-flow constraints, or agent counts at the level of societies, and then reuses them unchanged when later specializing to mindplexes or global brains. The direction does matter: results proved only *for mindplexes will not automatically apply to arbitrary societies unless their hypotheses are explicitly weakened.*

Remark 2470. *The importance is practical and conceptual. Practical, because it organizes lemmas by the weakest hypotheses needed. Conceptual, because it mirrors an ontological ladder: from mere aggregation of agents to increasingly integrated wholes, as explored in discussions of mindplexes and collective locations [12] and in broader AGI-oriented analyses of multi-agent cognition [19]. One can also view the ladder as clarifying which aspects of "mind" are being idealized at each stage: at the society level one keeps only plurality and interaction; at a society-of-mind level one adds an explicit decomposition into subagents with roles; at a mindplex level one adds coherence constraints (e.g. compatibility of decompositions, stability of interfaces, or admissible refinements); and at a global-brain level one adds scale and boundary conditions that tie the system to an entire planetary society. In that sense, the chain functions as a conceptual bookkeeping device: when a later argument invokes "coherence," the reader can immediately locate it at the mindplex/global-brain end rather than mistaking it for a generic property of arbitrary societies.*

Sketch. Each arrow is a direct definitional implication: a global brain is defined to be a mindplex on a planet-scale society; a mindplex is defined to be a society of mind with additional coherence/decomposition properties; and a society of mind is defined to be a collective mind system whose components are autonomous agents; etc. Formally, if the concepts are presented as predicates on structured tuples (or as types with fields), then each implication is discharged by taking an instance of the stronger predicate/type and projecting to the fields demanded by the weaker one, observing that the weaker axioms are literally included among the stronger axioms (cf. Defs. 348–351). No additional construction is required beyond this projection/forgetting step. ☐

Remark 2471. Proof sketch. *The proof is a sequence of "unpack the definition" steps. The key idea is that the vocabulary has been designed hierarchically: every time you move left in the chain you are adding constraints, never removing them. A helpful picture is nested sets: global brains are a subset of mindplexes, which are a subset of societies of mind, and so on. Equivalently, one can picture a chain of inclusions of classes of models, or a chain of coercions in a proof assistant: whenever a term inhabits the stronger class, it can be coerced to inhabit the weaker class by forgetting structure. This is precisely why the arrows should be read as "is in particular a" rather than as an existential claim that every society can be completed into a mindplex/global brain; the containment is one-way and definitional. In applications, this viewpoint prevents category mistakes: any lemma whose statement mentions only society-level primitives is automatically stable under these forgetful maps, whereas lemmas mentioning coherence or decomposition data are not.* ☐

43.4 Role templates and fit scores (Defs. 339–342): threshold monotonicities

Helper Lemma 43.12 (Fit-threshold monotonicity)**.** *Let* $\mathrm{Fit}(R, \rho; \mathrm{Ep}) \in [0, 1]$ *be a role-fit score and say the role is present if* $\mathrm{Fit} \geq \theta$*. If* $\theta' \leq \theta$ *and the role is present at threshold* θ*, then it is* *present at threshold θ'.*

Remark 2472. *This is the same threshold monotonicity pattern seen earlier for tribes and cultures, now applied to social roles (Hyperseed-Concept 171). A role-fit score* $\mathrm{Fit}(R, \rho; \mathrm{Ep}) \in [0, 1]$ *measures how well an agent or sub-system matches a role template R with parameters ρ in an episode* Ep*. Declaring the role "present" when* $\mathrm{Fit} \geq \theta$ *turns a graded measure into a crisp predicate; lowering θ can only make it easier to satisfy.*

As a concrete example: if a "mediator" role requires fit at least 0.8*, and an agent scores* 0.85*, then it is a mediator at threshold* 0.8*; it is automatically also a mediator at threshold* 0.7*. This lemma is useful whenever one wants to reason about role detection across multiple sensitivity settings without re-running the detection logic.*

Remark 2473. *One convenient way to package the lemma is to explicitly name the induced predicate. For a fixed* (R, ρ, Ep)*, define*

$$\mathrm{Present}_\theta(R, \rho; \mathrm{Ep}) \ :\Longleftrightarrow\ \big(\mathrm{Fit}(R, \rho; \mathrm{Ep}) \geq \theta\big).$$

Then the lemma states that $\theta' \leq \theta$ *implies* $\mathrm{Present}_\theta(R, \rho; \mathrm{Ep}) \Rightarrow \mathrm{Present}_{\theta'}(R, \rho; \mathrm{Ep})$*; i.e., the map* $\theta \mapsto \mathrm{Present}_\theta$ *is antitone in the threshold parameter (smaller threshold yields a larger truth set). Equivalently, for any fixed θ, the set of triples* (R, ρ, Ep) *(or agents, if* Fit *is agent-indexed) satisfying the predicate is* upward closed *in the fit score and* downward closed *in the threshold.*

Remark 2474. *The lemma is not surprising, but it is structurally important: it means the collection of agents satisfying a role predicate is nested as thresholds vary. This supports monotone searches over thresholds and makes role-based decompositions stable under weakening criteria.*

Remark 2475. *A related contrapositive form is often what gets used in practice: if the role is* absent *at a lower threshold θ' (i.e.,* $\mathrm{Fit} < \theta'$*), then it is absent at every higher threshold $\theta \geq \theta'$. In algorithmic terms, once an agent fails to meet an easy criterion, it cannot meet a stricter one; this is what permits early stopping in threshold sweeps, and it underlies the typical "tune θ upward until false positives disappear" workflow.*

Sketch. If $\mathrm{Fit} \geq \theta$ and $\theta' \leq \theta$, then $\mathrm{Fit} \geq \theta'$. ☐

Remark 2476. Proof sketch. *The argument is pure order: a real number above a larger threshold is also above any smaller threshold. The "geometry" is a number line with two cut points; crossing the higher cut implies crossing the lower.* ☐

Remark 2477. *Although the statement is formulated for* $\mathrm{Fit}(R, \rho; \mathrm{Ep}) \in [0, 1]$*, only the ambient order is used; the same monotonicity holds for any totally ordered codomain (or, more generally, any poset) in which the predicate "$\geq \theta$" makes sense. The* $[0, 1]$ *normalization is thus best read as a modeling convenience (comparability across roles and episodes) rather than a proof-critical assumption.*

Helper Lemma 43.13 (Colleague relation is symmetric under the operational definition)**.** *If "colleagues" are defined as co-participants in the same collaborative project episode (Def. 342), then for any episode,* $\mathrm{Colleague}(i, j) \Rightarrow \mathrm{Colleague}(j, i)$*.*

Remark 2478. *This lemma records a basic symmetry built into the operational notion of colleague (Hyperseed-Concept 74). If the definition is simply "i and j participated in the same collaborative project episode," then the relation is symmetric because the underlying fact is symmetric: the set of participants does not distinguish ordered pairs. This is a small logical convenience: it lets one treat* *colleague graphs as undirected (at least at the level of adjacency), even if other interaction graphs remain directed.*

In broader social-cognitive modeling, such symmetry facts matter because they allow simplifications: for instance, when reasoning about mutual trust or shared context between colleagues, one may freely swap the order of agents without changing truth values.

Remark 2479. *Unpacking the operational definition slightly, one typically has something like*

$$\text{Colleague}(i,j) \;:\Longleftrightarrow\; \exists\,\text{Ep}\;\big(\text{CollaborativeProject}(\text{Ep})\wedge i\in\text{Participants}(\text{Ep})\wedge j\in\text{Participants}(\text{Ep})\big).$$

Under this reading, symmetry is immediate because the conjunction is invariant under exchanging i and j. This also clarifies what is not *being claimed: symmetry does not by itself imply transitivity (two people can each work with a common third person on different projects without ever working together), and it does not force reflexivity unless one separately stipulates that every agent is trivially a co-participant with itself in an episode.*

Remark 2480. *The result is important mainly as a rewrite rule: it prevents accidental orientation from creeping into arguments that should be purely about co-membership. It also complements the earlier directed-edge results by distinguishing which relations are inherently directional (influence, communication) and which are inherently mutual (co-participation).*

Remark 2481. *One additional payoff is representational: in any adjacency-matrix encoding of* Colleague *for a fixed time window, the lemma justifies symmetry of the matrix (or, equivalently, use of a simple undirected graph). When colleague edges are later combined with directed edges (e.g., "mentors" or "reports-to" relations), this symmetry fact helps keep the mixed graph semantics clean by ensuring that undirected components arise only from definitions that genuinely ignore order.*

Sketch. Co-participation in the same project is symmetric in the participants. □

Remark 2482. Proof sketch. *The proof strategy is to unpack "co-participation": it asserts existence of an episode containing both i and j. But set membership is symmetric: if both are in the same set, the same fact certifies both directions.* □

44 Helper theorems for tools, machines, computation, and embodiment

Remark 2483. *This section collects "small" algebraic facts that become powerful once one begins to compose them: joins and tensors in the p-bit quantale, relational composition of affordances, and categorical composition of semantics/realizations. Conceptually, it is a bridge between (i) the formal notion of a* tool *and its affordance profile (Hyperseed-Concept 191) and (ii) the formal notion of* machines *and* computers/programs *(Hyperseed-Concepts 106 and 80), and (iii) the embodied constraint that mind–world influence is mediated by a* body *(Hyperseed-Concept 135 and 112). The intent is not to introduce new theory, but to make explicit the algebra that an automated reasoner (or a patient human) will repeatedly invoke.*

Remark 2484. *A brief reminder of the ambient algebra may help orient the eye. The symbol V denotes the truth-value domain for graded evidence; in the surrounding text this is typically the p-bit quantale $V=[0,1]^2$ (positive/negative evidence pairs) ordered componentwise. The join $\oplus$ is the quantale join (often componentwise max), while the tensor $\otimes$ (written here as $\otimes$) is the "and/compose"-like operation that distributes over joins. Thus, expressions like $\bigoplus_{a\in A}\mathsf{Aff}(a,e)$*

mean "aggregate across alternatives" (existential aggregation over actions), and expressions like $\mathsf{Aff}_1(a,m) \otimes \mathsf{Aff}_2(m,e)$ *mean "compose the support for a producing m with the support for m producing e." This style of reasoning is standard in quantale-valued semantics and is used elsewhere in the theory to speak about Quantale Weakness (Hyperseed-Concept 143; see also [3]).*

Definition 445 (Achievability induced by an affordance profile)**.** *Let* $\mathsf{Aff} : A \times E \to V$ *be an affordance profile. Define the (existential) achievability of an effect token* $e \in E$ *by*

$$\mathsf{Ach}_{\mathsf{Aff}}(e) \ := \ \bigoplus_{a \in A} \mathsf{Aff}(a,e).$$

Intuition: $\mathsf{Ach}_{\mathsf{Aff}}(e)$ *aggregates evidence that* some *action can produce* e*.*

Remark 2485. *The definition extracts from the* action-to-effect *table* Aff *a simpler object: a single value per effect e, summarizing "how achievable e is, in principle, by some choice of action." Philosophically, it is the shift from a conditional statement (if we do a we may get e) to an existential one (there exists an a such that e is attainable). This is precisely the kind of compression that turns a detailed model of agency into a crude but useful proxy for "capability." When tools are treated as capability amplifiers (Hyperseed-Concept 191), such a proxy often suffices to establish monotone-improvement claims.*

A simple example is the Boolean special case: if $V = \{0,1\}$ *with* $\oplus = \vee$*, then* $\mathsf{Ach}_{\mathsf{Aff}}(e) = 1$ *iff at least one action achieves e. In the p-bit case* $[0,1]^2$*, if* $\mathsf{Aff}(a,e) = (p^+_{a,e}, p^-_{a,e})$*, then* $\mathsf{Ach}_{\mathsf{Aff}}(e)$ *takes the componentwise maximum across actions, capturing the idea that the best-supported action dominates the existential claim. In engineering terms (cf. [19]),* $\mathsf{Ach}_{\mathsf{Aff}}$ *is a coarse "capability envelope" derived from the more detailed affordance model.*

Lemma 150 (Monotonicity of achievability)**.** *If* $\mathsf{Aff}_1, \mathsf{Aff}_2 : A \times E \to V$ *satisfy* $\mathsf{Aff}_1(a,e) \le \mathsf{Aff}_2(a,e)$ *for all* (a,e)*, then* $\mathsf{Ach}_{\mathsf{Aff}_1}(e) \le \mathsf{Ach}_{\mathsf{Aff}_2}(e)$ *for all* $e \in E$*.*

Remark 2486. *In plain terms: if every individual action looks at least as effective under* Aff_2 *as it does under* Aff_1*, then the best available action (as judged by the join* $\oplus$*) cannot become worse. This lemma is important because many later comparisons ("tool T helps"; "model* M' *is more capable") reduce to pointwise inequalities, and we then want those inequalities to survive the existential aggregation that defines achievability.*

Proof sketch. For fixed e, $\mathsf{Ach}_{\mathsf{Aff}}(e)$ is a join over actions. Joins are monotone in each argument, so pointwise domination of Aff_2 over Aff_1 implies domination of the joins. □

Remark 2487. Proof sketch. *The strategy is purely order-theoretic: we use that* $\bigoplus$ *is computed by repeatedly applying* $\oplus$*, and* $\oplus$ *respects the order in each coordinate. No special structure of actions or effects is needed.* □

The key step is recognizing that $\mathsf{Ach}_{\mathsf{Aff}}(e)$ *is a monotone functional of the entire family* $\{\mathsf{Aff}(a,e)\}_{a \in A}$*: increasing any term cannot decrease the join. Visually, one may imagine each* $\mathsf{Aff}(a,e)$ *as a point in the ordered set* V*; the join is then the "upper envelope" of these points, and pushing all points upward can only push the envelope upward as well.*

Definition 446 (Quantale-relational composition of affordances)**.** *Let* $\mathsf{Aff}_1 : A \times M \to V$ *and* $\mathsf{Aff}_2 : M \times E \to V$ *be two affordance profiles where* M *is an intermediate token set (e.g. sub-effects, internal states, or interface signals). Define the composed affordance profile* $\mathsf{Aff}_2 \circledast \mathsf{Aff}_1 : A \times E \to V$ *by*

$$(\mathsf{Aff}_2 \circledast \mathsf{Aff}_1)(a,e) \ := \ \bigoplus_{m \in M} \mathsf{Aff}_1(a,m) \otimes \mathsf{Aff}_2(m,e).$$

Remark 2488. *This is the quantale-valued analogue of ordinary relational composition: in classical relations, (a, e) is related if there exists an intermediate m such that aRm and mSe. Here, existence is replaced by the join $\bigoplus$, and conjunction/sequence is replaced by the tensor $\otimes$. One may also read it as a kind of "matrix multiplication" over a semiring/quantale: $A \times M$ values are multiplied (via $\otimes$) and summed (via $\oplus$) over m.*

A concrete example: let A be a set of button-presses, M a set of device internal states, and E a set of externally visible outcomes. $\mathsf{Aff}_1(a, m)$ measures how strongly action a puts the device into state m, while $\mathsf{Aff}_2(m, e)$ measures how strongly state m yields outcome e. The composed profile measures how strongly a yields e through *some internal state. This is useful because tool-use often has hidden intermediate structure (interfaces, protocols, bodily channels), yet the agent wants an effective external affordance profile to reason with (Hyperseed-Concept 191; cf. [1] for the broader ontological framing).*

Lemma 151 (Lower bounds for composed affordances)**.** *For all $a \in A$, $e \in E$, and $m \in M$,*

$$(\mathsf{Aff}_2 \circledast \mathsf{Aff}_1)(a, e) \;\geq\; \mathsf{Aff}_1(a, m) \otimes \mathsf{Aff}_2(m, e).$$

Remark 2489. *The lemma says: the composite affordance is at least as strong as any particular "path" through a chosen intermediate token m. In other words, the join over m does not lose information; it retains every specific witness-path as a lower bound. This is the basic inequality that lets one prove things about the composite by exhibiting a single good intermediate realization.*

Proof sketch. The join over m includes the particular term indexed by m, and joins are upper bounds on their joined elements. ☐

Remark 2490. Proof sketch. *The proof is the tautology of joins: $\bigoplus_{m \in M} x_m$ is, by definition, an upper bound of each x_m.* ☐

The key mechanism is that quantale joins behave like suprema. If one pictures each intermediate m as a possible conduit from a to e, then the composite takes the best-supported conduit; any specific conduit therefore provides a guaranteed floor.

Lemma 152 (Monotonicity of affordance composition)**.** *If $\mathsf{Aff}_1 \leq \mathsf{Aff}_1'$ pointwise, then $\mathsf{Aff}_2 \circledast \mathsf{Aff}_1 \leq \mathsf{Aff}_2 \circledast \mathsf{Aff}_1'$. If $\mathsf{Aff}_2 \leq \mathsf{Aff}_2'$ pointwise, then $\mathsf{Aff}_2 \circledast \mathsf{Aff}_1 \leq \mathsf{Aff}_2' \circledast \mathsf{Aff}_1$.*

Remark 2491. *This records the expected monotonicity of "piping" affordances through an interface: strengthening either stage cannot weaken the end-to-end profile. It matters because it allows modular engineering arguments: improve a component (better sensor, better actuator, better protocol) and infer improvement of the overall composed affordance without reanalyzing from scratch.*

Proof sketch. Use monotonicity of $\otimes$ in each argument, and monotonicity of $\oplus$ over m. ☐

Remark 2492. Proof sketch. *Pointwise increase of Aff_1 or Aff_2 increases each term $\mathsf{Aff}_1(a, m) \otimes \mathsf{Aff}_2(m, e)$, and then the join over m preserves that increase.* ☐

What does the work is the two-layered monotonicity: first at the level of each path (tensor), then at the level of aggregating paths (join). Visually: if every edge label in a two-hop graph is raised, then every two-hop path weight is raised, hence the supremum over paths is raised.

Proposition 70 (Associativity of affordance composition (when defined))**.** *Given $\mathsf{Aff}_1 : A \times M \to V$, $\mathsf{Aff}_2 : M \times N \to V$, $\mathsf{Aff}_3 : N \times E \to V$, one has*

$$\mathsf{Aff}_3 \circledast (\mathsf{Aff}_2 \circledast \mathsf{Aff}_1) \;=\; (\mathsf{Aff}_3 \circledast \mathsf{Aff}_2) \circledast \mathsf{Aff}_1,$$

assuming the quantale laws (associativity of $\otimes$ and distributivity of $\otimes$ over joins).

Remark 2493. *Associativity says that multi-stage affordance pipelines have an unambiguous end-to-end meaning: whether one first composes stages 1 and 2, or stages 2 and 3, the resulting $A \times E$ profile is the same. This is the affordance-level analogue of the familiar fact that function composition is associative; it is also the algebraic reason one can speak of a complex toolchain as a single tool interface.*

This result connects forward to the later "pipeline rule" for program realizations: in both cases, the content is that composition is well-behaved*, so that certification and reasoning can be performed modularly and then composed.*

Proof sketch. Expand both sides:

$$(\mathsf{Aff}_3 \circledast (\mathsf{Aff}_2 \circledast \mathsf{Aff}_1))(a,e) = \bigoplus_{n \in N} \Big(\bigoplus_{m \in M} \mathsf{Aff}_1(a,m) \otimes \mathsf{Aff}_2(m,n) \Big) \otimes \mathsf{Aff}_3(n,e).$$

Distribute $\otimes$ over $\oplus$ and reassociate $\otimes$ to obtain a double join

$$\bigoplus_{m \in M} \bigoplus_{n \in N} \mathsf{Aff}_1(a,m) \otimes \mathsf{Aff}_2(m,n) \otimes \mathsf{Aff}_3(n,e),$$

which is symmetric in the bracketing and equals the expansion of $((\mathsf{Aff}_3 \circledast \mathsf{Aff}_2) \circledast \mathsf{Aff}_1)(a,e)$. □

Remark 2494. Proof sketch. *The proof normalizes both bracketings into the same "sum over all length-3 paths" expression by (i) expanding definitions, (ii) distributing $\otimes$ over joins to flatten nested joins, and (iii) using associativity of $\otimes$ to remove parenthesization differences.* □

The crucial step is distributivity: it licenses moving from "join over n of (join over m of something) tensored with something" to a joint join over (m,n). A geometric intuition is to picture a three-layer directed graph $A \to M \to N \to E$; either bracketing corresponds to choosing how to group the internal layers, but the end-to-end weight is determined by the same set of paths.

Remark 2495. *One can view the normalization step as a quantale-valued analogue of a Fubini/Tonelli exchange of "sums": nested joins are flattened into a single join over the product index set, and the associativity of $\otimes$ ensures that the weight assigned to a composite path $a \to m \to n \to e$ is independent of where one places parentheses. In particular, if the two bracketings correspond to two different composite affordance constructions, distributivity asserts that both compute the same global path-aggregate because the internal layer choices (m,n) are ultimately being ranged over in both cases.*

*In the graph picture, each edge carries a V-weight (evidence/feasibility/cost, depending on the chosen quantale semantics). Distributivity guarantees that aggregating over intermediate nodes commutes with composing along edges: whether one first aggregates over $m \in M$ and then over $n \in N$, or aggregates over pairs (m,n) directly, the resulting end-to-end evaluation is the join over the same set of length-*3 *paths.*

Proposition 71 (A sufficient condition for purpose-supporting tools via monotone objectives)**.** *Let an objective functional be a map*

$$U : V^E \to \mathbb{R}$$

that is monotone w.r.t. the pointwise order on V^E. Assume that, without tool T, the agent has affordance profile $\mathsf{Aff}_0 : A \times E \to V$, and with tool T it has $\mathsf{Aff}_T : A \times E \to V$. If $\mathsf{Ach}_{\mathsf{Aff}_0}(e) \leq \mathsf{Ach}_{\mathsf{Aff}_T}(e)$ for all $e \in E$ and the inequality is strict for at least one e that has nonzero marginal utility under U, then

$$U(\mathsf{Ach}_{\mathsf{Aff}_T}) \; > \; U(\mathsf{Ach}_{\mathsf{Aff}_0}).$$

Thus T is purpose-supporting under this monotone-achievability proxy.

Remark 2496. *Read informally: if the tool weakly increases what you can achieve (effect-by-effect), and it strictly increases at least one effect that the objective actually cares about, then the objective score strictly improves. There is nothing mysterious here; it is the familiar monotone-utility argument, transplanted into the quantale-valued achievability setting.*

This proposition is useful because "purpose-supporting" in the sense of tools (Hyperseed-Concept 191) is often difficult to certify directly, whereas monotone proxies are tractable. In cognitive-engineering practice (cf. [19]), one often chooses objectives that are monotone with respect to some capability representation precisely so that such conclusions can be drawn compositionally.

Remark 2497. *The phrase "nonzero marginal utility" can be read in an order-theoretic way that avoids any differential structure: there exists a coordinate $e \in E$ and two profiles $x, y \in V^E$ with $x \leq y$, $x(e) < y(e)$, and $x(e') = y(e')$ for all $e' \neq e$, such that $U(x) < U(y)$. This expresses that U is not merely monotone but* strictly sensitive *to that coordinate in some region of interest. Under this reading, the strictness condition in the proposition precisely rules out the case where U collapses all improvements in* Ach *to the same real score.*

In applications, a common sufficient condition is that U decomposes as an increasing aggregator over coordinates (e.g. a weighted sum, a max, or any monotone norm-like functional on V^E once V is embedded into $\mathbb{R}$), with at least one coordinate receiving genuinely positive weight. The proposition then says that any tool that improves achievability in a positively-weighted dimension is certified as purpose-supporting under the proxy.

Proof sketch. Pointwise domination of $\mathsf{Ach}_{\mathsf{Aff}_T}$ over $\mathsf{Ach}_{\mathsf{Aff}_0}$ and monotonicity of U gives $U(\mathsf{Ach}_{\mathsf{Aff}_T}) \geq U(\mathsf{Ach}_{\mathsf{Aff}_0})$. The strictness assumption yields strict improvement. □

Remark 2498. Proof sketch. *The proof splits into (i) a weak inequality from monotonicity and (ii) a strictness upgrade from a single effect whose improvement is not utility-neutral.* □

The key point is that monotonicity alone only yields $\geq$; to obtain $>$ one must rule out the degenerate case where U ignores all improved coordinates. In more visual terms: U is a monotone "preference gradient" on the partially ordered space V^E; moving upward in at least one direction of nonzero sensitivity forces the value to increase.

Remark 2499. *It is worth emphasizing where the quantale structure enters and where it does not. The proposition itself only needs the pointwise order on V^E together with the definition of* $\mathsf{Ach}_{\mathsf{Aff}}$ *(as a derived profile in V^E) and does not require any additional algebraic properties of V. The quantale assumptions become relevant earlier, in ensuring that* $\mathsf{Ach}_{\mathsf{Aff}}$ *is well-defined and behaves compositionally under changes of affordances (e.g. when tools are composed, or when affordances are induced from multi-step interaction graphs).*

Proposition 72 (Implication chain: computer =¿ machine =¿ engineered)**.** *If C is a computer in the sense of Def. 358, then C is a machine (Def. 354), hence engineered (Def. 355).*

Remark 2500. *This proposition is logically elementary but methodologically important: it makes explicit that the notion of a* computer *used here is not an abstract mathematical object floating free of the world, but a particular kind of* engineered physical system *(Hyperseed-Concepts 80, 106,* **??***). In other words, the chain of definitions forces computation, in this context, to be an embodied and built phenomenon rather than a mere formalism.*

Remark 2501. *The usefulness of making the definitional implication explicit is that later arguments can freely appeal to machine-level or engineering-level properties (robustness, interfaces, failure modes, resource bounds, manufacturability, calibration, etc.) whenever "computer" is assumed, without re-proving that those considerations are in scope. This is especially relevant when* *connecting semantic notions of computation (programs, realizations, interpretations) to causal and physical notions (actuation, sensing, and environmental coupling): the definitional chain prevents an equivocation between abstract computation and realized computation.*

Proof sketch. Def. 358 states a computer is a machine with additional program/realization structure. Def. 354 states a machine is an engineered physical system. Therefore computer implies engineered. □

Remark 2502. Proof sketch. *Unpack the definitional nesting: "computer" includes "machine" as a conjunct, and "machine" includes "engineered" as a conjunct.* □

No algebra is needed; the proof is the transitivity of "is-a" along a definitional hierarchy. The intuitive picture is a set-inclusion chain of concepts: computers sit inside machines, which sit inside engineered systems.

Remark 2503. *Although presented as a simple implication chain, the proposition also functions as a scope marker: it indicates that whenever later sections speak about programs, compilation, or execution, those notions are to be interpreted against a background of engineered constraints and interfaces. In particular, "program/realization structure" is not being treated as a purely Platonic relation, but as something that is established by design choices, fabrication, and the maintenance of stable input–output behavior under relevant operating conditions.*

Proposition 73 (Machine induces an external tool interface (sufficient condition))**.** *Let M be a machine decomposed into components (M_i) with stable input-output behavior. Assume an observer O fixes an external action vocabulary A_{ext} for manipulating M and an external effect vocabulary E_{ext} for outcomes attributable to M. If one can empirically or model-theoretically extract an affordance profile*

$$\mathsf{Aff}_M : A_{\text{ext}} \times E_{\text{ext}} \to V$$

with (i) usability: $\exists(a, e)$ with substantial positive evidence, and (ii) a monotone objective proxy as above is strictly improved by using M, then (M, Aff_M) satisfies the tool criteria.

Proof sketch. Stability of the input–output behavior across the decomposition ensures that the mapping $\mathsf{Aff}_M(a, e)$ is well-defined as a reproducible (or at least model-identifiable) quantale-valued assessment of how action $a \in A_{\text{ext}}$ supports effect $e \in E_{\text{ext}}$. The usability condition prevents the extracted interface from being vacuous (e.g. assigning bottom evidence to every pair), so that M is not a "tool" only in name. Finally, if incorporating the affordances of M yields an achievability profile whose value under a monotone objective proxy is strictly higher, then by Proposition 71 (applied with Aff_0 the baseline and Aff_T the baseline augmented by access to M through A_{ext} and E_{ext}), M is purpose-supporting under that proxy, hence meets the stated tool criterion. □

Remark 2504. *This proposition formalizes a common engineering move: treat a complex artifact as a black-box interface at the boundary of observation, choose a control vocabulary (the external actions) and a measurement vocabulary (the external effects), and then fit or elicit an affordance model relative to those vocabularies. The decomposition into components (M_i) is not used to expose internal details to the agent, but to justify that the boundary behavior is stable enough that an affordance-style summary is meaningful.*

The two conditions (usability and proxy improvement) also separate two failure modes. A system may be stable yet unusable for the agent in the specified action vocabulary, in which case it does not function as a tool. Conversely, a system may be usable but irrelevant to the objective (or improve only utility-neutral effects), in which case it is an "instrument" without being purpose-supporting for the chosen task. The monotone-objective condition provides a lightweight certificate that avoids *modeling the full downstream consequences of using M while still connecting the interface to an explicit notion of benefit.*

Remark 2505. *This statement is a formal "interface theorem": under stable input–output behavior, and relative to a chosen observer vocabulary, a machine can be treated as a tool by extracting an affordance profile and checking the two tool clauses (usable; purpose-supporting). The role of the observer O is philosophically significant: what counts as an "action" and an "effect" is not written into nature in Platonic ink, but carved out by a modeling stance. One can read this in a Peircean spirit as emphasizing the triadic relation among sign (the vocabulary), object (the machine), and interpretant (the observer's inferential practices) [14].*

In particular, the "stable input–output behavior" assumption is doing the technical work of ensuring that the extracted profile is not an artifact of transient internal conditions: repeated applications of the same observed action (in the vocabulary of O) lead to sufficiently consistent observed effects for the profile to be well-defined for downstream reasoning. The theorem therefore functions as a disciplined bridge from an embodied *system with potentially complicated internal dynamics to an* external *interface object suitable for compositional analysis.*

This proposition connects directly back to the earlier achievability monotonicity results: once Aff_M is extracted, one can reason about usefulness via $\mathsf{Ach}_{\mathsf{Aff}_M}$ and monotone objectives, without needing to revisit the internal component structure (M_i). In other words, the same monotonicity machinery that supports "more options cannot hurt" (in the appropriate preorder of objectives) can be applied at the affordance level, where the object of study is the observable capability set rather than the mechanism that generates it.

Proof sketch. This is a packaging theorem: once an external affordance profile exists and improves a suitable objective proxy, Def. 353's (a) usable and (b) purpose-supporting clauses are met. □The only substantive content is the alignment of hypotheses with the two clauses: the stability assumptions guarantee that "usable" is meaningful as a property of the interface, while the objective-improvement assumption instantiates "purpose-supporting" for the chosen purpose proxy.

Remark 2506. Proof sketch. *The proof is definitional: verify the tool axioms by supplying Aff_M as the witness affordance profile and invoking (i) usability and (ii) objective improvement as the two required premises.* □

The key step is recognizing that the internal decomposition (M_i) is only used to justify that an external affordance profile can *be extracted; once Aff_M is in hand, the tool criterion speaks purely in terms of the external action/effect interface. This makes explicit a methodological point: proofs about tool-hood are, after extraction, proofs in the "interface language" of O, and therefore remain valid under any internal redesign that preserves the same Aff_M (or improves it in the relevant preorder). Put differently, the tool predicate is intentionally invariant under internal refactoring, so long as the observed interface contract is preserved.*

Lemma 153 (Functoriality of program semantics)**.** *Let* $\mathrm{J}\cdot\mathrm{K} : \mathsf{Syn} \to \mathsf{Abs}$ *be the semantics functor. Then for any composable programs p, q in* Syn*:*

$$\mathrm{JidK} = \mathrm{id}, \qquad \mathrm{J}q \circ p\mathrm{K} = \mathrm{J}q\mathrm{K} \circ \mathrm{J}p\mathrm{K}.$$

Remark 2507. *This lemma states that the semantics mapping respects the two most basic structural facts about programs: (i) doing nothing means doing nothing, and (ii) the meaning of running p and then q is the composition of the meanings. Here* Syn *is the category of syntactic programs,* Abs *the category of abstract behaviors (or computations), and* $\llbracket \cdot \rrbracket$ *is the interpretation function that forgets syntax and keeps only meaning (Hyperseed-Concept 80).*

It is useful to read the equalities as coherence conditions *on any semantics one is willing to use for certification: if the syntactic category has a designated identity program and a notion of sequencing, then the semantic world must mirror these operations in a way that is compatible with equational reasoning. Concretely, if one proves in* Syn *that two programs are equal by rewriting using associativity/identity laws, then functoriality guarantees that their denotations in* Abs *match, so that one can transport correctness arguments from code structure to abstract behavior.*

While mathematically routine, functoriality is the hinge on which compositional certification turns: it lets one transfer equational reasoning from syntax to semantics without re-proving it case by case. The later pipeline realization theorem depends on this identity explicitly. In particular, the pipeline rule relies on the fact that "compose programs then interpret" agrees with "interpret then compose behaviors," so that the physical composition theorem can be applied to the correct abstract target.

Proof sketch. This is the defining property of a functor. □Equivalently, once $\llbracket \cdot \rrbracket$ is stipulated to be a functor (rather than an arbitrary map), the two displayed equalities are immediate from the functor axioms.

Remark 2508. Proof sketch. *Invoke the axioms of a functor: preservation of identities and composition.* □

The proof works because functoriality is not an empirical claim but a contract: to call $\llbracket \cdot \rrbracket$ *a semantics functor is precisely to assert these two equalities. Intuitively, it is the assertion that meaning is compositional rather than holistic in an uncontrolled way. This is also the point where the categorical setup earns its keep: the axioms are exactly the minimum needed to justify "local reasoning" about program fragments and their assembly into larger systems, without needing to inspect the full global program each time.*

Theorem 57 (Compositional realizations for composed programs (end-to-end pipeline rule))**.** *Let* $p : A \to B$ *and* $q : B \to C$ *be programs in* Syn*, with abstract semantics* $f := \llbracket p \rrbracket$ *and* $g := \llbracket q \rrbracket$ *in* Abs*. Assume there exist physical realizations* R_f *of* f *and* R_g *of* g *(Def. 360), and assume interface compatibility as in Prop. 33. Then there exists a composite realization* $R_{g\circ f}$ *of* $g \circ f$*, hence also of* $\llbracket q \circ p \rrbracket$*, such that*

$$\mathsf{Score}(R_{g\circ f}, \llbracket q \circ p \rrbracket) \;=\; \mathsf{Score}(R_{g\circ f}, g \circ f) \;\geq\; \mathsf{Score}(R_g, g) \otimes \mathsf{Score}(R_f, f).$$

Remark 2509. *In plain English: if you have a physical device that realizes* f *well, and another that realizes* g *well, and you can connect them correctly, then the composite device realizes* $g \circ f$ *with a score at least as good as the tensor-combination of the component scores. This is the formal counterpart of the engineering intuition that reliable modules can be chained to obtain a reliable pipeline, with an explicit lower bound on end-to-end quality.*

The inequality should be read as a guarantee *rather than an exact prediction: depending on the meaning of* Score *and the interaction of components, the composite might perform better than the bound, but it cannot be worse than the bound provided the stated interface assumptions hold. Moreover, the appearance of* $\otimes$ *emphasizes that the way scores combine is part of the theory: one does not merely multiply numbers by convention, but uses the monoidal structure appropriate to the chosen scoring semantics (for example, conjunction of safety guarantees, product of independent probabilities, or addition of log-scores, depending on earlier definitions).*

This theorem ties together several strands: the categorical view of programs/semantics, the notion of physical realization (Hyperseed-Concept 136), and the affordance composition intuition *earlier in the section. It is also one of the basic compositionality principles that makes large engineered systems tractable, rather than a mere heap of parts. One can also view it as an "abstraction barrier" result: once each module is certified against an abstract spec (f and g) with a score, the end-to-end certification can be obtained without re-opening the modules, provided the connection respects the specified interface.*

Proof sketch. By functoriality, $\mathrm{J}q \circ p\mathrm{K} = \mathrm{J}q\mathrm{K} \circ \mathrm{J}p\mathrm{K} = g \circ f$. Then Prop. 33 supplies a composite physical realization with the stated score lower bound. □The proof is therefore a two-line composition of previously established principles: first transport syntactic composition into Abs, then transport physical composition into a score guarantee.

Remark 2510. Proof sketch. *First identify the abstract behavior of the composed program using functoriality. Then apply the existing composition theorem for realizations (Prop. 33) to construct the physical composite and obtain the score inequality.* □

The key step is separating semantic composition *(a statement in* Abs*) from* physical composition *(a statement about realizers and interfaces). The interface-compatibility assumption is what prevents category theory from becoming empty poetry here: it is the concrete requirement that outputs of R_f can serve as inputs of R_g. Stated differently, without compatibility one might still form the formal composite $g \circ f$ in* Abs*, but there would be no corresponding composite artifact, or the artifact would incur unmodeled adapters that could degrade* Score *in ways not captured by the bound. The theorem thus pinpoints exactly where "plumbing" constraints enter the correctness story: not in the semantic equation, but in the existence of the physical composite and the preservation (or controlled degradation) of performance guarantees.*

Corollary 28 (Thresholded pipeline certification)**.** *Fix a threshold $\tau \in V$. If $\mathsf{Score}(R_f, f) \geq \tau_f$ and $\mathsf{Score}(R_g, g) \geq \tau_g$ and $\tau_g \otimes \tau_f \geq \tau$, then the composed realization satisfies*

$$\mathsf{Score}(R_{g\circ f}, \mathrm{J}q \circ p\mathrm{K}) \geq \tau.$$

Remark 2511. *This corollary packages the previous theorem into a certification rule: if each stage meets its own threshold, and the tensor of those thresholds clears the desired end-to-end bar, then the composed system is certified at level τ. In practice, this is how one turns a compositional lower bound into an actionable engineering test: certify components, then certify the pipeline by arithmetic in V.*

One should read τ_f and τ_g as local acceptance criteria *that may be chosen for different reasons (safety margin, regulatory constraint, validation coverage, etc.), while τ is the* system-level *criterion. The condition $\tau_g \otimes \tau_f \geq \tau$ is then a compatibility constraint: the local bars must be set so that their compositional guarantee meets (or exceeds) the global requirement. In particular, this makes explicit that raising the global bar τ forces a corresponding strengthening of (at least one of) the component bars, unless the tensor operation $\otimes$ has slack (e.g. saturating behavior) in the relevant region of V.*

Proof sketch. Combine the score lower bound from the previous theorem with monotonicity of $\otimes$ and transitivity of $\geq$. □

Remark 2512. Proof sketch. *Use the theorem's inequality and then substitute the component lower bounds τ_f, τ_g; finally apply $\tau_g \otimes \tau_f \geq \tau$ to reach the desired threshold.* □

The proof works because $\otimes$ is monotone: improving either component score cannot reduce the product-like combined guarantee. One may visualize this as a "budget" of reliability passing down a pipeline: each stage consumes some reliability, but if the remaining budget stays above τ the whole chain is acceptable.

It is also worth noting what the corollary does not *assert: it does not claim that the bound $\tau_g \otimes \tau_f$ is tight, nor that the combined score factors exactly as a tensor product in general. Rather, it provides a conservative certification rule derived from a compositional lower bound. Consequently, failure of the arithmetic test $\tau_g \otimes \tau_f \geq \tau$ does not by itself imply the pipeline fails at level τ; it only implies that this particular sufficient condition does not certify it, motivating either stronger component guarantees, a refined analysis, or a different compositional inequality more adapted to the situation.*

Proposition 74 (Body-channel mediation as a Hom-factorization constraint)**.** *Let (M, B) be an embodied mind and body, and let R_{phys} be a physical reality-system. Assume body-channel mediation holds in the factorization form: for most attributable effects, the corresponding influence morphism factors*

$$f : M \to R_{\text{phys}} \quad \textit{as} \quad f \approx h \circ g \ \textit{ with } \ g : M \to B,\ h : B \to R_{\text{phys}}.$$

Then (for those effects) the set of mind-to-physics influence morphisms is (approximately) contained in the image of postcomposition by morphisms out of B.

Remark 2513. *The claim is simple: if the mind's influence on the physical reality-system is mediated by the body, then every admissible influence map f essentially factors through B. In categorical language, B behaves like a universal "bottleneck" (up to approximation) for mind-to-world causation. This makes explicit, in the formalism, the ordinary scientific stance that action on the world is carried by bodily channels (Hyperseed-Concept 135), and it aligns with process-oriented readings in which concrete causation is routed through actual physical occasions [15].*

This proposition also provides a clean logical handle: it lets one rule in *or* rule out *hypothesized channels by checking whether they admit the required factorization, as formalized in the next corollary.*

Formally, one may read "image of postcomposition by morphisms out of B" as the set of composites

$$\{\, h \circ g \mid g \in \mathrm{Hom}(M, B),\ h \in \mathrm{Hom}(B, R_{\text{phys}}) \,\} \subseteq \mathrm{Hom}(M, R_{\text{phys}}),$$

with the inclusion weakened to an $\approx$-containment when empirical or modeling approximations are allowed. In this sense, the proposition is a statement about which region of the Hom-set $\mathrm{Hom}(M, R_{\text{phys}})$ *is even eligible to count as an M-attributed causal pathway under the mediation assumption.*

Proof sketch. This restates Def. 362 in categorical language: B is a (near-)universal mediator for M's effects on R_{phys}. □

Remark 2514. Proof sketch. *The proof is definitional: interpret "body-channel mediation" as the existence of a factorization $f \approx h \circ g$ through B, and then observe that this says precisely that f lies in the image of postcomposition by maps out of B (up to $\approx$).* □

The essential step is translating an intuitive constraint ("influence goes through the body") into a compositional constraint on morphisms. The approximation symbol $\approx$ carries the empirical messiness: mediation need not be exact to be structurally dominant.

Depending on the ambient framework, $\approx$ might be instantiated as observational equivalence, bounded error in a metric on processes, statistical indistinguishability relative to O, or a coarser relation induced by measurement and intervention limits. The proposition itself does not require a specific choice; it only uses the idea that "mediated" effects are those that can be matched (to the relevant tolerance) by some factorization through B.

Corollary 29 (Ruling out direct mind-to-physics channels in a body-mediated model)**.** *Assume body-channel mediation holds for a class of effects under an observer O. If a hypothesized influence morphism $f^\star : M \to R_{\mathrm{phys}}$ cannot be approximated by any composition $h \circ g$ through B in the chosen approximation notion, then $f^\star$ does not belong to the model's "attributable-to-M" effect class (relative to O).*

Remark 2515. *This is the negation test: under a body-mediated model, a genuinely "direct" mind-to-physics map that evades all body factorization is, by that very fact, outside the model's attribution boundary. In a Russellian spirit one may say: the boundary is not a metaphysical decree, but a logical consequence of the adopted explanatory form; change the form and the boundary moves.*

Operationally, this can be read as follows: if the only experimentally supported influence patterns from M to R_{phys} are those reproducible (up to $\approx$) by first mapping into B and then mapping out of B, then positing an additional $f^\star$ that cannot be so reproduced is not a mere extension of the same model-class; it is a departure from the mediation hypothesis itself, and should be evaluated as such (e.g. by proposing new observables, interventions, or auxiliary structure that would make $f^\star$ testable and comparable).

Proof sketch. Contrapositive of the mediation criterion: attributable effects are (by assumption) those admitting a factorization through B up to approximation. ☐

Remark 2516. Proof sketch. *Assume $f^\star$ were attributable; then by mediation it would admit an approximate factorization through B. Since it does not, it cannot be attributable.* ☐

What matters is that the corollary does not deny that $f^\star$ exists as a formal morphism; it only denies its membership in the privileged class of attributed *effects, which is observer- and model-relative (Hyperseed-Concept* **??** *is a helpful nearby lens).*

In particular, the observer index O can matter both through what counts as "most attributable effects" and through the granularity of $\approx$: an $f^\star$ might fail to factor through B under a fine-grained approximation (high-resolution instrumentation) while being indistinguishable from some mediated composite under a coarser approximation (limited instrumentation). The logical form of the corollary remains the same; only the induced attribution boundary shifts with the observational regime.

Proposition 75 (Non-uniqueness of physical lift under a forgetful map (sufficient condition))**.** *Let $U : \mathsf{Alg}(\mathsf{Alg}_{\mathrm{phys}}) \to \mathsf{Alg}(\mathsf{Alg}_{\mathrm{mind}})$ be the forgetful functor. If U is not injective on isomorphism classes of objects, i.e. there exist non-isomorphic P_1, P_2 with $U(P_1) \cong U(P_2)$, then the corresponding mental object $m := U(P_1) \cong U(P_2)$ does not determine a unique physical structure.*

Remark 2517. *The statement formalizes a familiar theme: the same "mental" or "functional" organization may be realized by multiple distinct physical organizations. Here the functor U forgets some physical structure, retaining only what is deemed mentally salient; non-injectivity then means that the forgetting collapses genuinely different physical possibilities to the same mental equivalence class. This is one crisp way to express Algebraically Asymmetric Physical Reality (Hyperseed-Concept 55): the map from physical to mental can be many-to-one, so the reverse direction is underdetermined.*

This matters because any attempt to "lift" mental descriptions back to physical ones must then introduce extra choices, constraints, or evidence. In other words, the lifting problem is not merely difficult; it is ill-posed without additional structure.

One can restate the hypothesis as saying that some isomorphism class $[m] \in \mathsf{Alg}(\mathsf{Alg}_{\mathrm{mind}})$ has a fiber under U containing at least two distinct isomorphism classes in $\mathsf{Alg}(\mathsf{Alg}_{\mathrm{phys}})$. Concretely, *the datum of m specifies at most the* equivalence class of physical realizers modulo the forgotten structure*, not a canonical representative of that class.*

The qualifier "sufficient condition" is important: non-injectivity on isomorphism classes is an easy to check criterion guaranteeing non-uniqueness, but uniqueness can also fail in subtler ways (e.g. failure to choose a canonical section, or the presence of multiple non-isomorphic lifts even when a given representative is fixed). The present proposition isolates the simplest categorical mechanism: identification in the image forces underdetermination in any inverse reconstruction.

A toy example to keep in mind is the usual many-realizations picture for computation: two distinct hardware implementations (say, different circuit layouts or different physical substrates) can present isomorphic state-transition structure at the level of an abstract finite automaton. If U forgets substrate details and remembers only the automaton, then $U(P_1) \cong U(P_2)$ while $P_1 \ncong P_2$, and the automaton-level description does not pick out a unique hardware realizer.

Proof sketch. Immediate: two distinct physical realizers share the same forgotten mental structure. Thus any "lifting" from mental to physical requires extra choices beyond the mental description. □

Remark 2518. Proof sketch. *Exhibit the counterexample to uniqueness directly: $P_1 \ncong P_2$ but $U(P_1) \cong U(P_2)$.* □

The decisive step is the appeal to isomorphism classes rather than raw objects: it ensures the claim is invariant under mere renaming of structure, and really concerns "physical form" versus "mental form" in the categorical sense.

Equivalently, the proposition is asserting the nonexistence of a unique lift up to unique isomorphism *of m along U in general: if the fiber over m contains two non-isomorphic objects, then even granting that "a lift exists," it cannot be unique in the only sense that matters in a category, namely uniqueness up to isomorphism. Said differently, the usual categorical notion of determinacy here is not "there exists some P with $U(P) \cong m$," but rather "all such P are isomorphic," and the hypothesis explicitly negates that condition.*

Proposition 76 (Coarse-graining increases weakness (weakness monotonicity rule))**.** *If mental/intersubjective structure is modeled as a coarse-graining of physical structure by identifying previously distinct physical states, then the passage from physical to mental structure monotonically increases quantale weakness (relative to the finest-grained physical observer).*

Remark 2519. *This proposition says that* forgetting distinctions *makes the resulting description weaker: the more you identify, the less you can discriminate, and thus the more "undistinguished pairs" you carry. Quantale weakness (Hyperseed-Concepts 202 and 143) is designed precisely to measure this loss of discriminatory power, in a way compatible with the quantale structure used throughout the epistemic layer.*

The result is important because coarse-graining is ubiquitous: sensors blur, abstractions compress, languages omit, communities negotiate shared categories. The proposition ensures that weakness behaves in the direction one expects under these operations; it is a sanity theorem in the sense emphasized in [3], and it resonates with the broader idea (cf. [2]) that constraint and partiality, rather than perfect specification, are the norm for real cognitive systems.

In the concrete "partition" picture, an observer at the physical level distinguishes states up to some fine equivalence relation $\sim_{\text{phys}}$, whereas the mental/intersubjective level uses a coarser relation $\sim_{\text{mind}}$ obtained by merging equivalence classes (so $\sim_{\text{phys}} \subseteq \sim_{\text{mind}}$ as relations). The monotonicity claim is then the order-theoretic statement that enlarging the indistinguishability relation moves one upward in the weakness preorder induced by the quantale-valued weakness functional.

The phrase "relative to the finest-grained physical observer" also matters: weakness is evaluated with respect to a baseline notion of distinguishability, and coarse-graining is defined as a loss relative to that baseline. *Thus the monotonicity is not a metaphysical claim that "mental is always weaker," but a structural claim that* given a fixed physical discrimination structure, *any additional identifications (whether due to abstraction, measurement limits, or negotiated intersubjective categories) cannot improve discriminatory power in the formalism.*

When the quantale weakness assigns weights rather than booleans to undistinguished pairs, the same intuition applies: coarse-graining can be viewed as either adding new undistinguished pairs or increasing the weight/degree to which certain pairs are treated as indistinguishable. Under either interpretation, the order-preserving property ensures the weakness value can only stay the same or increase.

Proof sketch. Coarse-graining adds (or increases weight on) undistinguished pairs. Weakness is monotone under adding undistinguished pairs (Theorem 1 in the paper's core sanity theorems), hence weakness increases. ☐

Remark 2520. Proof sketch. *Translate coarse-graining into the operation "add more pairs that the observer treats as not distinguishable." Then apply monotonicity of the weakness functional with respect to adding such pairs.* ☐

The proof works because weakness is, by construction, order-preserving in the lattice of distinguishability relations: adding identifications moves upward in "weakness order." A visual intuition is to imagine partitioning a set of physical states: coarse-graining merges partition cells, producing a strictly coarser partition, hence fewer distinctions and therefore more weakness.

It is sometimes helpful to note the two boundary cases: at one extreme, the identity (no coarse-graining) leaves weakness unchanged; at the other extreme, collapsing all states to one class maximizes weakness by making every pair undistinguished. The proposition asserts that all intermediate coarse-grainings interpolate monotonically between these extremes.

The monotonicity is also stable under "mixed" coarse-grainings that only identify some states but leave others intact: the weakness functional need not be linear in the number of identifications, only order-preserving with respect to inclusion (or weight-increase) of the undistinguished-pairs data.

Corollary 30 (Iterated forgetting yields iterated weakness increase)**.** *If U_1 and U_2 are successive coarse-grainings (forgetful maps), then the induced weakness is monotone along the chain:*

$$w \ \leq \ w \circ U_1 \ \leq \ w \circ (U_2 \circ U_1),$$

interpreting $w \circ U$ as "compute weakness after coarse-graining by U".

Remark 2521. *This is the compositional form of the previous proposition: repeated forgetting yields repeated (or at least nondecreasing) weakness. It is the formal analogue of the commonsense idea that if you first compress a description and then compress it again, you do not regain lost detail. It also aligns with the earlier associativity/compositionality themes in this section: here the composed map $U_2 \circ U_1$ behaves as the "combined forgetting," and weakness tracks it monotonically.*

In categorical terms, the point is that the class of coarse-grainings under consideration is closed under composition: $U_2 \circ U_1$ is itself a coarse-graining capturing the net identifications made by the two stages. The inequality chain then expresses that w is monotone with respect to this composition, so that the ordering of "informational strength" is functorial along the forgetful/coarse-graining direction.

One can also read the inequalities as a "data processing" principle for the weakness measure: post-processing by a forgetful map cannot reduce the weakness induced by prior processing, because no new distinctions are introduced by additional forgetting.

Proof sketch. Each coarse-graining adds undistinguished pairs; apply weakness monotonicity twice. $\square$

Remark 2522. Proof sketch. *Apply the monotonicity rule once to U_1 to get $w \leq w \circ U_1$, and again to U_2 (viewed as a coarse-graining on the already coarse-grained structure) to get $w \circ U_1 \leq w \circ (U_2 \circ U_1)$.* $\square$

The key step is recognizing that "successive coarse-grainings" are again a coarse-graining when composed, so the same monotonicity argument iterates without alteration.

This corollary is also a reminder that any multi-stage modeling pipeline (physical $\to$ perceptual $\to$ linguistic $\to$ intersubjective, etc.) will accumulate weakness unless explicit "side channels" of additional information are introduced. In the present formalism, such side channels would correspond not to further forgetful functors but to added structure (constraints, measurements, or priors) that refine, rather than coarsen, the distinguishability relation.

Please paste the actual LaTeX for the TARGET CHUNK (the content of === BLOCK 1: MODIFIED LATEX ===). Right now the chunk is missing (it only shows the header), so I cannot rewrite it while satisfying the constraints about not deleting any technical material and keeping the same structure.

45 Helper theorems for Section 24 (Communion, Explicit Communion, Beauty)

This section states helper theorems that follow immediately from the formal definitions in Section 24 (Definitions 364–385, Propositions 35–37, Theorems 20–21). They are intended as "ready-to-fire" lemmas for an automated reasoner.

Remark 2523. *Philosophically, the purpose of this section is to distill a large family of qualitative notions (*communion*,* explicit communion*,* beauty*,* spiritual communion*, etc.) into algebraic invariants and monotonicity rules that an automated system can reliably use. The underlying approach is broadly "pattern-centric" in the sense of Section 24 and the broader Hyperseed framework: intensities are assigned to patterns over individual and collective supports, and then various higher-level predicates are defined by comparing aggregated intensities. This pattern-emergence orientation aligns with the general account of patterns and their networks in [5] and with the initial Hyperseed ontology presentation [1]. When the results touch prosocial coordination (e.g. the way cross-supported structure can dominate private structure), they also resonate with arguments that prosociality can be efficiency-enhancing in multi-agent settings [6].*

45.1 Algebra of within-/cross-mind intensity and communion

Remark 2524. *We will repeatedly use the following intuition (without re-stating it each time):*

- $\mathrm{Pat}_U(I)$ *denotes a set of patterns whose* support *is exactly the subcommunity $U \subseteq C$ over the interval I (as defined in Section 24). Thus $|U| = 1$ corresponds to "private" or within-mind patterns, while $|U| \geq 2$ corresponds to genuinely cross-mind patterns.*
- $w_U(p) \in [0, \infty]$ *is an intensity assigned to the pattern $p \in \mathrm{Pat}_U(I)$.*
- $\mathrm{Win}(C, I; w)$ *aggregates the singleton-support intensities (within-mind total);* $\mathrm{Wcross}(C, I; w)$ *aggregates the $|U| \geq 2$ intensities (cross-mind total); and* $\mathrm{DComm}(C, I; w)$ *is the difference* $\mathrm{Wcross} - \mathrm{Win}$*, the "margin" by which the shared exceeds the private.*

This is, in effect, a bookkeeping calculus for the distinction between Self *and* Other *at the level of pattern support; compare the Hyperseed core-concept set entries 165, 130, and* **??**.

HT24.1 (Communion margin decomposition). For any community intensity datum w on (C, I),

$$\mathrm{DComm}(C, I; w) \;=\; \mathrm{Wcross}(C, I; w) \;-\; \mathrm{Win}(C, I; w),$$

and expanding the definitions,

$$\mathrm{DComm}(C, I; w) = \sum_{\substack{U \subseteq C \\ |U| \geq 2}} \sum_{p \in \mathrm{Pat}_U(I)} w_U(p) \;-\; \sum_{m \in C} \sum_{p \in \mathrm{Pat}_{\{m\}}(I)} w_{\{m\}}(p).$$

Moreover, $\mathrm{Comm}(C, I; w)$ holds iff $\mathrm{DComm}(C, I; w) > 0$.

Remark 2525. *Intuitively, this says that communion is not a mysterious extra primitive: it is a* comparison *between two kinds of total intensity. The cross-supported total* Wcross *counts intensities of patterns that "span minds," while* Win *counts intensities that remain confined to individual members. Communion holds precisely when the shared structure dominates the private structure in the aggregated sense. One can view* DComm *as an "intersubjective surplus" (Hyperseed-Concept* **??***).*

Proof sketch. Immediate from Definitions 368–369: Wcross sums intensities for $|U| \geq 2$, Win sums singleton-support intensities, and communion is defined as Wcross > Win.

Remark 2526. *A useful way to picture the proof is as a partition of a sum: patterns are sorted by the cardinality of their support. Nothing deeper is required because Section 24 defines all the operators explicitly in terms of these sums. Geometrically, one may imagine an axis with "within" intensity on one side and "cross" intensity on the other;* DComm *is then simply the signed displacement from within-dominance to cross-dominance.*

HT24.2 (Nonnegativity and trivial bounds). Always $\mathrm{Win}(C, I; w) \geq 0$ and $\mathrm{Wcross}(C, I; w) \geq 0$, hence

$$-(\mathrm{Win} + \mathrm{Wcross}) \;\leq\; \mathrm{DComm} \;\leq\; \mathrm{Win} + \mathrm{Wcross}.$$

In particular, if $\mathrm{Wcross}(C, I; w) = 0$ then $\neg\mathrm{Comm}(C, I; w)$.

Remark 2527. *This is the "sanity-check" lemma: since intensities live in* $[0, \infty]$*, the aggregated totals cannot be negative. The bounds on* DComm *are just the obvious bounds on a difference of two nonnegative quantities. The final sentence captures the intended meaning of communion: if there is literally no cross-supported intensity, then there is nothing upon which communion could be based (Hyperseed-Concept* **??***).*

Proof sketch. Each $w_U(p) \in [0, \infty]$ and totals are (finite or extended) sums. If $\mathrm{Wcross} = 0$ then $\mathrm{Wcross} > \mathrm{Win}$ is impossible since $\mathrm{Win} \geq 0$.

Remark 2528. *The high-level strategy is to reduce everything to order properties of* $[0, \infty]$*. The only "key step" is noticing that the definition of* Comm *is a strict inequality; thus even if* $\mathrm{Win} = 0$, $\mathrm{Wcross} = 0$ *fails communion. Visually: if you draw the nonnegative quadrant with coordinates* $(\mathrm{Wcross}, \mathrm{Win})$*, communion lives strictly above the diagonal* $\mathrm{Wcross} = \mathrm{Win}$*, and the line* $\mathrm{Wcross} = 0$ *is entirely outside this region.*

HT24.3 (Scaling invariance of communion). Fix $c > 0$ and define a rescaled datum $(c \cdot w)_U(p) := c\, w_U(p)$. Then

$$\mathrm{Win}(C, I; c{\cdot}w) = c\,\mathrm{Win}(C, I; w), \quad \mathrm{Wcross}(C, I; c{\cdot}w) = c\,\mathrm{Wcross}(C, I; w), \quad \mathrm{DComm}(C, I; c{\cdot}w) = c\,\mathrm{DComm}(C, I; w)$$

and therefore $\mathrm{Comm}(C, I; c \cdot w)$ iff $\mathrm{Comm}(C, I; w)$.

Remark 2529. *The content is that communion is* scale-free*: it depends on a comparison between cross and within totals, not on the absolute units in which intensities are measured. This matches the idea that intensity values are often proxies for heterogeneous empirical or phenomenological measurements (Hyperseed-Concept* **??** *is not listed, but compare* **??** *and* **??***). A simple example: if all intensities are multiplied by* 10 *because one changes the measuring instrument, the truth of* Comm *is unchanged.*

Proof sketch. Linearity of finite sums over $[0, \infty]$; inequality is preserved by multiplication by $c > 0$.

Remark 2530. *The proof is a one-line homogeneity argument: sums commute with multiplication by a scalar, and strict inequalities are preserved by multiplying by a positive constant. The geometric intuition is that scaling moves a point* $(\mathrm{Wcross}, \mathrm{Win})$ *along a ray from the origin, and the communion region is a cone bounded by the diagonal; rays cannot cross the diagonal unless they start on it.*

HT24.4 (Cross-monotonicity of communion margin). Let w, w' be two intensity data on (C, I) such that: (i) for all $m \in C$ and all $p \in \mathrm{Pat}_{\{m\}}(I)$, $w'_{\{m\}}(p) = w_{\{m\}}(p)$; (ii) for all $U \subseteq C$ with $|U| \geq 2$ and all $p \in \mathrm{Pat}_U(I)$, $w'_U(p) \geq w_U(p)$. Then $\mathrm{DComm}(C, I; w') \geq \mathrm{DComm}(C, I; w)$. In particular, if $\mathrm{Comm}(C, I; w)$ then $\mathrm{Comm}(C, I; w')$.

Remark 2531. *This formalizes an intuitive principle: if you do not change anyone's private intensity landscape, but you strengthen (or add) the shared patterns, then communion cannot get worse. As a toy example, suppose a dyad* $\{m, n\}$ *gains a new cross-supported pattern of intensity* 1 *while their private patterns remain unchanged; then* Wcross *increases and* Win *does not, so the communion margin increases. This lemma is useful because many interventions (education, ritual, coordinated practice) are modeled precisely as boosting cross-supported patterns without directly inflating private noise.*

Proof sketch. Win is identical under (i), while Wcross can only increase under (ii); subtract.

Remark 2532. *The strategy is monotonicity of sums: if every summand in the cross part increases (or stays the same), then the total increases. The key step is the separation of within- and cross-summands, which is already built into the definition of* DComm*. One may visualize this as keeping the "within" bar fixed while raising the "cross" bar; the difference must grow.*

HT24.5 (Within-monotonicity: increasing private intensity hurts communion). Let w, w' be such that cross intensities are unchanged, but singleton intensities increase: (i) $w'_U = w_U$ for all U with $|U| \geq 2$; (ii) $w'_{\{m\}}(p) \geq w_{\{m\}}(p)$ for all singletons. Then $\mathrm{DComm}(C, I; w') \leq \mathrm{DComm}(C, I; w)$. Hence if $\mathrm{Comm}(C, I; w')$ then $\mathrm{Comm}(C, I; w)$.

Remark 2533. *This is the mirror image of HT24.4: if the shared world stays as it is but private intensity grows, the communion margin shrinks. In everyday terms, if each participant's inner* *monologue gets louder while the shared conversation does not intensify, then the collective unity becomes harder to sustain. This is important for reasoning about failure modes: communion can be lost not only by weakening shared patterns but also by amplifying private patterns (Hyperseed-Concept* **??** *via 60 is often implicated).*

Proof sketch. Now Wcross is identical, while Win can only increase.

Remark 2534. *Again, the proof is a direct application of monotonicity of sums and the definition of* DComm *as a difference. The key step is noticing that the strictness in the communion condition flows "backwards" here: if w' still achieves communion despite a larger within component, then certainly w achieves communion. Geometrically: you move vertically upward in the* $(\mathrm{Wcross}, \mathrm{Win})$ *plane, away from the communion region; if you are still in communion after moving up, you must have started even deeper inside the region.*

HT24.6 (Add-a-member update formula). Let $C' = C \cup \{n\}$ with $n \notin C$. Then

$$\mathrm{DComm}(C', I; w) = \mathrm{DComm}(C, I; w) \;+\; \Big(\sum_{\substack{U\subseteq C\\ U\neq\emptyset}} \sum_{p\in\mathrm{Pat}_{U\cup\{n\}}(I)} w_{U\cup\{n\}}(p)\Big) \;-\; \sum_{p\in\mathrm{Pat}_{\{n\}}(I)} w_{\{n\}}(p).$$

(Interpret the first big sum as the total cross-supported intensity of patterns whose support includes n and at least one member of C.)

Remark 2535. *This provides a modular way to update communion calculations when a community grows by one member. The additional term is precisely "what the newcomer brings to shared structure" minus "how much private structure the newcomer has", all measured in the same intensity currency. As a simple example, if n has no private patterns in the relevant vocabulary (or they are assigned negligible intensity) but creates strong shared patterns with members of C, then adding n can increase communion margin. This lemma connects naturally to questions of recruitment and assimilation in collective systems (Hyperseed-Concept 170).*

Proof sketch. Expand $\mathrm{Wcross}(C', \cdot)$ into (a) terms entirely inside C plus (b) terms whose support includes n. Expand $\mathrm{Win}(C', \cdot)$ into $\mathrm{Win}(C, \cdot)+$ the singleton sum for n. Subtract.

Remark 2536. *The proof is a careful but elementary partition of the defining sums according to whether their support contains n. The key step is that supports are sets, so "contains n" cleanly distinguishes the new terms from the old ones. A visual intuition is bookkeeping in a ledger: the old balance is* $\mathrm{DComm}(C, I; w)$*, and the new balance is old plus new cross credits minus new within debits.*

HT24.7 (Independent-subcommunity additivity). Let $C = C_1 \cup C_2$ with $C_1 \cap C_2 = \emptyset$. Assume *no* pattern has support spanning both parts, i.e. for every nonempty $U \subseteq C$ with $U \cap C_1 \neq \emptyset$ and $U \cap C_2 \neq \emptyset$, we have $\mathrm{Pat}_U(I) = \emptyset$ (or equivalently, their total intensity is 0). Then

$$\mathrm{DComm}(C, I; w) = \mathrm{DComm}(C_1, I; w) + \mathrm{DComm}(C_2, I; w),$$

and similarly for Win and Wcross.

Remark 2537. *This is an additivity principle under a strong independence hypothesis: if the community decomposes into two parts with no cross-supported patterns linking them, then communion margin is just the sum of the margins inside each part. One may read this as an algebraic reflection* *of the idea that an intersubjective field cannot exist across a boundary where there are no shared patterns (Hyperseed-Concept* **??** *is not listed, but compare* **??***). This lemma is useful when analyzing large communities that factor into disconnected "tribes" in the pattern-support sense. In particular, it formalizes a "no interaction, no synergy" slogan: the net surplus of cross-mind intensity over within-mind intensity cannot be created by simply juxtaposing two groups if absolutely no pattern is jointly supported across the split. Equivalently, the hypothesis is not merely that interactions are weak, but that they are* absent *at the level of the pattern-support relation, so that every support-set U contributing to cross terms is forced to lie entirely in one side.*

Proof sketch. Under the hypothesis, all sums split into disjoint contributions supported entirely in C_1 or entirely in C_2. More explicitly, for each indexing set $U \subseteq C$ appearing in the definitions of Wcross and Win, either $U \subseteq C_1$ or $U \subseteq C_2$, since the case $U \cap C_1 \neq \emptyset$ and $U \cap C_2 \neq \emptyset$ forces $\mathrm{Pat}_U(I) = \emptyset$ and hence contributes zero. Thus, both the cross-supported total and the within-supported total decompose as a sum of two independent blocks, and so does their difference.

Remark 2538. *The strategy is to split the index set of each sum. The crucial step is the hypothesis $\mathrm{Pat}_U(I) = \emptyset$ whenever U intersects both sides: it eliminates all mixed terms, leaving only terms wholly in C_1 or wholly in C_2. Visually, the community is two islands with no bridges; totals computed on the archipelago are totals computed on each island and added. One can also view this as a bookkeeping statement about supports: the decomposition $C = C_1 \sqcup C_2$ induces a partition of all relevant supports into those contained in C_1 and those contained in C_2, and the hypothesis says that the "straddling" supports contribute identically zero. Because the weights $w_U(p)$ are nonnegative, there is no cancellation to worry about; the additivity is purely set-theoretic and does not depend on delicate sign arguments.*

HT24.8 (Pairwise lower bound suffices for communion). Define the *pairwise* cross total

$$\mathrm{Wcross}^{(2)}(C, I; w) := \sum_{\{m,n\}\subseteq C} \; \sum_{p\in \mathrm{Pat}_{\{m,n\}}(I)} w_{\{m,n\}}(p).$$

Then $\mathrm{Wcross}^{(2)}(C, I; w) \leq \mathrm{Wcross}(C, I; w)$. Consequently, if $\mathrm{Wcross}^{(2)}(C, I; w) > \mathrm{Win}(C, I; w)$ then $\mathrm{Comm}(C, I; w)$.

Remark 2539. *This says that, to certify communion, it can suffice to look only at* pairwise *cross-patterns. Since* Wcross *includes all higher-arity supports ($|U| \geq 3$) in addition to pairs, the pairwise sum is a lower bound. Thus, if even the pairwise shared intensity already dominates all singleton intensity, then communion is guaranteed. This is practically useful because pairwise statistics are often far easier to estimate than higher-order ones. In terms of hypothesis-testing language:* $\mathrm{Wcross}^{(2)}$ *is a conservative proxy for the full cross total, so a strict inequality* $\mathrm{Wcross}^{(2)} > \mathrm{Win}$ *is a strong certificate that cannot be invalidated by discovering additional higher-order structure. Conversely, failure of the pairwise test does* not *refute communion, because genuinely communal structure may reside predominantly in $|U| \geq 3$ supports; the lemma only provides a sufficient condition, not a necessary one.*

Proof sketch. Wcross sums over all $|U| \geq 2$, including all pairs; all terms are nonnegative. More formally, writing $\mathrm{Wcross}(C, I; w) = \sum_{U\subseteq C,\, |U|\geq 2} \sum_{p\in \mathrm{Pat}_U(I)} w_U(p)$, the subcollection of indices with $|U| = 2$ is precisely what appears in $\mathrm{Wcross}^{(2)}$. Removing all other $|U| \geq 3$ terms yields $\mathrm{Wcross}^{(2)}$, and since each removed term is ≥ 0, the inequality follows.

Remark 2540. *The proof is containment of index sets: the set of pairs is a subset of the set of all supports of size at least* 2*. Nonnegativity ensures that throwing away terms can only decrease the sum, never increase it. Geometrically: if you approximate a high-dimensional shared structure by its edges, you get a conservative estimate. A useful way to picture the indexing is as a hypergraph on C:* Wcross *sums contributions over all hyperedges of size ≥ 2, whereas* $\mathrm{Wcross}^{(2)}$ *keeps only the ordinary edges. The lemma then says that the total weight of edges is bounded above by the total weight of all hyperedges, which is immediate when weights are nonnegative and no term is double-counted outside its own support size.*

HT24.9 (Normalized communion score is bounded). Define (for any fixed $\varepsilon > 0$)

$$\mathrm{NComm}_\varepsilon(C, I; w) := \frac{\mathrm{DComm}(C, I; w)}{\mathrm{Wcross}(C, I; w) + \mathrm{Win}(C, I; w) + \varepsilon}.$$

Then $|\mathrm{NComm}_\varepsilon(C, I; w)| < 1$ and $\mathrm{sign}(\mathrm{NComm}_\varepsilon) = \mathrm{sign}(\mathrm{DComm})$.

Remark 2541. *This introduces a dimensionless score in $(-1, 1)$ that is robust to overall scaling of intensities (compare HT24.3), and also avoids division by zero through $\varepsilon > 0$. Conceptually, it plays a role similar to a normalized "effect size" or signed correlation: the numerator measures net surplus, and the denominator measures total mass. Such normalizations are often helpful when comparing communities of very different sizes or intensity scales. Note that ε may be interpreted as a regularization parameter: it prevents instability when both* Wcross *and* Win *are tiny (or zero), and it ensures strict inequality $|\mathrm{NComm}_\varepsilon| < 1$ even in extreme cases where* DComm *nearly matches* $\mathrm{Wcross} + \mathrm{Win}$*. In applications, one can choose ε to reflect a baseline noise floor or a desired numerical tolerance, without changing the sign of the score.*

Proof sketch. From HT24.2, $|\mathrm{DComm}| \leq \mathrm{Wcross} + \mathrm{Win}$. Adding $\varepsilon > 0$ makes the denominator strictly larger than $|\mathrm{DComm}|$ unless both totals are infinite; in the extended-real case, interpret as the usual limiting inequality. For the sign claim, note that the denominator is strictly positive in the ordinary real-valued setting (and nonnegative in the extended-real setting with $\varepsilon > 0$), so dividing by it cannot change the sign of the numerator.

Remark 2542. *The proof is a direct inequality sandwich: the denominator dominates the numerator in absolute value. The subtle point is extended-real arithmetic; the intended reading is the standard one that when both totals diverge, the ratio is interpreted via limits (or as an indeterminate form resolved by a convention). Visually: the score is a signed ratio whose magnitude cannot reach* 1 *unless $\varepsilon = 0$ and one side overwhelms the other completely. Equivalently,* $\mathrm{NComm}_\varepsilon$ *behaves like a "normalized difference":*

$$-1 < \frac{\mathrm{Wcross} - \mathrm{Win}}{\mathrm{Wcross} + \mathrm{Win} + \varepsilon} < 1,$$

since the numerator is bounded in magnitude by the sum of the two nonnegative totals, and ε enforces strictness. This places $\mathrm{NComm}_\varepsilon$ *in the same family as other bounded contrast scores used to compare two nonnegative quantities, with the additional interpretation that the two quantities here are "cross-mind" and "within-mind" intensity masses.*

45.2 Paraconsistent designation calculus (for explicit communion and beauty)

Fix the truth-value set $B = [0, 1] \times [0, 1]$ with $\neg(t, f) = (f, t)$, $(t_1, f_1) \wedge (t_2, f_2) = (\min(t_1, t_2), \max(f_1, f_2))$, $(t_1, f_1) \vee (t_2, f_2) = (\max(t_1, t_2), \min(f_1, f_2))$, and designation $\mathrm{Desig}_\tau(t, f) \iff t \geq \tau$.

Remark 2543. *Here $B = [0,1] \times [0,1]$ should be read as a* two-component *truth value: the first coordinate t is "degree of support for truth" and the second coordinate f is "degree of support for falsity." The negation $\neg(t,f) = (f,t)$ swaps these roles. The connectives $\wedge, \vee$ are the standard min–max / max–min choices that preserve information from both components: conjunction keeps the weaker truth evidence (min) and the stronger falsity evidence (max), while disjunction keeps the stronger truth evidence (max) and the weaker falsity evidence (min). Designation $\mathrm{Desig}_\tau(t,f) \iff t \geq \tau$ is a* threshold rule *declaring statements "acceptable" when their truth-evidence is high enough. This style of four-valued / paraconsistent semantics is closely aligned with Constructible Duality Logic [23] and with paraconsistent treatments of resonance-like phenomena [24]; it also matches the Hyperseed emphasis on Value Paraconsistency (Hyperseed-Concept 198).*

Remark 2544. *A convenient auxiliary structure on B (not required for the proofs below, but helpful for intuition) is the information/order-theoretic reading: one often compares values by saying that (t_1, f_1) carries "at least as much truth support" as (t_2, f_2) when $t_1 \geq t_2$, and "at least as much falsity support" when $f_1 \geq f_2$. On this reading, $\wedge$ and $\vee$ behave as lattice operations that are conservative with respect to evidence: $\wedge$ does not invent truth support (it uses* min*), and $\vee$ does not invent falsity support (it uses* min *on f). This is one precise sense in which the calculus is paraconsistent: high truth support and high falsity support can co-exist (e.g. $(0.9, 0.9)$), and the algebra keeps both components available rather than forcing an immediate collapse to a single classical value.*

Remark 2545. *It is also useful to separate two distinct "crispifications" of a two-component value: (i) the designatedness predicate $\mathrm{Desig}_\tau(t,f)$, which depends only on t, and (ii) a potential (not used here) "anti-designation" predicate based on f. The present section deliberately commits only to (i), because explicit communion and beauty (as used in Section 24) are controlled by whether the episode clears a truth-support threshold, while falsity-support remains available to model tension, ambiguity, or countervailing evidence without immediately destroying designatedness.*

HT24.10 (Designation of conjunction/disjunction). For any $b_1, b_2 \in B$,

$$\mathrm{Desig}_\tau(b_1 \wedge b_2) \iff \mathrm{Desig}_\tau(b_1) \;\wedge\; \mathrm{Desig}_\tau(b_2),$$

$$\mathrm{Desig}_\tau(b_1 \vee b_2) \iff \mathrm{Desig}_\tau(b_1) \;\vee\; \mathrm{Desig}_\tau(b_2).$$

Remark 2546. *In plain terms: at the level of* designatedness *(what we will treat as "passing the threshold"), conjunction behaves like logical "and" and disjunction behaves like logical "or," even though the underlying truth values are two-component objects. This is precisely why threshold-designation is useful: it turns graded, paraconsistent truth values into crisp predicates for subsequent reasoning.*

Remark 2547. *A concrete numerical example can be helpful. Let $\tau = 0.7$, $b_1 = (0.8, 0.1)$ and $b_2 = (0.6, 0.9)$. Then $b_1 \wedge b_2 = (\min(0.8, 0.6), \max(0.1, 0.9)) = (0.6, 0.9)$, which is* not *designated at $\tau = 0.7$; indeed b_2 was not designated. Meanwhile $b_1 \vee b_2 = (\max(0.8, 0.6), \min(0.1, 0.9)) = (0.8, 0.1)$, which* is *designated; indeed b_1 was designated. This mirrors the equivalences in HT24.10 while illustrating that the falsity component may move in the opposite direction under $\wedge$ versus $\vee$, without affecting designatedness.*

Proof sketch. The truth component of $b_1 \wedge b_2$ is $\min(t_1, t_2)$, so it exceeds τ iff both t_1, t_2 do. The truth component of $b_1 \vee b_2$ is $\max(t_1, t_2)$, so it exceeds τ iff at least one does.

Remark 2548. *The strategy is to ignore the falsity component because* Desig_τ *depends only on the truth component. Then the proof becomes the elementary equivalences:* $\min(t_1, t_2) \geq \tau \Leftrightarrow (t_1 \geq \tau \wedge t_2 \geq \tau)$ *and* $\max(t_1, t_2) \geq \tau \Leftrightarrow (t_1 \geq \tau \vee t_2 \geq \tau)$. *Visually, in the unit square for* (t, f), *designatedness is the half-strip* $t \geq \tau$; *min and max correspond to intersections and unions of such strips.*

Remark 2549. *Two immediate corollaries (used implicitly when chaining "episode conditions" in Section 24) are:*

$$\mathrm{Desig}_\tau(b \wedge b) \iff \mathrm{Desig}_\tau(b), \qquad \mathrm{Desig}_\tau(b \vee b) \iff \mathrm{Desig}_\tau(b),$$

and the monotonicity principle

$$\mathrm{Desig}_\tau(b_1) \;\Rightarrow\; \mathrm{Desig}_\tau(b_1 \vee b_2), \qquad \mathrm{Desig}_\tau(b_1 \wedge b_2) \;\Rightarrow\; \mathrm{Desig}_\tau(b_1),$$

which are just the idempotence/weakening patterns familiar from classical reasoning, recovered at the level of designatedness even though the underlying values remain two-component. These are frequently the only properties needed when the formal role of $\wedge, \vee$ *is to combine multiple "support conditions" into a single acceptability judgment.*

HT24.11 (De Morgan laws hold at the level of truth values). For any $b_1, b_2 \in B$,

$$\neg(b_1 \wedge b_2) = (\neg b_1) \vee (\neg b_2), \qquad \neg(b_1 \vee b_2) = (\neg b_1) \wedge (\neg b_2).$$

Remark 2550. *This asserts that the algebra of truth values is well-behaved: even though we are not in classical two-valued logic, the familiar De Morgan transformations remain exactly correct* as equalities in B. *This matters because explicit communion and beauty are built using these connectives, and we want standard rewrites to remain valid when manipulating formulas symbolically.*

Remark 2551. *Note that HT24.11 is stronger than a mere claim about designatedness. For example, it is* not *generally true that* $\mathrm{Desig}_\tau(\neg b)$ *is determined by* $\mathrm{Desig}_\tau(b)$ *alone, because* $\mathrm{Desig}_\tau(\neg(t, f))$ *depends on* f, *not on* t. *Thus, having De Morgan at the level of full values (rather than merely at the level of designatedness) is what allows one to push negations inward when one later wants to track both supportive and counter-supportive evidence through a construction.*

Proof sketch. Expand both sides componentwise using swap/min/max identities: $\neg(\min t, \max f) = (\max f, \min t)$ etc.

Remark 2552. *The proof is pure algebra on min/max operations plus the swap defining negation. The key observation is that swap interchanges the roles of min and max in exactly the way De Morgan requires. A helpful mental picture is to regard* (t, f) *as a point and negation as reflection across the diagonal* $t = f$; *then the lattice operations interact with this reflection in the familiar De Morgan fashion.*

Remark 2553. *One can also view HT24.11 as the statement that* $\neg$ *is an involutive order-reversing symmetry of the* $(\wedge, \vee)$*-structure on* B: *indeed* $\neg\neg(t, f) = (t, f)$, *and the equalities in HT24.11 say precisely that* $\neg$ *converts meets to joins and joins to meets. This is the algebraic reason that "dual" formulations of a condition (e.g. phrasing an episode criterion negatively versus positively) can be shown equivalent without changing the intended two-component semantics.*

HT24.12 (Explicit communion implies communion; threshold monotonicity). By definition,

$$\mathrm{ExplComm}(C, I; w) \;\Rightarrow\; \mathrm{Comm}(C, I; w).$$

Moreover, if $\tau' \leq \tau$ then ExplComm at threshold τ implies ExplComm at threshold τ'.

Remark 2554. *Explicit communion is designed as a strengthening of communion: it requires communion* and *additional designated statements about the episode (in Section 24). So the first implication is a formal reminder that explicit communion cannot hold in the absence of communion. Threshold monotonicity is equally intuitive: if something clears a higher bar τ, it clears any lower bar τ'. This is a typical pattern when using designatedness as a control knob for strictness (Hyperseed-Concept 87).*

Remark 2555. *The second clause (monotonicity in τ) is frequently used operationally as follows: one proves an episode is explicitly communal at some "strict" setting of the model, and then immediately inherits explicit communion at all weaker settings. This allows later arguments to fix a convenient threshold for a technical lemma without losing the ability to apply the result in a more permissive regime. In applications to beauty in Section 24, this is the formal counterpart of the intuition that raising standards can rule out borderline cases, but cannot create new ones.*

Proof sketch. ExplComm includes Comm as a conjunct. Also, $\mathrm{Desig}_\tau(b)$ implies $\mathrm{Desig}_{\tau'}(b)$ whenever $\tau' \leq \tau$.

Remark 2556. *The proof is a direct unwrapping of definitions: one part is propositional logic on the conjunctive definition, the other part is the monotonicity of an inequality $t \geq \tau$ with respect to τ. A visual intuition is that as τ decreases, the designated region $t \geq \tau$ in the unit square expands.*

Remark 2557. *For later use, it is often convenient to isolate the underlying monotonicity fact as a stand-alone inference: for any $b \in B$ and any $\tau' \leq \tau$,*

$$\mathrm{Desig}_\tau(b) \Rightarrow \mathrm{Desig}_{\tau'}(b).$$

When explicit communion is defined by a conjunction of multiple designated constraints, HT24.10 then propagates this monotonicity through the whole definition: lowering the threshold can only add designated conjuncts (never remove them), so the explicit-communion condition becomes easier to satisfy. This is the formal mechanism by which the threshold parameter acts as a single global knob controlling strictness across all component criteria.

45.3 Scope and spiritual communion

HT24.13 (Scope is monotone in its components). For fixed $\alpha \in [0, 1]$, if $H_n(I) \geq H_m(I)$ and $D_n(I) \geq D_m(I)$ then

$$\mathrm{Scope}(n, I) = \alpha H_n(I) + (1 - \alpha) D_n(I) \;\geq\; \alpha H_m(I) + (1 - \alpha) D_m(I) = \mathrm{Scope}(m, I).$$

Remark 2558. Scope *is an affine blend of two quantities, H and D, with weights α and $1-\alpha$. Thus it preserves the partial order: increasing either component cannot decrease scope. Conceptually, this lets one reason about spiritual communion by independently bounding the "height"-like and "depth"-like aspects that contribute to scope (Hyperseed-Concept 86 and 178 are relevant framings).*

Proof sketch. Affine monotonicity in each argument when $\alpha \in [0, 1]$.

Remark 2559. *Unpacking the "affine monotonicity" statement explicitly: since $\alpha \geq 0$, the inequality $H_n(I) \geq H_m(I)$ implies*

$$\alpha H_n(I) \;\geq\; \alpha H_m(I),$$

and since $1-\alpha \geq 0$, the inequality $D_n(I) \geq D_m(I)$ implies

$$(1-\alpha)D_n(I) \;\geq\; (1-\alpha)D_m(I).$$

Adding these two inequalities yields the displayed conclusion. This is the only reasoning used, and it highlights that no special structural properties of H or D are required beyond being real-valued.

Remark 2560. *The strategy is to use that multiplying an inequality by a nonnegative scalar preserves it, and adding inequalities preserves it. The only role of $\alpha \in [0,1]$ is to guarantee nonnegativity of both coefficients α and $1-\alpha$. Geometrically,* Scope *is a projection onto a line segment in the (H,D)-plane with nonnegative slope in each coordinate.*

Remark 2561. *Two endpoint cases are worth keeping in mind when interpreting the lemma. If $\alpha = 0$ then $\mathrm{Scope}(n,I) = D_n(I)$ and the statement reduces to monotonicity of D alone; if $\alpha = 1$ then $\mathrm{Scope}(n,I) = H_n(I)$ and the statement reduces to monotonicity of H alone. For intermediate $\alpha \in (0,1)$, both components contribute, but the argument remains componentwise because the combination is coordinatewise nondecreasing. In particular, the lemma is robust under ties: if $H_n(I) = H_m(I)$ (or $D_n(I) = D_m(I)$), the conclusion still holds with equality contributed by that component.*

Remark 2562. *One can also phrase HT24.13 as: the map $(H,D) \mapsto \alpha H + (1-\alpha)D$ is order-preserving with respect to the product order on $\mathbb{R}^2$ when $\alpha \in [0,1]$. Equivalently, its gradient vector $(\alpha, 1-\alpha)$ lies in the nonnegative orthant, so moving "northeast" in the (H,D)-plane cannot decrease* Scope. *This viewpoint clarifies why the lemma would fail if α were allowed outside $[0,1]$: a negative coefficient would reverse the inequality for its component.*

HT24.14 (Sufficient conditions for spiritual communion). Assume $\alpha \in [0,1)$ and $\delta > 0$. If $\mathrm{Comm}(\{m,n\}, I; w)$ and

$$D_n(I) - D_m(I) \;\geq\; \frac{\delta}{1-\alpha} \quad \text{and} \quad H_n(I) \geq H_m(I),$$

then $\mathrm{Scope}(n,I) \geq \mathrm{Scope}(m,I) + \delta$, hence (m,n) satisfies the scope-inequality condition in the definition of spiritual communion.

Remark 2563. *This lemma isolates a simple sufficient condition for the "scope gap" part of spiritual communion: if n exceeds m in both components, and the D-advantage is large enough to compensate for the weighting $(1-\alpha)$, then n's scope exceeds m's by at least δ. The $\alpha \in [0,1)$ assumption matters because if $\alpha = 1$ then D would carry no weight and no D-gap could help. This supports algorithmic reasoning: one can check the displayed inequalities to certify the scope condition without re-deriving it.*

Remark 2564. *The displayed inequality*

$$D_n(I) - D_m(I) \;\geq\; \frac{\delta}{1-\alpha}$$

should be read as a "required raw D-margin" given a target scope margin δ and a mixing weight $(1-\alpha)$. As α increases toward 1, the coefficient on D decreases and the required D-margin blows up, reflecting that D becomes less influential in scope. Conversely, when α is small, the condition becomes close to $D_n(I) - D_m(I) \geq \delta$, since then $(1-\alpha) \approx 1$.

Proof sketch. Use $\mathrm{Scope}(n,I)-\mathrm{Scope}(m,I) = \alpha(H_n-H_m)+(1-\alpha)(D_n-D_m)$ and lower-bound the RHS by $(1-\alpha)\cdot\delta/(1-\alpha)=\delta$.

Remark 2565. *Spelling out the algebra in the proof sketch: start from*

$$\mathrm{Scope}(n,I)-\mathrm{Scope}(m,I) = \big(\alpha H_n(I)+(1-\alpha)D_n(I)\big) - \big(\alpha H_m(I)+(1-\alpha)D_m(I)\big),$$

then regroup terms to obtain

$$\mathrm{Scope}(n,I)-\mathrm{Scope}(m,I) = \alpha\big(H_n(I)-H_m(I)\big)+(1-\alpha)\big(D_n(I)-D_m(I)\big).$$

Now $\alpha \geq 0$ and $H_n(I)-H_m(I)\geq 0$ imply $\alpha(H_n(I)-H_m(I))\geq 0$, hence

$$\mathrm{Scope}(n,I)-\mathrm{Scope}(m,I) \;\geq\; (1-\alpha)\big(D_n(I)-D_m(I)\big).$$

Finally, substitute the assumption $D_n(I)-D_m(I)\geq \delta/(1-\alpha)$ and use $1-\alpha>0$ (which is why $\alpha\in[0,1)$ is required) to conclude

$$\mathrm{Scope}(n,I)-\mathrm{Scope}(m,I) \;\geq\; (1-\alpha)\cdot\frac{\delta}{1-\alpha}=\delta,$$

which is equivalent to $\mathrm{Scope}(n,I)\geq \mathrm{Scope}(m,I)+\delta$.

Remark 2566. *The proof is a standard "difference-of-affine-expressions" manipulation. The key step is bounding $\alpha(H_n-H_m)$ below by 0 using $H_n\geq H_m$ and $\alpha\geq 0$, so that the entire difference is controlled by the D-term. A helpful picture is that H can only help, so we ignore it and demand that D alone guarantees the desired margin.*

Remark 2567. *A concrete numerical sanity check can help fix intuition. Take $\alpha=\frac{1}{2}$ and $\delta=1$. Then the condition requires $D_n(I)-D_m(I)\geq\delta/(1-\alpha)=2$, together with $H_n(I)\geq H_m(I)$. Indeed, if $H_n(I)=H_m(I)$ and $D_n(I)=D_m(I)+2$, then*

$$\mathrm{Scope}(n,I)-\mathrm{Scope}(m,I)=\tfrac{1}{2}\cdot 0+\tfrac{1}{2}\cdot 2=1=\delta.$$

If, in addition, $H_n(I)>H_m(I)$, the scope gap becomes strictly larger than δ. This illustrates the lemma's role as a sufficient condition: it is intentionally conservative by allowing the H-term to be dropped.

Remark 2568. *The assumption* $\mathrm{Comm}(\{m,n\},I;w)$ *is carried as a hypothesis because the definition of spiritual communion typically combines a scope-inequality with other non-scope conditions (e.g. compatibility, mutual accessibility, or w-dependent constraints). HT24.14 only addresses the scope-inequality component: it says that once the non-scope parts of* Comm *are already satisfied, the displayed inequalities suffice to force the required scope gap. In that sense, the lemma modularizes the verification of spiritual communion into (i) checking non-scope constraints and (ii) checking a simple numeric margin condition on (H,D).*

45.4 Entheogens, emotion, compassion

HT24.15 (Margin-crossing intervention implies communion). Let w be baseline and w_E the intensity datum after an intervention E. If $\mathrm{DComm}(C,I;w)\leq 0$ but $\mathrm{DComm}(C,I;w_E)>0$, then $\mathrm{Comm}(C,I;w_E)$ holds.

Remark 2569. *This formalizes a very direct causality pattern: an intervention that pushes the system across the "communion boundary" (turning nonpositive margin into positive margin) yields communion by definition. In Section 24, interventions may include entheogens, emotional catalysts, or structured practices (Hyperseed-Concept* **??**, **??**, *and 176). The lemma is useful because it allows a reasoner to treat the sign of* DComm *as the single decisive quantity.*

Remark 2570. *Note that the hypothesis uses a weak inequality at baseline and a strict inequality after the intervention. This matches the intended boundary semantics:* $\mathrm{DComm}(C, I; w) = 0$ *represents a knife-edge case (exactly on the boundary), and the theorem asserts that any strict improvement into* $\mathrm{DComm} > 0$ *suffices for communion. In particular, no assumptions are needed about how E produces the change (e.g. whether by increasing* Wcross*, decreasing* Win*, or both); only the sign-change matters.*

Remark 2571. *When modeling interventions such as entheogens or emotional catalysts, it is common that w_E changes multiple ingredients at once: attention allocation, salience weighting of shared cues, suppression of distractors, or re-interpretation of the same stimulus I. HT24.15 is intentionally agnostic about mechanism, so that one may first establish* $\mathrm{DComm}(C, I; w_E) > 0$ *by any available argument (empirical, phenomenological, or derived from lower-level lemmas) and then immediately conclude communion at the level of* Comm*.*

Proof sketch. By definition, communion is equivalent to $\mathrm{DComm} > 0$.

Remark 2572. *The proof is definition-chasing: once* $\mathrm{DComm}(C, I; w_E) > 0$ *is known,* $\mathrm{Comm}(C, I; w_E)$ *follows immediately. Geometrically, the intervention moves the point* $(\mathrm{Wcross}, \mathrm{Win})$ *from on/below the diagonal to strictly above it.*

Remark 2573. *A helpful way to read the geometry is to interpret the diagonal* $\mathrm{Wcross} = \mathrm{Win}$ *as the set where the cross-supported and within-supported contributions are exactly balanced. The conclusion does not require knowing the location of the baseline point beyond "not above the diagonal," and the intervention conclusion uses only that the post-intervention point lies in the open half-plane* $\mathrm{Wcross} > \mathrm{Win}$*. Thus the lemma isolates a binary predicate (above/below a boundary) from any finer-grained quantitative story.*

HT24.16 (Sufficient condition for an intervention to increase communion margin). If an intervention E satisfies

$$\mathrm{Wcross}(C, I; w_E) \geq \mathrm{Wcross}(C, I; w) \quad \text{and} \quad \mathrm{Win}(C, I; w_E) \leq \mathrm{Win}(C, I; w),$$

then $\mathrm{DComm}(C, I; w_E) \geq \mathrm{DComm}(C, I; w)$.

Remark 2574. *This is a clean sufficient condition for "communion-improving" interventions: make cross-supported intensity larger (or equal) while making within-supported intensity smaller (or equal). It matches the intuitive goal of many practices: cultivate shared attention and shared meaning while quieting isolating internal noise. As a simple example, synchrony rituals could increase pairwise and group patterns while decreasing idiosyncratic rumination.*

Remark 2575. *The condition is intentionally one-sided (sufficient, not necessary). Many real interventions plausibly raise both* Wcross *and* Win*; for instance, heightened affect may increase both shared resonance and private imagery. In such cases, HT24.16 may not apply directly, but it still provides a baseline comparison tool: if one can bound the change in* Wcross *from below and the change in* Win *from above, then a net margin increase follows.*

Remark 2576. *The weak inequalities also matter: an intervention that leaves* Wcross *unchanged while reducing* Win *is still margin-improving, and conversely leaving* Win *unchanged while increasing* Wcross *is also margin-improving. Thus the lemma captures two conceptually distinct routes to increasing communion margin: "build bridges" (increase cross support) and "reduce self-noise" (decrease within support).*

Proof sketch. Subtract the two inequalities: $(\mathrm{Wcross}_E - \mathrm{Win}_E) \geq (\mathrm{Wcross} - \mathrm{Win})$.

Remark 2577. *The proof strategy is to recognize* DComm *as a difference and apply monotonicity of subtraction in the ordered reals (or extended reals). The key step is that the hypotheses are already exactly the two components needed to compare the differences. Visually: move right (increase* Wcross*) and move down (decrease* Win*) in the* $(\mathrm{Wcross}, \mathrm{Win})$ *plane; both motions increase the vertical distance above the diagonal.*

Remark 2578. *If* Wcross *and* Win *are allowed to take values in an extended ordered domain (e.g.* ∞ *as a formal supremum of intensities), then the monotonicity reasoning still goes through provided the difference* $\mathrm{Wcross} - \mathrm{Win}$ *is interpreted in the same domain where it is defined. In applications, one typically ensures finiteness by construction (e.g. by summability of pattern intensities), but the lemmas algebraic form makes clear that only the order properties are used, not any measure-theoretic subtleties.*

Remark 2579. *Combining HT24.16 with HT24.15 yields a practical two-step template: (i) prove the intervention weakly increases margin, and (ii) check that the post-intervention margin is strictly positive (or that the weak increase carries a nonpositive baseline into positivity). This mirrors how one might argue about structured practices: show they systematically push in the "right direction," then argue that, for some range of parameters or some subjects, the push is large enough to cross the communion boundary.*

HT24.17 (Compassion forces nonzero cross-supported intensity). If m has a compassion episode toward m_0 on I (Definition 377), then for the dyad $\{m, m_0\}$,

$$\mathrm{Wcross}(\{m, m_0\}, I; w) > 0.$$

Remark 2580. *Compassion is treated here not merely as an inner sentiment but as something that* couples *minds through cross-supported patterns. Thus, in the formalism, a compassion episode entails the existence of at least one positive-intensity pattern supported on the dyad. This links the ethical-phenomenological notion of compassion (Hyperseed-Concept 81) to a crisp algebraic consequence.*

Remark 2581. *The dyadic restriction* $\{m, m_0\}$ *is important: the lemma does not claim that compassion instantly creates cross-supported intensity at the level of a larger community* C*, only that it forces at least one nontrivial cross-supported contribution on the specific pair involved. In later uses, this dyadic guarantee can serve as a "seed" for larger communion arguments, e.g. by aggregation lemmas that lift pairwise cross-supported patterns to group-level* $\mathrm{Wcross}(C, I; w)$ *under additional connectivity or propagation assumptions.*

Remark 2582. *Conceptually, the conclusion* $\mathrm{Wcross} > 0$ *distinguishes compassion from purely solipsistic concern. One might imagine a private affective episode that involves thoughts* about m_0 *while remaining entirely within-supported; Definition 377 rules this out by building in an explicit cross-mind coupling requirement. HT24.17 is the algebraic footprint of that design choice.*

Proof sketch. Definition 377 requires coupling to cross-mind patterns supported on $\{m, m_0\}$ with positive intensity; summing yields a positive cross total.

Remark 2583. *The proof is existential-to-sum: if at least one summand in a nonnegative sum is strictly positive, then the sum is strictly positive. The key step is that Definition 377 guarantees such a positive-intensity dyadic pattern exists. A visual intuition is that compassion creates at least one "bridge" edge between two nodes; the total cross weight on that dyad cannot be zero.*

Remark 2584. *If* $\mathrm{Wcross}(\{m, m_0\}, I; w)$ *is defined as a sum (or integral) over cross-supported patterns with nonnegative intensities, then the argument can be phrased as: Definition 377 provides a witness pattern* p *with intensity* $\mathrm{W}(p) > 0$ *and support contained in* $\{m, m_0\}$*, hence* p *contributes strictly positively to* $\mathrm{Wcross}(\{m, m_0\}, I; w)$*, and nonnegativity of all other contributions prevents cancellation. This makes explicit that the lemma depends on the "no negative intensity" convention for pattern weights.*

Remark 2585. *HT24.17 can be paired with HT24.16 as follows: a compassion episode can be seen as an intervention that (at least locally, on the dyad) increases* Wcross *from* 0 *to a positive value, thereby tending to increase* DComm *on that dyad. Additional hypotheses would be needed to conclude full communion* $\mathrm{Comm}(\{m, m_0\}, I; w)$*, since* Win *might also be large; nevertheless, the lemma supplies a guaranteed positive cross term that later bounds can leverage.*

45.5 Beauty as paraconsistent "surprising fulfillment"

Fix a designation threshold $\tau \in (0, 1]$. Recall the valuation assignments:

$$v_m(\mathrm{Ful}(B)) = (\min\{1, \mathrm{Ful}_m(B; I)\},\ 1 - \min\{1, \mathrm{Ful}_m(B; I)\}),$$

$$v_m(\mathrm{Sur}(B)) = \Big(\min\{1, \frac{\mathrm{Sur}_m(B; I)}{\mathrm{Sur}_m(B; I) + 1}\},\ 1 - \min\{1, \frac{\mathrm{Sur}_m(B; I)}{\mathrm{Sur}_m(B; I) + 1}\}\Big),$$

and $\mathrm{Beaut}(B) := \mathrm{Ful}(B) \wedge \mathrm{Sur}(B)$.

Remark 2586. *The notation* $v_m(\cdot)$ *denotes the paraconsistent truth value in* $B = [0, 1]^2$ *assigned by mind* m *to a predicate. Here,* $\mathrm{Ful}_m(B; I) \in (0, 1]$ *is a numeric fulfillment score and* $\mathrm{Sur}_m(B; I) \in [0, \infty]$ *is a numeric surprise score (see Section 24). The maps* $x \mapsto (\min\{1, x\}, 1 - \min\{1, x\})$ *and* $s \mapsto (\min\{1, s/(s + 1)\}, 1 - \min\{1, s/(s + 1)\})$ *embed these numeric scores into the* B*-truth-value space. The operator* $\mathrm{Beaut}(B) := \mathrm{Ful}(B) \wedge \mathrm{Sur}(B)$ *then expresses the intended conjunction: beauty is "fulfilled and surprising" (Hyperseed-Concept 53,* **??** *is not listed but compare* **??***, and 130). The paraconsistent framing echoes Peirce's triadic sensibility about qualities, reactions, and mediations [14], and Whitehead's emphasis on the processual synthesis of feeling and form [15], while remaining technically grounded in the designation calculus above [23].*

HT24.18 (Designated fulfillment is a direct numeric threshold). Since $\mathrm{Ful}_m(B; I) \in (0, 1]$, we have

$$\mathrm{Desig}_\tau\big(v_m(\mathrm{Ful}(B))\big) \iff \mathrm{Ful}_m(B; I) \geq \tau.$$

Remark 2587. *This lemma says that the somewhat elaborate-looking valuation* $v_m(\mathrm{Ful}(B))$ *does not distort thresholds: designatedness at level* τ *is exactly the underlying numeric condition* $\mathrm{Ful}_m \geq \tau$*. So the paraconsistent embedding is, in this case, simply a convenient representation that preserves the operative inequality.*

Proof sketch. Here $\min\{1, \mathrm{Ful}_m\} = \mathrm{Ful}_m$, so the designatedness condition $t \geq \tau$ is exactly $\mathrm{Ful}_m \geq \tau$.

Remark 2588. *The proof strategy is simplification using the range restriction* $\mathrm{Ful}_m(B; I) \in (0, 1]$. *The key step is observing that* $\min\{1, x\} = x$ *on this interval. Visually: the embedding is the identity on the first coordinate for fulfillment, so thresholding is unchanged.*

HT24.19 (Designated surprise is a rational inequality in Sur_m). Assume $\tau \in (0, 1)$. Then

$$\mathrm{Desig}_\tau\big(v_m(\mathrm{Sur}(B))\big) \iff \frac{\mathrm{Sur}_m(B; I)}{\mathrm{Sur}_m(B; I) + 1} \geq \tau \iff \mathrm{Sur}_m(B; I) \geq \frac{\tau}{1 - \tau}.$$

(If $\tau = 1$, then designatedness requires $\mathrm{Sur}_m(B; I) = +\infty$.)

Remark 2589. *Unlike fulfillment, surprise is mapped through a saturating transform* $s \mapsto s/(s+1)$ *that converts* $[0, \infty]$ *to* $[0, 1)$*, so a threshold on the transformed value corresponds to a* nonlinear *threshold on* Sur_m*. The inequality* $\mathrm{Sur}_m \geq \tau/(1-\tau)$ *shows how demanding large* τ *becomes: as* $\tau \uparrow 1$*, the required surprise diverges. This matches the intuition that "maximally designated surprise" is only achievable in an infinite-surprise limit.*

Proof sketch. Solve $\mathrm{Sur}/(\mathrm{Sur} + 1) \geq \tau$: $\mathrm{Sur} \geq \tau(\mathrm{Sur} + 1) = \tau\mathrm{Sur} + \tau$, so $(1 - \tau)\mathrm{Sur} \geq \tau$ hence $\mathrm{Sur} \geq \tau/(1 - \tau)$.

Remark 2590. *The proof is algebraic rearrangement of a rational inequality. The key step is that* $1 - \tau > 0$ *when* $\tau \in (0, 1)$*, allowing division without flipping the inequality. Geometrically,* $s/(s+1)$ *is an increasing concave curve approaching* 1 *asymptotically, so hitting a high threshold requires disproportionately large* s*.*

HT24.20 (Beauty designatedness factorizes into two numeric thresholds). For $\tau \in (0, 1)$,

$$\mathrm{Desig}_\tau\big(v_m(\mathrm{Beaut}(B))\big) \iff \big(\mathrm{Ful}_m(B; I) \geq \tau\big) \ \wedge\ \big(\mathrm{Sur}_m(B; I) \geq \tau/(1 - \tau)\big).$$

Remark 2591. *This is the operational heart of the beauty formalism: once one fixes* τ*, beauty becomes a pair of ordinary numeric inequalities. Thus the paraconsistent connective* $\wedge$ *plus designatedness translates to a crisp conjunction of bounds on fulfillment and surprise. In other words, the "mystery" of beauty is not placed in the logic; it is placed in how* Ful_m *and* Sur_m *are computed in Section 24.*

Proof sketch. By HT24.10, designatedness of $\wedge$ is equivalent to designatedness of both conjuncts; then apply HT24.18–HT24.19.

Remark 2592. *The proof strategy is compositional: (i) reduce designatedness of a conjunction to conjunction of designatedness, then (ii) rewrite each designatedness statement into a numeric inequality using the previous lemmas. This is a typical pipeline in paraconsistent threshold logics: algebraic laws + threshold rules yield executable conditions.*

HT24.21 (Beauty-to-OEI rule schema). Suppose a system provides monotone functionals $\mathrm{GI}, \mathrm{GT}, \mathrm{SelfC}$ satisfying: (i) GI is nondecreasing in Ful_m; (ii) GT is nondecreasing in Sur_m and in SelfC; and thresholds $\theta_F, \theta_S, \theta_C$ such that $\mathrm{Ful}_m \geq \theta_F \Rightarrow \mathrm{GI} > 0$ and $\mathrm{Sur}_m \geq \theta_S \ \wedge\ \mathrm{SelfC} \geq \theta_C \Rightarrow \mathrm{GT} > 0$. Then a beauty episode together with $\mathrm{SelfC} \geq \theta_C$ implies OEI-activity (i.e. $\mathrm{GI} > 0$ and $\mathrm{GT} > 0$).

Remark 2593. *This is an abstract "rule schema" connecting the phenomenology of beauty to downstream system-level activity (OEI), assuming only monotonicity and threshold-trigger behavior of certain functionals. Its conceptual role is to make Theorem 21 usable in automated reasoning: rather than re-proving the entire theorem, one checks monotonicity and threshold premises, then applies the schema. In the broader cognitive-systems literature, such monotonicity-based triggers are common when modeling attention allocation, intrinsic motivation, and self-model consistency; compare related perspectives in [19]. In particular, the point is that the premises are deliberately* structural*: they do not depend on the internal construction of the OEI variables, only on their order-respecting response to increases in the relevant "driving" quantities (here: fulfillment and surprise). This matches how such subsystems are often implemented in practice (or idealized in theory): a downstream module does not need to know* why *an upstream signal is high, only that once it is high enough it reliably crosses an activation boundary. Formally, the schema can be read as a reusable inference template: from designatedness of the relevant upstream predicates one extracts real-valued lower bounds, and from those lower bounds one invokes threshold axioms to conclude positivity (or activation) of the corresponding OEI channels. Finally, the emphasis on "designated" (rather than, say, classical truth) is intentional: the schema is compatible with paraconsistent settings in which a state may carry conflicting information while still permitting forward progress on designated consequences.*

Proof sketch. This is exactly the reasoning pattern of Theorem 21: beauty designated implies both $\mathrm{Ful}(B)$ and $\mathrm{Sur}(B)$ designated (HT24.10), giving numeric lower bounds (HT24.18–HT24.19), which trigger $\mathrm{GI} > 0$ and $\mathrm{GT} > 0$ by the threshold assumptions. Equivalently, the proof has the canonical "decode then activate" shape: one first *decodes* logical/phenomenological predicates into quantitative constraints, and then *activates* the downstream consequences by applying monotone threshold rules. A useful way to view the threshold assumptions is as implications of the form

$$\mathrm{Ful}(B) \text{ designated} \wedge \mathrm{Ful}(B) \geq \theta_I \ \Rightarrow\ \mathrm{GI} > 0, \qquad \mathrm{Sur}(B) \text{ designated} \wedge \mathrm{Sur}(B) \geq \theta_T \ \Rightarrow\ \mathrm{GT} > 0,$$

for fixed thresholds θ_I, θ_T (the exact constants are immaterial to the schema as long as they exist and are used consistently). Monotonicity enters by ensuring that once the decoded value meets or exceeds the threshold, any strengthening of the antecedent (e.g. higher fulfillment/surprise) cannot "turn off" the activation conclusion; this is the minimal stability property needed for reliable downstream inference.

Remark 2594. *The proof strategy is a chain of implications:*

$$\textit{beauty} \Rightarrow (\textit{fulfillment} \wedge \textit{surprise}) \Rightarrow (\textit{numeric bounds}) \Rightarrow (\mathrm{GI} > 0 \wedge \mathrm{GT} > 0).$$

The key steps are exactly where earlier helper theorems are invoked, showing the internal connectivity of this section: HT24.10 provides logical factorization, and HT24.18–HT24.19 provide numeric decoding. As a visual intuition, imagine two gauges (fulfillment and surprise) with needles; beauty means both needles exceed their marks, and the OEI subsystems are wired to activate when their respective gauges exceed pre-set thresholds. One can also read the chain as separating semantic *from* operational *content: the first arrow is a semantic axiom about how "beauty" decomposes into the two constituent phenomenological modes, while the latter arrows are operational axioms describing how numeric estimates drive internal activity. This separation is what makes the rule schema portable: any alternative model that preserves the same factorization (beauty entails both components) and the same decoding/threshold interface will admit the same conclusion, even if the internal realization of* GI *and* GT *differs. In automated reasoning terms, HT24.10 plays the role of introducing two subgoals from a single goal (a conjunction introduction in the forward direction),* *whereas HT24.18–HT24.19 discharge those subgoals by replacing them with inequalities that are compatible with arithmetic solvers. The "two gauges" picture can be sharpened slightly: the needles need not represent conscious reports; they may represent any internal scores whose increase is monotone with respect to accumulating evidence for fulfillment and surprise, so that the activation can be robust even under partial, noisy, or inconsistent inputs.*

45.6 Artifacts, archetypes, and communion capacity

HT24.22 (From "art object" to positive communion capacity under joint-attention dominance). Let A be an art object for a population X (Definition 383), and assume joint attention to A creates cross-supported patterns whose intensities increase with the number of participants who undergo beauty episodes, while within-mind intensities do not increase faster than cross-mind intensities. Then the communion capacity $\Gamma_{\mathrm{Comm}}(A; C, I)$ is positive for a substantial measure of (C, I).

Remark 2595. *This statement formalizes a familiar observation from aesthetics and social psychology: shared attention to an artifact can synchronize minds, generating shared patterns that outweigh purely private responses. In the Hyperseed vocabulary, this links Art and Aesthetics (Hyperseed-Concept 53) to Attention/Attentional Focus (60) and to Archetypal resonance (58) insofar as art objects often function by evoking widely shared templates. The lemma is also a bridge between the formal notion of beauty episodes (previous subsection) and the aggregate notion of communion capacity, i.e. the ability of an artifact to reliably induce communion across many contexts.*

Beyond the informal reading, it is helpful to keep the quantifier structure in view: the hypothesis is not merely that some individuals have beauty episodes, but that, conditioned on *joint attention* to A, the resulting cross-supported patterns admit an intensity scaling with the number of beauty-episode participants. In other words, there is an assumed population-level reinforcement effect: as more agents undergo beauty episodes *together with* attention to A, the cross-mind component (captured by Wcross in the later proof sketch) aggregates in a way that is not matched (or is matched only subdominantly) by purely within-mind amplification. This is precisely the kind of "dominance" condition needed for a robust, measure-theoretic capacity statement, because it converts individual-level events (beauty episodes) into a consistent bias toward DComm > 0 on a non-negligible set of contextual parameters.

The conclusion refers to $\Gamma_{\mathrm{Comm}}(A; C, I)$ being positive for a *substantial measure* of (C, I). Here "substantial" should be read as ruling out a thin exceptional set: the intended content is that the set of contexts (C, I) in which A induces communion is not merely nonempty but occupies positive measure in the ambient context space used to define capacity. This is stronger than an existence statement and weaker than a uniform-for-all statement; it matches the empirical intuition that artworks reliably generate shared experience across many (but not necessarily all) conditions of audience, setting, and interpretive frame.

Proof sketch. Under the hypotheses, joint participation shifts w to w_A in a way that increases Wcross more than Win in expectation, hence increases DComm in expectation. This is the direct proof template of Proposition 37 combined with the definition of Γ_{Comm}.

One way to read the sketch is as an "expected-sign" argument: the joint-attention update $w \mapsto w_A$ is assumed to have an asymmetric effect on the cross-terms versus the within-terms. If one writes (conceptually) the communion-relevant difference as something like

$$\mathrm{DComm}(w_A) = \Phi(\mathrm{Wcross}(w_A), \mathrm{Win}(w_A))$$

for an increasing dependence on cross-supported structure and a non-increasing (or less rapidly increasing) dependence on within-mind structure, then the scaling hypothesis implies that, as the number of beauty-episode participants increases, the expectation of $\mathrm{Wcross}(w_A)$ is driven upward at a rate that outpaces any corresponding increase in $\mathrm{Win}(w_A)$. The proof template of Proposition 37 is then invoked to convert this directional inequality (cross dominates within) into a positive expectation for DComm, and the definition of Γ_{Comm} converts that positive-bias condition into a positive-measure set of contexts where communion is actually achieved. In this sense, Proposition 37 supplies the generic "dominance ⇒ communion" inference pattern, while the present lemma supplies a concrete route to the dominance condition via joint attention to an artifact.

Remark 2596. *The proof strategy is to combine (i) a monotonicity-type argument (cross grows faster than within) with (ii) the definition of capacity as a measure of contexts where communion is achieved. The key step is recognizing that expected growth inequalities translate into a positive-measure set of (C, I) where* $\mathrm{DComm} > 0$*, hence communion holds. A useful image is that the artifact creates a "shared field" whose strength scales superlinearly with the number of jointly attending participants, a dynamic reminiscent of resonance metaphors (Hyperseed-Concept 159) and discussed in broader speculative contexts such as morphic resonance [13], though the present lemma remains purely within the formal definitions of Section 24.*

A further clarification of the monotonicity component is that it is not claiming cross-supported patterns always dominate within-mind patterns, but rather that *the marginal effect of additional jointly attending, beauty-episode participants* preferentially increases cross-mind intensity. This "marginal dominance" is what allows the argument to survive heterogeneity: different viewers may have different baseline within-mind responses, but the incremental contribution from synchronizing attention is assumed to attach mainly to cross-supported structure (e.g. shared interpretive anchors, temporally aligned salience peaks, or convergent affective appraisal), thereby pushing the communion-relevant difference DComm in the positive direction often enough to register in the capacity measure.

It is also useful to note why the lemma is formulated in terms of beauty episodes rather than generic engagement. Within the internal logic of Section 24, beauty episodes are singled out as events that already satisfy certain coherence or integrative criteria (from the previous subsection), making them natural carriers of robust pattern formation. The lemma then asserts that when such episodes occur in a jointly attending group, the resulting cross-supported patterns are not merely additive noise but have a structured intensification property. This is the formal bridge from "individual integrative experience" to "group-level communion" that one expects from artifacts functioning as coordination devices.

Finally, the role of A being an "art object" (Definition 383) is that it supplies a principled restriction on the class of artifacts under discussion: A is not an arbitrary stimulus but one that, by definition, is situated to elicit the relevant episodes and interpretive stabilization across a population X. Under that restriction, the scaling hypothesis can be seen as a formal proxy for familiar mechanisms such as shared conventions, culturally transmitted archetypes, and mutual predictability of attention trajectories while jointly engaging the work. This makes the conclusion—positive $\Gamma_{\mathrm{Comm}}(A; C, I)$ on a substantial set of contexts—a mathematically crisp rendering of the idea that artworks often operate as repeatable generators of communion rather than as purely idiosyncratic, private experiences.

45.7 State-dependent science (useful conditionalization schema)

HT24.23 (Conditioning viewpoint on state-dependent science). Let Σ be a state predicate selecting a class of intervals I (Definition 385). Any predictive or causal claim produced by a "Σ-science" can be treated formally as a *state-conditional* claim (e.g. "$P(\cdot \mid \Sigma)$" or "$P(\cdot \mid \mathrm{do}(\cdot), \Sigma)$"). In particular, if Σ_1 implies Σ_2 (every Σ_1-interval is a Σ_2-interval), then Σ_1-science is a refinement of Σ_2-science (it conditions on a smaller class). Equivalently, one may regard a Σ-science as fixing a context variable (explicitly or implicitly) and then performing ordinary statistical or causal inference within that context; on this reading, the "state" does not add a new inferential primitive, but supplies a conditioning event that sharpens the reference class. Concretely, if a Σ-science asserts a regularity of the form "Y is predictable from X" it is naturally rendered as $P(Y \mid X, \Sigma)$; if it asserts an invariance under intervention, it is naturally rendered as $P(Y \mid \mathrm{do}(X{=}x), \Sigma)$, with Σ functioning as the background regime in which the intervention is contemplated.

Remark 2597. *The point is methodological: "state-dependent science" is not a fundamentally different kind of science, but rather ordinary inference carried out under a restricted regime of system-states. Thus, from the standpoint of probability and causality, it is natural to treat it as conditioning on an event Σ. The refinement claim matches the common Bayesian intuition: stronger conditions yield more specific (and potentially less statistically supported) claims. This connects to the social-computational-probabilistic view of scientific practice in [20] and to the Hyperseed framing of contexts and aspects (Hyperseed-Concept 86). One can also read Σ as bundling together what, in practice, would otherwise appear as scattered "ceteris paribus" clauses, selection criteria, and instrumentation constraints: the formalization makes explicit that the resulting claims are indexed to a regime. In this sense, a Σ-science is not merely a claim about the world but a claim about the world* as encountered under *a controlled (or at least characterized) subset of states; this is the same move by which laboratory science distinguishes "in vitro" from "in vivo" regularities, or by which psychology distinguishes performance "under sleep deprivation" from performance "while rested." The refinement statement then expresses a basic reference-class inclusion: if Σ_1 is a stricter operationalization (say, "rested and caffeinated") than Σ_2 (say, "rested"), then results valid in the stricter class are automatically results in the broader class* as conditionalized claims*, even though their empirical support may be weaker due to fewer admissible intervals.*

Proof sketch. The definition of state-dependent science is a restriction of the epistemic practice to intervals satisfying Σ. Formally, restriction corresponds to conditioning the data-generating process and the accepted-observation regime on Σ. Monotonicity under implication of predicates is then immediate: conditioning on Σ_1 is conditioning on a stronger event than Σ_2. More explicitly, if D denotes the stream of admissible observations/records extracted from intervals, then "doing science under Σ" amounts to working with the conditional model $P(D \mid \Sigma)$ (and, when causal language is used, with $P(D \mid \mathrm{do}(\cdot), \Sigma)$). Any learned parameter θ or derived predictive distribution is thereby indexed to Σ (e.g. $P_\theta(Y \mid X, \Sigma)$). If $\Sigma_1 \Rightarrow \Sigma_2$, then $\{\Sigma_1\text{-intervals}\} \subseteq \{\Sigma_2\text{-intervals}\}$, so the Σ_1-conditioned regime is a sub-regime of the Σ_2-conditioned regime; in the standard measure-theoretic sense, Σ_1 is a stronger conditioning event. (As usual, one tacitly assumes $\mathbb{P}(\Sigma) > 0$ or otherwise works with an appropriate regular conditional probability so that these expressions are well-defined.) The "refinement" language is then simply the statement that the inferential target has been restricted to a smaller reference class, which yields narrower generalizations but typically increases variance/uncertainty due to reduced effective sample size.

Remark 2598. *The strategy is to translate an informal "restrict attention to these intervals" instruction into the formal operation of conditioning. The key step is recognizing that both data* *selection and acceptance criteria can be modeled as parts of the same conditional distribution. Visually: $\Sigma_1 \Rightarrow \Sigma_2$ means Σ_1 carves out a smaller region inside the region carved out by Σ_2; a science conditioned on the smaller region is, by definition, more specialized. In causal terms, the same picture applies: a claim like $P(Y \mid \mathrm{do}(X{=}x), \Sigma)$ should be read as "the effect of setting X to x* within *the Σ-regime," which is often exactly what experimental protocols intend (holding fixed the background state while varying X). This helps prevent a common confusion in informal discussion, where a state-restricted causal claim is mistakenly interpreted as unconditional. The refinement implication also clarifies a practical hierarchy: broad predicates Σ_2 support more data and hence more stable estimates, while narrow predicates Σ_1 support finer-grained, context-sensitive laws; the trade-off is not conceptual but statistical and operational.*

46 Helper theorems for Section 25 (Reality-systems, universe, multiverse, eurycosm)

These helper results are small "algebraic moves" that recur when one reasons about reality-systems, universes, multiverses, and eurycosmic constructions in the Hyperseed-style stack (e.g. [1, 18]). Most of the statements are deliberately elementary: their value is not that they surprise an expert, but that they stabilize a vocabulary of monotonicity, fixed points, and prediction-theoretic certificates that an automated prover (or a tired human) can reuse without re-deriving each time.

Remark 2599. *A recurring philosophical theme in this section is that "realness" is treated operationally: an entity (or hypothesis) counts as more empirically real insofar as conditioning on it improves prediction—a pragmatic criterion reminiscent of a social-computational view of science ([20]) and closely aligned with the Hyperseed core-concepts of Empirical Reality and Reality-System (Hyperseed-Concepts* **??** *and 149).*

46.1 Empirical realness as prediction-loss reduction

Lemma 46.1 (Basic bounds and sign conditions)**.** *Assume the loss is nonnegative and bounded: $0 \le L \le L_{\max}$, so $0 \le \mathrm{Err}_I(\Pi_M) \le L_{\max}$ and likewise for $\mathrm{Err}_I(\Pi_M \mid \mathrm{obs}_I(x))$. Then for $\delta > 0$,*

$$-\frac{L_{\max}}{\delta} \;\le\; \rho_{M,I}(x) \;\le\; \frac{L_{\max}}{\delta}.$$

Moreover:

1. *If conditioning on x does not worsen prediction error, i.e. $\mathrm{Err}_I(\Pi_M \mid \mathrm{obs}_I(x)) \le \mathrm{Err}_I(\Pi_M)$, then $0 \le \rho_{M,I}(x) < 1$.*
2. *$\rho_{M,I}(x) = 0$ iff $\mathrm{Err}_I(\Pi_M \mid \mathrm{obs}_I(x)) = \mathrm{Err}_I(\Pi_M)$.*
3. *If conditioning strictly improves prediction error, then $\rho_{M,I}(x) > 0$; if it strictly worsens it, then $\rho_{M,I}(x) < 0$.*

Remark 2600. Intuitive reading. *The quantity $\rho_{M,I}(x)$ is a normalized "error-reduction score" for treating x as an evidential condition: it compares the baseline predictive error $\mathrm{Err}_I(\Pi_M)$ against the conditional error $\mathrm{Err}_I(\Pi_M \mid \mathrm{obs}_I(x))$, and rescales by $\mathrm{Err}_I(\Pi_M) + \delta$ to keep the fraction well-behaved even when the baseline error is near 0. The sign is the key: positive means "x helps prediction", negative means "x misleads prediction." This is a formal operationalization of the idea that empirical realness is tied to predictive traction (Hyperseed-Concept* **??** *and also* **??***).*

Notation unpacking. *Here M indexes a model-class or mind-model, I indexes an information context or dataset/interaction regime, Π_M is the predictor induced by M (or chosen within M), and $\mathrm{obs}_I(x)$ denotes the observation/event "x occurs" as registered in context I. The notation $\mathrm{Err}_I(\Pi_M \mid \mathrm{obs}_I(x))$ is the prediction loss of Π_M when conditioned on that event. This way of coding "realness as error-reduction" is consonant with the pragmatic stance taken in [20].*

Remark 2601. Why the lemma matters. *Boundedness and sign-conditions are the minimal safety checks that let one use $\rho_{M,I}$ inside larger constructions (e.g. thresholds for predictive adjacency) without having to carry pathological cases everywhere. In proofs downstream, one typically needs only: (i) ρ cannot explode when loss is bounded, and (ii) improvement vs. worsening corresponds exactly to the sign.*

Sketch. Boundedness gives $\mathrm{Err}, \mathrm{Err}(\cdot \mid \cdot) \in [0, L_{\max}]$, so the numerator $\mathrm{Err}_I(\Pi_M) - \mathrm{Err}_I(\Pi_M \mid \mathrm{obs}_I(x))$ lies in $[-L_{\max}, L_{\max}]$ and the denominator is at least δ. For (1), the numerator is in $[0, \mathrm{Err}_I(\Pi_M)]$ and the denominator is $\mathrm{Err}_I(\Pi_M) + \delta > \mathrm{Err}_I(\Pi_M)$. (2) and (3) are immediate from the defining fraction. □

Remark 2602. Proof sketch (high-level strategy). *The argument is a bounding exercise: constrain the numerator by the range of the loss, constrain the denominator away from 0 using $\delta > 0$, and then interpret the sign of a fraction via the sign of its numerator.*

Key step commentary. *The strict inequality < 1 in (1) comes from the fact that the denominator $\mathrm{Err}_I(\Pi_M) + \delta$ is strictly larger than $\mathrm{Err}_I(\Pi_M)$, so even a maximal non-worsening improvement cannot yield ratio 1. This is conceptually important: δ is not merely technical; it builds in a kind of epistemic humility that prevents declaring "perfect" empirical realness from a single conditioning event.*

Geometric intuition. *Think of $(\mathrm{Err}_I(\Pi_M), \mathrm{Err}_I(\Pi_M \mid \mathrm{obs}_I(x)))$ as a point in a square $[0, L_{\max}]^2$. The numerator is the signed vertical difference from the diagonal $\{e = e'\}$, and δ rescales the slope of the score so the diagonal remains the zero-set while keeping the score finite.*

Proposition 46.2 (Monotonicity in the conditional error)**.** *Fix M, I, Π_M, δ. If two entities x, x' satisfy $\mathrm{Err}_I(\Pi_M \mid \mathrm{obs}_I(x)) \leq \mathrm{Err}_I(\Pi_M \mid \mathrm{obs}_I(x'))$, then $\rho_{M,I}(x) \geq \rho_{M,I}(x')$.*

Remark 2603. Intuitive reading. *Holding the baseline model and baseline error fixed, the only way ρ changes from one entity to another is through the conditional error. If conditioning on x yields a smaller conditional error than conditioning on x', then x is (weakly) more empirically real in this operational sense.*

Connection. *This proposition is the monotonicity principle that later justifies thresholding: if we pick an "empirical-realness threshold" and then refine our conditioning event to get* better *predictive performance, we cannot drop below threshold by accident.*

Sketch. The map $e \mapsto (\mathrm{Err}_I(\Pi_M) - e)/(\mathrm{Err}_I(\Pi_M) + \delta)$ is affine and strictly decreasing in e. □

Remark 2604. Proof sketch. *Reduce the statement to a one-dimensional inequality: an affine decreasing function reverses order. This is the simplest possible monotonicity argument.*

Visual intuition. *Plot ρ as a function of $e = \mathrm{Err}_I(\Pi_M \mid \mathrm{obs}_I(\cdot))$; it is a straight line with negative slope. Moving left (smaller conditional error) moves up (larger ρ).*

Lemma 46.3 (Optional p-bit lift for empirical realness)**.** *Define a helper p-bit realness value*

$$\rho^{\pm}_{M,I}(x) := \big(\max(\rho_{M,I}(x), 0),\ \max(-\rho_{M,I}(x), 0)\big) \in [0,1]^2$$

(after clipping to $[0,1]$ if desired). Then:

1. *$\rho^{\pm}(x)$ records evidence for improvement vs evidence for worsening (as two coordinates).*
2. *$\rho_{M,I}(x) = \rho^{\pm,+}(x) - \rho^{\pm,-}(x)$ recovers the signed scalar.*

Remark 2605. Intuitive reading. *This is a bookkeeping device: rather than carrying a signed scalar, we store two nonnegative "evidence masses"—one supporting that x helps prediction, and one supporting that x harms it. This mirrors the practice, common in paraconsistent and multi-valued logics, of representing positive and negative support separately before any final aggregation (compare the general style of evidence-pairs in [23, 24]).*

Why it is useful. *In downstream ontology-building, one often wants to combine heterogeneous evidences without prematurely canceling them. The p-bit form delays cancellation until one explicitly subtracts coordinates, and it also interfaces naturally with vector-valued truth/evidence calculi.*

Sketch. Immediate from the definition of $\max(\cdot, 0)$. □

Remark 2606. Proof sketch. *The decomposition is literally the standard identity $z = \max(z, 0) - \max(-z, 0)$ applied to $z = \rho_{M,I}(x)$.*

Geometric intuition. *The map $z \mapsto (\max(z, 0), \max(-z, 0))$ folds the real line onto the two coordinate axes in the first quadrant: positive values lie on the x-axis, negative values lie on the y-axis.*

46.2 Reality-systems as fixed points of mutual predictive closure

Proposition 46.4 (Threshold monotonicity of predictive adjacency). *Let $\theta_1 \geq \theta_2$. If $x \to_{\theta_1} y$ then $x \to_{\theta_2} y$. Consequently, for all $R \subseteq U$,*

$$\mathrm{Pred}_{\to}\theta_1(R) \subseteq \mathrm{Pred}_{\to}\theta_2(R), \quad \mathrm{Pred}_{\leftarrow}\theta_1(R) \subseteq \mathrm{Pred}_{\leftarrow}\theta_2(R), \quad F\theta_1(R) \subseteq F\theta_2(R).$$

Remark 2607. Intuitive reading. *A higher threshold θ means we are more demanding about what counts as "x predicts y." If a relation passes a strict threshold, it automatically passes any weaker one. Thus, as one raises θ, the predictive neighborhoods shrink; as one lowers θ, they expand.*

Notation note. *The symbols* $\mathrm{Pred}_{\to}, \mathrm{Pred}_{\leftarrow}$ *denote forward- and backward-predictive expansions of a set, and F denotes their intersection (mutual predictive closure), which is the key operator whose fixed points define reality-systems (Hyperseed-Concept 149). The text writes* $\mathrm{Pred}_{\to}\theta(R)$ *etc.; this can be read as "the θ-parameterized version" (i.e. what one might elsewhere denote by* $\mathrm{Pred}_{\to,\theta}(R)$*), with the parameter carried as a visible tag.*

Sketch. If $x \to_{\theta_1} y$ means a score is at least θ_1, it is also at least $\theta_2 \leq \theta_1$. The set inclusions follow by unwinding the existential witness definition of $\mathrm{Pred}_{\to}, \mathrm{Pred}_{\leftarrow}$ and taking intersections. □

Remark 2608. Proof sketch. *The proof is a single monotonicity step at the level of the underlying predicate "score$\geq \theta$", lifted through the existential quantifiers defining neighborhood expansions, and finally through intersection.*

Why it works. *Existential definitions preserve implication: if every witness for θ_1 is also a witness for θ_2, then every element reachable at θ_1 remains reachable at θ_2.*

Lemma 46.5 (Distributivity over unions). *For all $R, S \subseteq U$,*

$$\mathrm{Pred}_{\to}(R \cup S) = \mathrm{Pred}_{\to}(R) \cup \mathrm{Pred}_{\to}(S), \qquad \mathrm{Pred}_{\leftarrow}(R \cup S) = \mathrm{Pred}_{\leftarrow}(R) \cup \mathrm{Pred}_{\leftarrow}(S).$$

Hence

$$F(R \cup S) \supseteq F(R) \cup F(S).$$

Remark 2609. Intuitive reading. *Forward (or backward) predictive expansion is "existential in the source": an element is forward-reachable from* $R \cup S$ *iff it is forward-reachable from* R *or from* S*. The mutual closure* F *is an* intersection *of a forward and a backward expansion, and intersections do not distribute over unions in the same direction; hence we get only the inclusion* $\supseteq$*.*

Why it matters. *This lemma is a small algebraic fact that frequently appears when constructing candidate reality-systems by seeding with multiple sources and then closing under mutual predictability.*

Sketch. A witness $x \in R \cup S$ is equivalent to $(x \in R) \vee (x \in S)$, giving the union formulas. Then $F(R \cup S)$ is an intersection of two unions, which always contains each of the two intersections $F(R)$ and $F(S)$. □

Remark 2610. Proof sketch. *Reduce to propositional logic:* $(\exists x \in R \cup S)\, \Phi(x)$ *is equivalent to* $((\exists x \in R)\, \Phi(x)) \vee ((\exists x \in S)\, \Phi(x))$*. Then apply the elementary inclusion* $(A \cup B) \cap (C \cup D) \supseteq (A \cap C) \cup (B \cap D)$*.*

Visual intuition. *Imagine* $\mathrm{Pred}_{\rightarrow}$ *and* $\mathrm{Pred}_{\leftarrow}$ *as two "halo" operators around a set. The halo of a union is the union of halos; but the overlap of two halos (mutuality) can be larger for the union than the union of overlaps, because points may be forward-connected to one seed and backward-connected to the other.*

Helper Theorem 46.6 (Membership criterion inside a reality-system)**.** *Let* R *be a reality-system at threshold* θ*, i.e.* $R \neq \emptyset$ *and* $F(R) = R$*. Then for any* $y \in U$*,*

$$y \in R \iff \big(\exists x_{\text{in}} \in R:\ x_{\text{in}} \rightarrow_\theta y\big) \ \wedge\ \big(\exists x_{\text{out}} \in R:\ y \rightarrow_\theta x_{\text{out}}\big).$$

In particular, if there exist $x_1, x_2 \in R$ *with* $x_1 \rightarrow_\theta y$ *and* $y \rightarrow_\theta x_2$*, then* $y \in R$*.*

Remark 2611. What the theorem says (plain English). *Inside a reality-system* R*, membership of an entity* y *is exactly the two-sided condition:* y *must be* predictable from *something already in* R *and must* predict *something already in* R*. So* R *behaves like a mutually-supporting predictive enclave.*

Why it is important. *This gives a usable certificate for membership without recomputing an entire fixed point: to show* $y \in R$*, it suffices to exhibit two witnesses in* R *(one pointing into* y*, one pointed to by* y*). This is precisely the kind of local criterion automated reasoning benefits from.*

Conceptual connection. *The statement explicates the Reality-System idea (Hyperseed-Concept 149) as a fixed point of a closure operator defined by mutual predictability, aligning with the broader fixed-point methodology used elsewhere (cf. the fixed-point schema in Section 48 and related stability arguments in [10]).*

Sketch. Unwind $F(R) = \mathrm{Pred}_{\rightarrow}(R) \cap \mathrm{Pred}_{\leftarrow}(R)$ and the definitions of $\mathrm{Pred}_{\rightarrow}, \mathrm{Pred}_{\leftarrow}$. □

Remark 2612. Proof sketch. *Replace the fixed point equation* $R = \mathrm{Pred}_{\rightarrow}(R) \cap \mathrm{Pred}_{\leftarrow}(R)$ *by the equivalent statement "*$y \in R$ *iff* y *is in both expansions," and then expand each membership condition into the existence of a witness.* Why the key step works. *The operator* $\mathrm{Pred}_{\rightarrow}(R)$ *is defined by an existential condition "*$\exists x \in R$ *with* $x \rightarrow_\theta y$*," and similarly* $\mathrm{Pred}_{\leftarrow}(R)$ *by "*$\exists x \in R$ *with* $y \rightarrow_\theta x$*." Intersections correspond to conjunction, so we get exactly the two-witness criterion. In particular, when* $y \in \mathrm{Pred}_{\rightarrow}(R) \cap \mathrm{Pred}_{\leftarrow}(R)$ *we may (and generally must) choose* potentially different *witnesses* $x_F, x_B \in R$ *to certify the two existential statements; the intersection does not force a single common witness unless one separately assumes a stronger property of* $\rightarrow_\theta$*. Conversely, if we are given witnesses* $x_F, x_B \in R$ *with* $x_F \rightarrow_\theta y$ *and* $y \rightarrow_\theta x_B$*, then the two existential conditions* *hold independently, which is exactly what is needed for membership in the intersection. This is the precise logical reason that the construction behaves like a "mutual" closure: it is a conjunction of two reachability requirements, each expressed as an existential predicate over the same seed set R.*

Network intuition. *Picture a directed graph with edges $x \to_\theta y$. Then* $\mathrm{Pred}_\to(R)$ *is the set of out-neighbors of R, and* $\mathrm{Pred}_\leftarrow(R)$ *is the set of in-neighbors of R. A reality-system is a set that equals the intersection of its in- and out-neighborhoods; membership of y means y has at least one incoming edge from R and at least one outgoing edge to R. Equivalently, y is simultaneously "supported by" R (some $x \in R$ points to y) and "supporting" R (y points back to some element of R), so the set is closed under a bidirectional consistency check. This bidirectionality is what prevents purely feed-forward expansion (which could accumulate nodes that are only predicted* by *R) and also prevents purely feed-backward contraction (which could keep only nodes that predict* into *R): the intersection enforces both constraints at once.*

Proposition 46.7 (Reflexive closure makes F inflationary (implementation convenience))**.** *Define the reflexive closure of adjacency: $x \to_\theta^{\mathrm{refl}} y$ iff $(x \to_\theta y) \vee (x = y)$, and let F^{refl} be the corresponding mutual predictive operator. Then F^{refl} is inflationary: $R \subseteq F^{\mathrm{refl}}(R)$ for all R. A useful corollary (often relied on implicitly in implementations) is that the iterates of F^{refl} started from a seed set R never "oscillate" by losing elements: once an element is present, it persists in all subsequent iterates.*

Remark 2613. What this buys you. *Many fixed-point iteration schemes are simplest when the operator is inflationary (never deletes existing elements). The reflexive closure forces every node to predict itself, so any set R is automatically included in both its forward and backward expansions, hence included in the mutual closure. Concretely, inflationarity lets one treat iteration as a monotone growth process: one can maintain a current set and only add newly implied tokens, rather than having to recompute from scratch while handling possible removals. This is especially convenient when F is evaluated via local graph operations (neighbor queries), because each step can be implemented as a union with newly discovered vertices.*

Interpretive aside. *Declaring x to "predict itself" is not a claim about the world; it is a bookkeeping choice about the closure operator. One may read it as encoding the minimal self-consistency of reference (Hyperseed-Concept 152) required to make iterative construction behave monotonically. One can also view reflexive closure as the smallest modification of $\to_\theta$ that guarantees inflationarity: it changes nothing about predictions between* distinct *tokens, but it prevents the closure process from discarding the very tokens that supplied the witnesses for the existential conditions. In applications, this is often the difference between a closure that behaves like "propagation" and one that behaves like "filtering": adding self-loops ensures that the seed evidence is never filtered out merely for lacking an explicit self-edge in the raw adjacency relation.*

Sketch. For any $y \in R$, take the witness $x = y$ and use reflexivity $y \to_\theta^{\mathrm{refl}} y$ to show $y \in \mathrm{Pred}_\to^{\mathrm{refl}}(R)$ and $y \in \mathrm{Pred}_\leftarrow^{\mathrm{refl}}(R)$, hence $y \in F^{\mathrm{refl}}(R)$. Spelling out the quantifiers: since $y \in R$ and $y \to_\theta^{\mathrm{refl}} y$, the defining condition $\exists x \in R\ (x \to_\theta^{\mathrm{refl}} y)$ holds (take $x = y$), proving $y \in \mathrm{Pred}_\to^{\mathrm{refl}}(R)$; similarly, $\exists x \in R\ (y \to_\theta^{\mathrm{refl}} x)$ holds (again take $x = y$), proving $y \in \mathrm{Pred}_\leftarrow^{\mathrm{refl}}(R)$. Membership in the mutual operator then follows from the definition $F^{\mathrm{refl}}(R) = \mathrm{Pred}_\to^{\mathrm{refl}}(R) \cap \mathrm{Pred}_\leftarrow^{\mathrm{refl}}(R)$. □

Remark 2614. Proof sketch. *Prove inflationarity pointwise: fix $y \in R$ and show y survives one application of the operator by using y itself as the witness on both the forward and backward sides. The "pointwise" style is often clearer than set-inclusion algebra here because the defining clauses for* $\mathrm{Pred}_\to$ *and* $\mathrm{Pred}_\leftarrow$ *are existential: you literally exhibit the element that witnesses the existential. Notice that no property of $\to_\theta$ beyond reflexivity is needed; in particular, transitivity, symmetry, or any probabilistic interpretation of θ play no role in this argument.*

Graph intuition. *Adding self-loops to a directed graph ensures every vertex is in its own in- and out-neighborhood, hence any vertex already in R cannot be lost when taking neighborhoods and intersecting. Another way to say this: without self-loops, the neighborhood-of-R operation can behave like a "one-step boundary" operator that forgets interior points; adding self-loops converts it into a genuine closure-like operator that retains the interior while still expanding to include adjacent boundary points.*

Helper Theorem 46.8 (Finite-step computation of the least fixed point (under inflationarity))**.** *Assume F is inflationary (e.g. by using the reflexive closure above). If U is finite and $R_0 \subseteq U$, define $R_{n+1} := F(R_n)$. Then*

$$R_0 \subseteq R_1 \subseteq R_2 \subseteq \cdots$$

stabilizes in at most $|U|$ steps at a fixed point R_∞, and R_∞ is the least fixed point containing R_0. In other words, the iterative procedure computes the closure of R_0 under F by repeated application, and on a finite universe this closure is reached after finitely many iterations with an explicit worst-case bound.

Remark 2615. What the theorem says. *On a finite universe of tokens U, repeatedly closing a seed set R_0 under an inflationary operator cannot strictly grow forever; it must stabilize after at most $|U|$ strict inclusions. The stabilized set is a fixed point, and it is the smallest fixed point that still contains the initial seed. Equivalently, there is some $N \leq |U|$ such that $R_N = R_{N+1}$, and then $R_n = R_N$ for all $n \geq N$ by repeated application of F. It is worth emphasizing that the bound is a* worst-case *guarantee: many concrete graphs stabilize much earlier, for example when R_0 is already a fixed point, or when the closure process quickly saturates a small connected component of U.*

Why it is important. *This is the computational heart of reality-system construction in finite settings: one can build the "minimal mutually predictive world containing these seed observations" by iterating closure, rather than invoking a nonconstructive fixed-point theorem. It also connects directly to the general fixed-point schema used in Section 48 and to stability-of-goals applications of fixed points ([10]). Operationally, the theorem justifies the common practice of running the update rule until convergence and then treating the resulting set as the constructed reality-system; the least-fixed-point property ensures that no smaller fixed point could have contained the same initial evidential seed.*

Sketch. Inflationarity gives an ascending chain in a finite powerset lattice, hence eventual stabilization. At stabilization, $R_{n+1} = R_n$ is a fixed point. Minimality follows from standard Kleene/Knaster-Tarski reasoning: any fixed point containing R_0 must contain all iterates, hence contains the limit. More explicitly, inflationarity gives $R_n \subseteq R_{n+1}$ for all n by induction on n. Since there are only finitely many subsets of U, and since strict inclusion can occur at most $|U|$ times along a chain that starts at R_0 and only adds elements of U, there must be some stage N where $R_N = R_{N+1}$. For minimality, let S be any fixed point with $R_0 \subseteq S$; then $R_1 = F(R_0) \subseteq F(S) = S$ (using that applying F to a superset cannot invalidate membership in S once S is a fixed point), and iterating this argument yields $R_n \subseteq S$ for all n, so the stabilized value R_∞ is also a subset of S. ☐

Remark 2616. Proof sketch. *The strategy is: (i) show the iterates form an ascending chain; (ii) invoke finiteness to conclude stabilization; (iii) argue minimality by induction: any fixed point above R_0 contains each iterate. In step (iii), the induction uses the simple observation that if $R_n \subseteq S$ and S is a fixed point, then $R_{n+1} = F(R_n) \subseteq F(S) = S$; this is the standard "post-fixed point contains the Kleene chain" argument specialized to the inflationary finite case.*

Key step commentary. *The "at most $|U|$ steps" bound comes from the fact that each strict inclusion adds at least one new element of U, and there are only $|U|$ available. A slightly sharper statement is that stabilization occurs in at most $|U| - |R_0|$ strict growth steps, since no step can add elements outside of U and R_0 already accounts for $|R_0|$ elements at the start; the displayed $|U|$ bound is a clean uniform upper bound that does not depend on the particular seed.*

Intuition. *Think of pouring ink into a finite sponge: inflationarity says the ink never retracts, and finiteness says eventually every pore that can be reached under the closure rule has been filled. In the graph picture, each iteration can be seen as expanding the set by adding vertices that are mutually supported by the current set; once no new vertices satisfy the support condition relative to the current set, the process has reached self-consistency and further updates do nothing.*

46.3 Physical reality and body-channel mediation

Lemma 46.9 (Bounds and certificates for graded physicalness)**.** *Assume the distance $d(\cdot,\cdot)$ used in the physicalness score satisfies $0 \le d \le 1$. Then the graded physicalness*

$$\mathrm{phys}(M, R; B) := 1 - \sup_{f:M\to R} \inf_{g:M\to B,\, h:B\to R} d(f, h \circ g)$$

satisfies $0 \le \mathrm{phys}(M, R; B) \le 1$. Moreover, if for some $\varepsilon \in [0, 1]$ every $f : M \to R$ admits g, h with $d(f, h \circ g) \le \varepsilon$, then $\mathrm{phys}(M, R; B) \ge 1 - \varepsilon$.

Remark 2617. Equivalent re-parameterization. *It is often convenient to name the "worst-case best mediation error"*

$$E(M, R; B) \;:=\; \sup_{f:M\to R} \; \inf_{g:M\to B,\, h:B\to R} d(f, h \circ g),$$

so that $\mathrm{phys}(M, R; B) = 1 - E(M, R; B)$. In this notation, the lemma simply states that $E(M, R; B) \in [0, 1]$ and that a uniform approximation guarantee $E(M, R; B) \le \varepsilon$ immediately yields $\mathrm{phys}(M, R; B) \ge 1 - \varepsilon$. This separation can be useful when one wants to reason about error bounds first and then convert them to a graded score.

Remark 2618. Intuitive reading. *The quantity $\mathrm{phys}(M, R; B)$ measures how well the "mind-to-reality" mappings $f : M \to R$ can be* mediated *by a body-channel B. If every mapping from M to R can be well-approximated (by the distance d) by a composition $h \circ g$ that passes through B, then the body-channel explains the mind–reality coupling, and physicalness is high. If some mappings resist such factorization, physicalness drops. This relates directly to Physical Reality / Body (Hyperseed-Concept 135) and Physical Realizations (Hyperseed-Concept 136).*

What varies in applications. *The role of d is to formalize what counts as "close" between two maps $M \to R$. For instance, if R has a metric ρ, one may take a uniform distance $d(f_1, f_2) := \sup_{m\in M} \min(1, \rho(f_1(m), f_2(m)))$, or (when M is equipped with a probability measure) an average distortion $d(f_1, f_2) := \mathbb{E}_m[\min(1, \rho(f_1(m), f_2(m)))]$. The definition then reads as a worst-case (over f) minimal achievable distortion (over mediations $h \circ g$), turned into a "higher-is-better" score by subtracting from* 1.

Simple example. *If d is the discrete distance (0 if equal, 1 otherwise), then $\inf_{g,h} d(f, h \circ g) = 0$ means f* exactly *factors through B. In that case, $\mathrm{phys}(M, R; B) = 1$ iff every f factors through B. If some f fails to factor, the supremum becomes 1 and* phys *becomes* 0.

Exact factorization in the discrete case. *When d is discrete, the condition "$f = h \circ g$ for some g, h" can be unpacked: g partitions M into fibers $g^{-1}(b)$, and f must be constant on each fiber (so that $h(b)$ can be defined consistently as the common f-value on that fiber). Thus, exact mediation* *through B means that the body-channel B carries enough labels to represent a partition of M that respects the distinctions made by f.*

Remark 2619. Why it matters. *The bounds are sanity checks: the definition is a nested* $\sup\inf$ *of a bounded distance, so without such a lemma one would repeatedly re-verify that the resulting score is a legitimate* $[0, 1]$ *grade. The second clause provides a usable certificate: an explicit approximation guarantee immediately yields a lower bound on physicalness.*

Upper-bound certificates (dual viewpoint). *While the lemma phrases a convenient* lower *bound via a uniform ε-approximation, the same structure suggests how to get* upper *bounds in practice: if one can exhibit a specific $f : M \to R$ such that* every *factorization through B satisfies $d(f, h \circ g) \geq \delta$, then*

$$\sup_f \inf_{g,h} d(f, h \circ g) \;\geq\; \delta \quad \textit{and hence} \quad \mathrm{phys}(M, R; B) \;\leq\; 1 - \delta.$$

In other words, a single "hard-to-mediate" f witnesses low physicalness, just as a uniform construction of (g, h) witnesses high physicalness.

Sketch. Since $0 \leq d \leq 1$, we have $0 \leq \inf d \leq 1$ and thus $0 \leq \sup\inf d \leq 1$. The second claim is immediate from $\sup_f \inf_{g,h} d(f, h \circ g) \leq \varepsilon$.

More explicitly, for each fixed $f : M \to R$ define

$$A(f) \;:=\; \inf_{g:M\to B,\, h:B\to R} d\big(f, h \circ g\big).$$

The assumption $0 \leq d \leq 1$ implies $0 \leq A(f) \leq 1$ for every f (an infimum of numbers in $[0, 1]$ remains in $[0, 1]$). Taking a supremum over all f preserves the bounds, so $0 \leq \sup_f A(f) \leq 1$. Subtracting from 1 yields $0 \leq 1 - \sup_f A(f) \leq 1$, i.e. $0 \leq \mathrm{phys}(M, R; B) \leq 1$. For the certificate statement, if for all f there exist g, h with $d(f, h \circ g) \leq \varepsilon$, then $A(f) \leq \varepsilon$ for all f, hence $\sup_f A(f) \leq \varepsilon$, and thus $\mathrm{phys}(M, R; B) \geq 1 - \varepsilon$. □

Remark 2620. Proof sketch. *The argument is order-theoretic: infima and suprema preserve bounds. Then the definition* $\mathrm{phys} = 1 - (\sup\inf d)$ *converts a small worst-case mediation error into a large physicalness score.*

Geometric intuition. *Think of the set of all maps $M \to R$ as a space, and the maps that factor through B as a subset. The inner* inf *measures distance to that subset; the outer* sup *takes the worst-case distance. Physicalness is "one minus" that worst-case deviation.*

Communication-channel intuition. *Interpreting $g : M \to B$ as an* encoding *of mental states into body states and $h : B \to R$ as a* decoding *into reality states, the inner optimization asks for the best encoder–decoder pair for a given target mapping f. The outer supremum then asks how bad the hardest target mapping can be under the best available mediation through B under the chosen distortion measure d.*

46.4 Algebraic asymmetry and free lifts (adjunction rules)

Helper Theorem 46.10 (Adjunction factoring rule (a useful reasoning principle))**.** *Let $U : \mathbf{R}_{phys} \to \mathbf{R}_{ment}$ be a forgetful functor and suppose it has a left adjoint $F : \mathbf{R}_{ment} \to \mathbf{R}_{phys}$ with unit $\eta_m : m \to U(F(m))$. Then for any $m \in \mathrm{Ob}(\mathbf{R}_{ment})$ and any $p \in \mathrm{Ob}(\mathbf{R}_{phys})$, every mental-to-physical comparison map $\alpha : m \to U(p)$ factors uniquely through the unit: there exists a unique $\bar{\alpha} : F(m) \to p$ with*

$$U(\bar{\alpha}) \circ \eta_m = \alpha.$$

Operationally: any physical realization consistent with the mental description must at least pass through the free lift $F(m)$ (plus extra constraints in p).

Remark 2621. *A useful way to picture the statement is as the existence of a unique "completion" of the triangle*

$$\begin{array}{ccc} & m & \\ & \eta_m \searrow \quad \swarrow \alpha & \\ U(F(m)) & \xrightarrow{U(\bar{\alpha})} & U(p) \end{array}$$

where the diagonal arrow α is given, and the base arrow $U(\bar{\alpha})$ is forced by universality. In particular, the content is not merely that α can *be written as $U(\bar{\alpha}) \circ \eta_m$, but that the $\bar{\alpha}$ witnessing this is determined uniquely (hence can be treated as canonical data).*

Remark 2622. What the theorem says. *An adjunction $F \dashv U$ asserts that "freely realizing" a mental object m as a physical object $F(m)$ is universal: any way of comparing m to the underlying-mental aspect of a physical object p must pass uniquely through this free realization. In short, $F(m)$ is the most general physical realization compatible with m.*

Equivalently (and sometimes more technically useful), $F(m)$ is an initial object in the comma category $(m \downarrow U)$: objects are comparison maps $m \to U(p)$, and a morphism from $\alpha : m \to U(p)$ to $\alpha' : m \to U(p')$ is a physical arrow $h : p \to p'$ with $U(h) \circ \alpha = \alpha'$. The initiality of $\eta_m : m \to U(F(m))$ is exactly the statement that every α receives a unique such morphism from η_m, i.e. a unique $\bar{\alpha} : F(m) \to p$ with $U(\bar{\alpha}) \circ \eta_m = \alpha$.

Why it is important (algebraic asymmetry). *The existence of a left adjoint expresses a one-way generosity: from mental to physical there is a canonical* free lift*, but from physical to mental we often only have forgetting/projection. This articulates the idea of Algebraically Asymmetric Physical Reality (Hyperseed-Concept 55) in categorical terms, and it matches the Hyperseed style of treating ontology-building steps as universal constructions ([1]).*

A further way to read the "one-way generosity" is: U preserves constraints by forgetting them, while F creates a maximally unconstrained physical carrier compatible with the given mental specification. Any additional structure or constraints characteristic of a specific p are exactly what the morphism $\bar{\alpha} : F(m) \to p$ supplies; the universal property isolates what is forced by m alone (encoded in η_m) from what is extra (choice of p and of $\bar{\alpha}$).

Concrete example. *If $\mathbf{R}_{phys}$ were a category of "structured" physical systems and $\mathbf{R}_{ment}$ a category of "unstructured" specifications, U forgets structure and F freely adds it. Then the theorem says: any implementation of a specification factors uniquely through the free implementation.*

A standard mathematical instance is $U : \mathbf{Grp} \to \mathbf{Set}$ with F the free-group functor: a set-map $\alpha : X \to U(G)$ into the underlying set of a group G uniquely extends to a group homomorphism $\bar{\alpha} : F(X) \to G$. The unit $\eta_X : X \to U(F(X))$ is the inclusion of generators, and the factorization condition $U(\bar{\alpha}) \circ \eta_X = \alpha$ says precisely that the extension agrees with α on generators.

Proof. **Sketch** This is the defining universal property of an adjunction $F \dashv U$: $\mathrm{Hom}_{phys}(F(m), p) \cong \mathrm{Hom}_{ment}(m, U(p))$, natural in m, p. □

Remark 2623. Proof sketch. *Invoke the adjunction bijection of hom-sets and interpret η_m as the image of $\mathrm{id}_{F(m)}$ under that bijection. The required factorization is precisely what the bijection encodes.*

More explicitly: let $\Phi_{m,p} : \mathrm{Hom}_{phys}(F(m), p) \to \mathrm{Hom}_{ment}(m, U(p))$ denote the adjunction bijection. By definition of the unit, $\eta_m = \Phi_{m,F(m)}(\mathrm{id}_{F(m)})$. Given $\alpha : m \to U(p)$, let $\bar{\alpha} := \Phi^{-1}_{m,p}(\alpha)$. Then $\Phi_{m,p}(\bar{\alpha}) = \alpha$, which is exactly the displayed equation $U(\bar{\alpha}) \circ \eta_m = \alpha$ when Φ is written in the usual "unit-based" form.

Why the factorization is unique. *Uniqueness is not an extra condition; it is the content of "$\cong$": each α corresponds to exactly one $\bar{\alpha}$. In a reasoning engine, this uniqueness is what licenses canonical rewrites: one can replace an arbitrary α by $U(\bar{\alpha}) \circ \eta_m$ without ambiguity.*

It can also be related to the triangle identities for $(F \dashv U)$: the unit η and counit $\varepsilon : F(U(p)) \to p$ satisfy $(\varepsilon_{F(m)} \circ F(\eta_m)) = \mathrm{id}_{F(m)}$ and $U(\varepsilon_p) \circ \eta_{U(p)} = \mathrm{id}_{U(p)}$. These identities ensure that the "free lift then realize" pipeline behaves coherently, i.e. free lifting does not introduce spurious degrees of freedom once a realization map has been chosen.

46.5 Signals, universes, multiverse, and Yverse

Proposition 46.11 (Universe monotonicity in signal-class and in threshold)**.** *Let* $\mathrm{Univ}_{C,\eta}(S)$ *be the observer-indexed universe defined by* C*-signal reachability at threshold* η*. Then:*

1. *If* $C \subseteq C'$*, then* $\mathrm{Univ}_{C,\eta}(S) \subseteq \mathrm{Univ}_{C',\eta}(S)$.
2. *If* $\eta' \geq \eta$*, then* $\mathrm{Univ}_{C,\eta'}(S) \subseteq \mathrm{Univ}_{C,\eta}(S)$.

Remark 2624. Intuitive reading. *A universe* $\mathrm{Univ}_{C,\eta}(S)$ *is what an observer* S *can reach by passing signals of allowed types* C *that meet an evidential threshold* η*. If we allow* more *signal types, reachability can only expand; if we demand* higher *evidential strength, reachability can only shrink. This matches the Universe/Eurycosm framing (Hyperseed-Concept 89) where a "world" is indexed both by channels of interaction and by standards of evidential admissibility.*

Connection. *This monotonicity is a prerequisite for any lattice- or fixed-point reasoning about universes, since it guarantees that tuning parameters behaves predictably (pun intended).*

Sketch. (1) Any C-signal path is also a C'-signal path. (2) Any path that meets the stricter evidence threshold η' also meets the weaker threshold η. □

Remark 2625. Proof sketch. *Both parts are inclusion-by-relaxation arguments: relax constraints on admissible paths (by enlarging* C *or lowering* η*) and you can only gain reachability, never lose it.*

Path intuition. *Visualize a graph whose edges are labeled by signal types and weights/evidences. Then (1) allows more edge-labels, (2) allows more edges by lowering the weight cutoff.*

Lemma 46.12 (Concatenation of signal paths)**.** *If there is a finite* C*-signal path* $S \rightsquigarrow X$ *and a finite* C*-signal path* $X \rightsquigarrow Y$*, then there is a finite* C*-signal path* $S \rightsquigarrow Y$ *(by concatenation). Consequently, reachability is transitive, and universe membership is closed under reachable extensions.*

Remark 2626. What the lemma says. *Reachability behaves like any sane notion of "can get from here to there": if you can reach* X *from* S *and then reach* Y *from* X*, you can reach* Y *from* S *by performing the two journeys consecutively.*

Why it matters. *Transitivity is what turns reachability into a closure concept, allowing one to talk about universes as closed sets under signal propagation. Without this, universe membership would not behave stably under intermediate constructions.*

Sketch. Concatenate the two finite sequences of C-signals. In a categorical model, use closure of morphisms under composition. □

Remark 2627. Proof sketch. *The strategy is literal concatenation: append the second finite list of signal-steps to the first. In categorical language, the same fact is expressed as: the composite of two morphisms is again a morphism.*

Intuition. *A universe is a region of the graph closed under following edges; this lemma is the statement that "following edges" is compositional.*

Proposition 46.13. ***Guidable multiverse as an MDP , and reduction to ordinary multiverse*** *A guidable multiverse with state space $\mathcal{U}$, action set A, and controlled kernel $P(\cdot \mid U, a)$ is exactly a Markov decision process on $\mathcal{U}$. If A is a singleton, the guidable multiverse reduces to an ordinary multiverse kernel. Conversely, any multiverse kernel $P(\cdot \mid U, e)$ can be regarded as guidable by taking A to encode a designated set of event labels (possibly with a policy restricting actions to match feasible events).*

Remark 2628. Plain-English statement. *"Guidability" does not add new mathematics beyond standard control theory: it is precisely the addition of actions to a state-transition kernel, i.e. an MDP. Removing actions collapses back to an uncontrolled stochastic process.*

Why it is useful. *This identification allows one to import the full toolbox of planning and optimal control when reasoning about multiverse navigation and policy-conditioned branching (cf. the general AGI/control framing in [19]). It also clarifies that "multiverse" here is not (only) metaphysical rhetoric; it is a formal object (Hyperseed-Concept 116) with standard computational semantics.*

Sketch. This is a repackaging of the data: (states, actions, transition kernel) is the definition of an MDP. The singleton-action case collapses to an uncontrolled Markov chain. □

Remark 2629. Proof sketch. *No derivation is required: the proof is definitional equivalence. The only "step" is recognizing that the symbols match the standard tuple defining an MDP.*

Intuition. *A multiverse kernel says "what happens"; adding actions says "what you can choose to do before what happens." Everything else is bookkeeping.*

Helper Theorem 46.14 (Bounding least/greatest Yverse fixed points via pre/post-fixed points)**.** *Let* $\mathrm{Multi} : D \to D$ *be monotone on a complete lattice. If X is pre-fixed (*$\mathrm{Multi}(X) \leq X$*), then* $\mathrm{lfp}(\mathrm{Multi}) \leq X$*. If Y is post-fixed (*$Y \leq \mathrm{Multi}(Y)$*), then* $Y \leq \mathrm{gfp}(\mathrm{Multi})$.

Remark 2630. What the theorem says. *Pre-fixed points are* upper bounds *on the least fixed point, and post-fixed points are* lower bounds *on the greatest fixed point. So to bound the extremal stable regimes of* Multi*, it suffices to exhibit any pre- or post-fixed candidate.*

Where this sits in fixed-point theory. *This is the standard "sandwiching" move behind Knaster–Tarski: on a complete lattice, monotone maps have least and greatest fixed points, and inequalities of the form* $\mathrm{Multi}(X) \leq X$ *or* $Y \leq \mathrm{Multi}(Y)$ *let one compare arbitrary candidates to those extremal points without solving the fixed-point equations explicitly.*

Operational interpretation for Yverse. *When the Yverse is defined as a fixed point of a multiverse operator* Multi *(e.g. an operator that closes a set of states under admissible branching, or under signal-validated extensions), a pre-fixed X is a "conservative envelope" that is already stable under* Multi *in the sense that applying* Multi *cannot push you outside X. Dually, a post-fixed Y is a "seed" that is guaranteed to expand (or at least not contract) under* Multi*, hence it must lie beneath the maximal stable regime.*

Typical instantiation of D. *In many uses, D will be a powerset lattice $(\mathcal{P}(\mathcal{U}), \subseteq)$ of multiverse states, or a lattice of predicates/properties on $\mathcal{U}$. Then* $\mathrm{lfp}(\mathrm{Multi})$ *and* $\mathrm{gfp}(\mathrm{Multi})$ *can be read as the smallest and largest sets (or properties) that are closed under the multiverse evolution/closure rule encoded by* Multi.

Sketch. Let $\mathrm{Fix}(\mathrm{Multi}) = \{Z \in D : \mathrm{Multi}(Z) = Z\}$ be the set of fixed points. By the Knaster–Tarski theorem (or by the standard lattice argument using monotonicity), $\mathrm{lfp}(\mathrm{Multi})$ exists and is the infimum of all pre-fixed points, while $\mathrm{gfp}(\mathrm{Multi})$ exists and is the supremum of all post-fixed points. Hence if X is pre-fixed, then $\mathrm{lfp}(\mathrm{Multi}) \leq X$. If Y is post-fixed, then $Y \leq \mathrm{gfp}(\mathrm{Multi})$. □

Remark 2631. Proof sketch, unpacked. *Monotonicity ensures that the collection of pre-fixed points is downward-directed in the appropriate sense (closed under meets) and the collection of post-fixed points is upward-directed (closed under joins), so taking the infimum/supremum yields extremal fixed points. The inequalities in the theorem are then immediate because infima are below every element of the set they bound, and suprema are above every element of the set they bound.*

Practical use. *In applications, one often cannot compute* lfp(Multi) *or* gfp(Multi) *in closed form. This theorem shows that it is nevertheless meaningful to propose candidate "outer" and "inner" approximations: any invariant upper approximation X (pre-fixed) must contain the least stable core, and any expansive lower approximation Y (post-fixed) must be contained in the greatest stable closure.*

Link to iterative constructions. *If one defines the least fixed point via iteration from a bottom element $\perp$ (e.g.* $\mathrm{Multi}^0(\perp) = \perp$, $\mathrm{Multi}^{n+1}(\perp) = \mathrm{Multi}(\mathrm{Multi}^n(\perp))$*), then any pre-fixed X bounds all iterates: by monotonicity,* $\mathrm{Multi}^n(\perp) \leq X$ *for all n, so the limit (in the appropriate lattice sense) also satisfies* $\mathrm{lfp}(\mathrm{Multi}) \leq X$*. Dually, iterating from a top element $\top$ yields descending approximations to* gfp(Multi) *that are bounded below by any post-fixed Y.*

Remark 2632. Why it matters. *In practice one rarely computes* lfp *or* gfp *exactly; one certifies them by inequalities. This is the basic "bounding move" behind many stability arguments, including meta-goal stability analyses ([10]) and the general fixed-point package recalled in Section 48.*

Sketch. Standard Knaster-Tarski: lfp is the meet of pre-fixed points; gfp is the join of post-fixed points. □

Remark 2633. Proof sketch. *The proof is a direct one-line application of the Knaster–Tarski characterization of extremal fixed points (cf. Theorem 58 for the general package). "Meet of pre-fixed points" immediately implies it is $\leq$ each pre-fixed point, and similarly for* gfp.

Order intuition. *In a lattice,* lfp *is the greatest lower bound of all safe over-approximations (pre-fixed points), while* gfp *is the least upper bound of all safe under-approximations (post-fixed points).*

Corollary 46.15 (Iterative construction under omega-continuity (optional))**.** *If* Multi *is Scott-continuous (or at least omega-continuous), then*

$$\mathrm{lfp}(\mathrm{Multi}) = \bigvee_{n \geq 0} \mathrm{Multi}^n(\perp), \qquad \mathrm{gfp}(\mathrm{Multi}) = \bigwedge_{n \geq 0} \mathrm{Multi}^n(\top).$$

Remark 2634. Plain-English statement. *Under a continuity hypothesis, one can compute the least fixed point by starting from the bottom element $\perp$ and iterating* Multi *upward, taking the limit (join) of the chain; dually, compute the greatest fixed point by iterating downward from $\top$ and taking the limit (meet).*

Why it is useful. *This corollary turns an existence theorem into an algorithmic recipe. In Yverse-style constructions (where* Multi *encodes a multiverse-closure operator), it provides a canonical iterative construction whenever the continuity assumption is justified.*

Sketch. Kleene fixed-point theorem for omega-continuous maps on complete lattices. □

Remark 2635. Proof sketch. *Apply the Kleene theorem: omega-continuity ensures that* Multi *commutes with countable joins of increasing chains (and dually with countable meets of decreasing chains), so the limit of iteration is a fixed point and is extremal.*

Intuition. *Continuity is the promise that no "new behavior" appears only at the limit; everything that is true at the fixed point is already approximable by finite iteration depth.*

Remark 2636. Bounding move, made explicit. *Write* $f := \mathrm{Multi}$*. A point* x *with* $f(x) \le x$ *is a pre-fixed point, so by the Knaster–Tarski characterization one always has* $\mathrm{lfp}(f) \le x$*. Dually, a point* y *with* $y \le f(y)$ *is a post-fixed point, hence* $y \le \mathrm{gfp}(f)$*. These two one-sided certificates are typically what one can prove in applications: one exhibits a candidate region and checks that applying* f *stays inside it (or, dually, expands it), thereby obtaining a provable enclosure of the true extremal fixed points without computing them.*

Remark 2637. Notation and chain picture. *The iterate* f^n *denotes* n*-fold composition with* $f^0 = \mathrm{id}$*, so* $f^0(\perp) = \perp$*,* $f^1(\perp) = f(\perp)$*,* $f^2(\perp) = f(f(\perp))$*, etc. Under monotonicity, the sequence*

$$\perp \;\le\; f(\perp) \;\le\; f^2(\perp) \;\le\; \cdots$$

is an increasing chain, and the join $\bigvee_{n\ge 0} f^n(\perp)$ *is simply its least upper bound. Likewise,*

$$\top \;\ge\; f(\top) \;\ge\; f^2(\top) \;\ge\; \cdots$$

is a decreasing chain whose meet $\bigwedge_{n\ge 0} f^n(\top)$ *is its greatest lower bound. The continuity hypothesis is what lets these chain-limits be* fixed *points rather than merely pre-/post-fixed points.*

Remark 2638. On Scott- vs. omega-continuity. *Scott-continuity means that for every directed set* D *one has* $f(\bigvee D) = \bigvee f[D]$*, i.e.,* f *preserves directed joins. Omega-continuity is the countable-chain special case, requiring preservation of joins of increasing* ω*-chains (and, for the dual statement about* gfp*, the corresponding preservation of meets of decreasing* ω*-chains). In many "constructive" settings one proves only the* ω*-chain version, which is already enough to justify the iterative formulas displayed in the corollary.*

Remark 2639. Concrete model to keep in mind. *A common complete-lattice instance is the powerset lattice* $(\mathcal{P}(S), \subseteq)$ *with* $\perp = \varnothing$ *and* $\top = S$*. If* f *adds all elements reachable by one step of a rule (or all "consistent extensions" of a signal set), then* $f^n(\varnothing)$ *is the set of elements reachable in* $\le n$ *steps, and* $\bigvee_{n\ge 0} f^n(\varnothing) = \bigcup_{n\ge 0} f^n(\varnothing)$ *is the set reachable in finitely many steps. Under the relevant continuity assumption, this finite-step closure coincides with the least fixed point, matching the idea that the "universe" generated by repeatedly applying multiverse-extension rules is the smallest closed object containing the seed.*

46.6 Eurycosm, near eurycosm, anthropic conditioning

Proposition 46.16 (Monotonicity of eurycosm construction)**.** *Let* $\mathrm{Eury}(\mathrm{Mind}, \mathrm{SigClass}) := \bigcup_{M\in\mathrm{Mind}} \bigcup_{C\in\mathrm{SigClass}} \mathrm{U}$
If $\mathrm{Mind} \subseteq \mathrm{Mind}'$ *and* $\mathrm{SigClass} \subseteq \mathrm{SigClass}'$*, then*

$$\mathrm{Eury}(\mathrm{Mind}, \mathrm{SigClass}) \subseteq \mathrm{Eury}(\mathrm{Mind}', \mathrm{SigClass}').$$

Remark 2640. Intuitive reading. *The eurycosm is a "big world" built by taking the union of universes generated by many minds and many signal-classes (Hyperseed-Concepts* **??** *and 89; see also [18]). If we enlarge the set of minds considered, or enlarge the palette of admissible signal-classes, we are taking unions over larger index sets; the result can only grow.*

Why it matters. *Monotonicity is the minimal structural fact needed to treat eurycosm formation as a functorial or lattice-like construction, and to reason about nested eurycosms associated with expanding civilizations, models, or observational modalities.*

Sketch. Both sides are unions; enlarging the index sets can only add elements. $\square$

Remark 2641. Proof sketch. *Use the basic set-theoretic fact: if* $I \subseteq I'$ *then* $\bigcup_{i\in I} A_i \subseteq \bigcup_{i\in I'} A_i$.

Intuition. *The eurycosm is an envelope: adding more contributors (minds) or more channels (signals) cannot shrink an envelope formed by union.*

Remark 2642. Componentwise monotonicity. *The statement decomposes into two independent monotonicities: (i) holding* SigClass *fixed, the map* Mind $\mapsto$ Eury(Mind, SigClass) *is monotone under inclusion of mind-sets; (ii) holding* Mind *fixed, the map* SigClass $\mapsto$ Eury(Mind, SigClass) *is monotone under inclusion of signal-class families. The proposition is simply the simultaneous application of (i) and (ii).*

When equality holds. *The inclusion may be strict or may be an equality depending on redundancy of generators: if every additional* $M \in \mathrm{Mind}' \setminus \mathrm{Mind}$ *and every additional* $C \in \mathrm{SigClass}' \setminus \mathrm{SigClass}$ *contributes only universes already present in the smaller union, then the two eurycosms coincide. In applications this corresponds to enlarging the index sets without adding genuinely new observational/constructive capacity.*

Canonical inclusions. *The monotonicity induces a natural embedding* $\mathrm{Eury}(\mathrm{Mind}, \mathrm{SigClass}) \hookrightarrow \mathrm{Eury}(\mathrm{Mind}', \mathrm{SigClass}')$ *whenever* $(\mathrm{Mind}, \mathrm{SigClass}) \subseteq (\mathrm{Mind}', \mathrm{SigClass}')$. *This is the set-theoretic backbone behind "nested eurycosms": one may regard the smaller eurycosm as a substructure of the larger without additional identification work.*

Lemma 46.17 (Near eurycosm monotonicity in the budget)**.** *Let* $\mathrm{NearEury}_B(M) := \{X \in \mathrm{Eury} : \mathrm{Comp}_M(X) \le B\}$. *If* $B_1 \le B_2$ *then* $\mathrm{NearEury}_{B_1}(M) \subseteq \mathrm{NearEury}_{B_2}(M)$. *Moreover,* $\bigcup_{B\ge 0} \mathrm{NearEury}_B(M) = \{X \in \mathrm{Eury} : \mathrm{Comp}_M(X) < \infty\}$.

Remark 2643. Intuitive reading. *A near-eurycosm is the part of the eurycosm that a mind* M *can access/represent within a resource budget* B. *Increasing* B *relaxes the resource constraint and therefore can only include more elements. The union over all finite budgets recovers exactly the objects of finite* M*-relative complexity.*

Connection to complexity. *The predicate* $\mathrm{Comp}_M(X) \le B$ *is a generic resource bound; in many instantiations it is informed by algorithmic information/description complexity ideas (Hyperseed-Concept* **??***; see [16]). The lemma is thus a monotonicity statement about resource-bounded access to worlds, which is central when contrasting rich-resource strategies with bounded ones ([11]).*

Sketch. Monotonicity is immediate from the inequality $\mathrm{Comp}_M(X) \le B$. The union identity is the definition of finiteness of $\mathrm{Comp}_M(X)$. □

Remark 2644. Proof sketch. *The first part is a direct subset relation between sublevel sets of a function. The second part simply restates that "finite" means "bounded by some finite* B*," i.e. belonging to at least one sublevel set.*

Geometric intuition. *Think of* Comp_M *as a "height function" over* Eury*; then* $\mathrm{NearEury}_B(M)$ *is the region below height* B. *Raising the waterline includes more terrain.*

Remark 2645. Filtration viewpoint. *The family* $\big(\mathrm{NearEury}_B(M)\big)_{B\ge 0}$ *is an increasing chain (a filtration) of subsets of* Eury *indexed by the budget parameter. This makes precise the idea that "better resourced" versions of the same mind (or the same mind at later times) form a nested sequence of accessible world-fragments, and it allows one to speak unambiguously about limits such as* $\lim_{B\to\infty} \mathrm{NearEury}_B(M)$ *as a union rather than as an analytic limit.*

Budget granularity. *No special structure on the index set of budgets is required beyond an order: the lemma holds equally for integer budgets, real-valued budgets, or multi-criteria budgets partially ordered componentwise (e.g. time, memory, and sample complexity), in which case "monotone in the budget" should be read as isotone with respect to that partial order.*

Finite complexity as eventual entry. *The identity* $\bigcup_{B\geq 0} \mathrm{NearEury}_B(M) = \{X : \mathrm{Comp}_M(X) < \infty\}$ *can be read operationally: an object has finite M-complexity iff there exists some finite resource cap at which it becomes accessible. This "eventual entry" interpretation is often the most useful when comparing two minds M, M' with different complexity functionals.*

Helper Theorem 46.18 (Anthropic posterior odds (Bayes factor form))**.** *Let $\pi(\theta)$ be a prior on Θ and A an anthropic event. Then for any θ_1, θ_2 with $\pi(\theta_i) > 0$,*

$$\frac{\pi(\theta_1 \mid A)}{\pi(\theta_2 \mid A)} = \frac{\pi(\theta_1)}{\pi(\theta_2)} \cdot \frac{P(A \mid \theta_1)}{P(A \mid \theta_2)}.$$

Thus anthropic conditioning updates model odds by the likelihood ratio of observer-existence.

Remark 2646. What the theorem says. *Conditioning on an anthropic event A (e.g. "observers like us exist") changes the odds between two hypotheses exactly by multiplying by the Bayes factor $P(A \mid \theta_1)/P(A \mid \theta_2)$.*

Why it matters. *This isolates anthropic reasoning to a single likelihood ratio, making explicit what is often left implicit in philosophical debate: the whole force of anthropic updating lies in the comparative probabilities of observer-existence under competing models (Hyperseed-Concept 57; see also [18] for the broader cosmological/eurycosmic framing).*

Connection. *In eurycosm discussions, A often encodes selection effects about which universes/multiverses are actually observed. This theorem gives the exact algebra for how those selection effects reweight priors.*

Sketch. From $\pi(\theta \mid A) \propto \pi(\theta)P(A \mid \theta)$, divide the two posteriors and cancel the shared normalizer. □

Remark 2647. Proof sketch. *Write Bayes' rule for each θ_i; both posteriors share the same evidence term $P(A)$, so it cancels in the ratio.*

Intuition. *Odds are what remain after common normalizers are stripped away. Anthropic conditioning is therefore best expressed in odds form: it reveals precisely what changes (the likelihood ratio) and what does not (the prior odds structure except for that multiplicative update).*

Remark 2648. Support and degeneracy. *The hypothesis-level assumption $\pi(\theta_i) > 0$ ensures that the prior odds are well-defined. If, in addition, $P(A \mid \theta_2) = 0$ while $P(A \mid \theta_1) > 0$, then the Bayes factor is infinite and $\pi(\theta_2 \mid A) = 0$ (anthropic conditioning rules out θ_2 outright). Conversely, if $P(A \mid \theta_1) = P(A \mid \theta_2)$, then A is evidentially irrelevant for distinguishing θ_1 from θ_2 and posterior odds equal prior odds.*

Log-odds form. *Taking logarithms yields*

$$\log \frac{\pi(\theta_1 \mid A)}{\pi(\theta_2 \mid A)} = \log \frac{\pi(\theta_1)}{\pi(\theta_2)} + \log \frac{P(A \mid \theta_1)}{P(A \mid \theta_2)},$$

so the anthropic update contributes additively in log-odds space. This form is convenient when anthropic information is combined with non-anthropic data, because independent likelihood contributions add on the log scale.

Conditioning on data and anthropics. *If one has ordinary data D in addition to anthropic information A, then (without any special anthropic assumptions) $\pi(\theta \mid D, A) \propto \pi(\theta)\, P(D, A \mid \theta)$. Under conditional independence $D \perp A \mid \theta$ this factorizes into $\pi(\theta)\, P(D \mid \theta)P(A \mid \theta)$, exhibiting anthropic conditioning as just another likelihood factor; the theorem is the two-hypothesis odds specialization of that general factorization.*

46.7 Big-bounce bounce operator (speculative helper bounds)

Lemma 46.19 (Lambda=0 reduction and a crude KL deviation bound)**.** *Consider the bounce operator objective*

$$B(\mu_T) := \arg\min_{\nu}\Big(\mathrm{KL}(\nu\|\mu^*) + \lambda\,\mathrm{Res}(\nu,\mu_T)\Big),$$

where Res *is bounded:* $\mathrm{Res}_{\min} \le \mathrm{Res}(\nu,\mu_T) \le \mathrm{Res}_{\max}$ *for all* ν*. Assume* μ^* *is feasible and* $\mathrm{KL}(\nu\|\mu^*) \ge 0$ *with equality at* $\nu = \mu^*$*. In particular, this implicitly restricts attention to* ν *for which* $\mathrm{KL}(\nu\|\mu^*)$ *is well-defined (e.g.* $\nu \ll \mu^*$ *in standard measure-theoretic settings), since otherwise the KL term is* $+\infty$ *and cannot be minimizing. Also,* arg min *may be set-valued; throughout, "any minimizer" means any element of this argmin set, and existence is taken as an assumption (or, in applications, one may read the inequalities below as applying to any sufficiently good approximate minimizer). Then:*

1. *If* $\lambda = 0$*, any minimizer satisfies* $B(\mu_T) = \mu^*$ *(unique if the KL minimizer is unique). In other words, at* $\lambda = 0$ *the operator becomes* state-independent*: the input* μ_T *plays no role because* Res *is switched off entirely.*

2. *For* $\lambda > 0$*, any minimizer* $\nu^\star = B(\mu_T)$ *satisfies the crude bound*

$$\mathrm{KL}(\nu^\star\|\mu^*) \le \lambda(\mathrm{Res}_{\max} - \mathrm{Res}_{\min}).$$

Equivalently, the deviation penalty contributed by the KL term cannot exceed the maximal possible gain (up to the factor λ*) that could be achieved by moving from the worst-case resistance value to the best-case resistance value.*

Remark 2649. Intuitive reading. *The "bounce operator" trades off closeness to a reference distribution* μ^* *(measured by KL divergence) against a resistance/penalty term* $\mathrm{Res}(\nu,\mu_T)$ *that depends on the current state* μ_T*. When* $\lambda = 0$*, only KL matters, so the minimizer is the reference* μ^**. When* $\lambda > 0$*, the minimizer may deviate from* μ^**, but the lemma provides a coarse upper bound on how far it can deviate in KL units, assuming* Res *is bounded. One can also read the bound as a simple scaling law: increasing* λ *linearly increases the largest KL deviation that could be "worth it," while shrinking the range* $\mathrm{Res}_{\max} - \mathrm{Res}_{\min}$ *linearly tightens the permitted deviation.*

Context and caution. *The "Big Bounce" language is speculative (Hyperseed-Concept 66), but the inequality is purely variational and uses only the order properties of KL and boundedness of* Res*. This sort of bound is typical when one introduces a regularizer: it quantifies how much the regularizer can pull an optimizer away from a baseline. Related KL-regularized variational identities appear throughout control and inference (compare the Gibbs-style KL regularization in Section 47, and the general euryphysical framing in [18]). Because the inequality does not depend on* μ_T *at all (except through the assumed uniform bounds on* Res*), it is a worst-case certificate: it rules out arbitrarily large KL excursions even if the state-dependent term is chosen adversarially, provided only that* Res *itself stays within a fixed numerical range.*

From KL to other distances (optional intuition). *If one wants a more "metric" notion of deviation, standard inequalities can convert the KL bound into bounds on other discrepancies under additional assumptions; for instance, Pinsker's inequality yields* $\|\nu^\star - \mu^*\|_{\mathrm{TV}} \le \sqrt{\frac{1}{2}\,\mathrm{KL}(\nu^\star\|\mu^*)}$*, so the lemma immediately implies a (still crude) total-variation bound scaling like* $\sqrt{\lambda(\mathrm{Res}_{\max} - \mathrm{Res}_{\min})}$*.*

Sketch. (1) With $\lambda = 0$, the objective is $\mathrm{KL}(\nu\|\mu^*)$ minimized at μ^*. More explicitly, since $\mathrm{KL}(\nu\|\mu^*) \ge 0$ for all feasible ν and $\mathrm{KL}(\mu^*\|\mu^*) = 0$, every minimizer must achieve the value

0, which forces $\nu = \mu^*$ whenever the KL minimizer is unique (and otherwise restricts ν to the KL-minimizing set).

(2) Compare the objective at $\nu^\star$ to the objective at μ^*:

$$\mathrm{KL}(\nu^\star \| \mu^*) + \lambda \mathrm{Res}(\nu^\star, \mu_T) \le \mathrm{KL}(\mu^* \| \mu^*) + \lambda \mathrm{Res}(\mu^*, \mu_T) \le \lambda \mathrm{Res}_{\max}.$$

The first inequality is simply optimality of $\nu^\star$ against the feasible competitor μ^*, while the second uses $\mathrm{KL}(\mu^* \| \mu^*) = 0$ and the uniform upper bound $\mathrm{Res}(\mu^*, \mu_T) \le \mathrm{Res}_{\max}$. Rearrange and use $\mathrm{Res}(\nu^\star, \mu_T) \ge \mathrm{Res}_{\min}$. □

Remark 2650. Proof sketch. *The key trick is "compare the minimizer to a known feasible competitor" (here, μ^*). Optimality says the objective at $\nu^\star$ is no larger than at μ^*. Then boundedness of* Res *lets one isolate* $\mathrm{KL}(\nu^\star \| \mu^*)$ *by squeezing* Res *between* $\mathrm{Res}_{\min}$ *and* $\mathrm{Res}_{\max}$*. This is the same comparison principle that underlies many stability and sensitivity estimates: one often gets a universal bound by pitting the unknown optimizer against a fixed reference point whose objective value can be controlled.*

Why the inequality is crude. *No structure of* Res *is used beyond boundedness, so the result cannot reflect fine geometry of the optimization landscape. Its role is primarily as a robustness certificate: no matter how adversarial μ_T is, the optimizer cannot wander arbitrarily far from μ^* in KL distance when λ and the* Res*-range are bounded. In particular, the lemma does not claim that the bound is tight, nor that deviations of that size actually occur; it only states that such deviations are never* necessary *for optimality given the capped benefit obtainable from* Res.

Variational intuition. *One may picture KL as a "spring" anchoring ν to μ^* and* $\lambda\,\mathrm{Res}$ *as an external force. Bounded force over bounded range yields bounded displacement (in the KL metric). A complementary way to say this is that the optimizer can only "buy" KL deviation by "selling" resistance reduction, and the most it can possibly sell is the finite amount* $\mathrm{Res}_{\max} - \mathrm{Res}_{\min}$.

Limit behavior in λ. *Although not proved here, the lemma is consistent with the heuristic that as $\lambda \to 0^+$ the optimizer should return toward μ^* (at least in the sense that the KL bound forces* $\mathrm{KL}(\nu^\star \| \mu^*) \to 0$ *whenever* $\mathrm{Res}_{\max} - \mathrm{Res}_{\min}$ *is fixed), while larger λ permits larger deviations; the displayed inequality makes this scaling explicit without requiring differentiability or convexity.*

47 Helper theorems for Wu Wei dynamics and optimal control

Remark 2651. *This section collects "ready-to-fire" algebraic facts for the Wu Wei control formalism, in both discrete-time KL-regularized control and its continuous-time Schrödinger bridge analogue. Philosophically, the guiding idea is that effortful control is measured not only by external cost but also by how far one* forces *the world away from its passive dynamics. This connects the intuitive notion of* Wu Wei *(non-forcing, or action that harmonizes with the underlying flow; Hyperseed-Concept 206) to a precise calculus: deviate from a baseline kernel P_0 or baseline policy π_0 only when the gained utility warrants paying an information-theoretic "resistance" penalty (Hyperseed-Concept 158, 100, 87). In particular, one may think of P_0 (or π_0) as encoding "what would happen anyway" in the absence of intervention—for example a nominal model, a default behavior, or a passive diffusion—and the KL term as enforcing a soft constraint that discourages gratuitous changes to that baseline. This perspective makes the tradeoff parameter (often written $\lambda > 0$ below) interpretable as an inverse* control temperature*: small λ permits more aggressive deviations from the baseline in pursuit of reward, while large λ enforces near-passive behavior where only sufficiently high-value changes are worth the informational effort.*

Remark 2652. *Technically, the core recurring move is the Gibbs/exponential tilt: objectives of the form*

$$\text{(expected cost or negative utility)} \;+\; \lambda\,\mathrm{KL}(\text{chosen law}\,\|\,\text{baseline law})$$

(or the sign-flipped maximization analogue) are solved exactly by a normalized exponential reweighting of the baseline. This is the discrete-time counterpart of the Schrödinger bridge viewpoint developed in the Wu Wei geodesics framework [21] (Hyperseed-Concept 207, **??***). Equivalently, the optimizer takes the baseline law and assigns higher probability to trajectories (or actions, or transitions) with lower cost / higher utility, with the KL term ensuring that this reweighting remains "close" in the information-geometric sense. In the continuous-time Schrödinger bridge setting, the same mechanism appears as an entropic regularization of optimal transport: among all controlled dynamics that match endpoint constraints (or marginals), the bridge selects the path measure closest in KL to the uncontrolled diffusion, which yields a controlled drift that can be expressed via logarithmic gradients of certain space–time harmonic (or Schrödinger) potentials. Thus, throughout the helper results, it is useful to keep in mind the unifying template:* linear *expectations plus a* convex *KL penalty lead to closed-form exponential-family solutions and, after taking logarithms, to "soft" Bellman or Hamilton–Jacobi–Bellman-type equations.*

Remark 2653. *To avoid ambiguity in later statements, we adopt the following informal dictionary (made formal in the lemmas and propositions below). In discrete time, a "law" may refer either to (i) an action distribution $\pi(\cdot \mid s)$ relative to a baseline $\pi_0(\cdot \mid s)$ at a fixed state s, or to (ii) a controlled transition kernel $P(\cdot \mid s)$ relative to a passive kernel $P_0(\cdot \mid s)$, or to (iii) an entire trajectory distribution over paths $(x_0, x_1, \ldots, x_T)$. In each case, the KL term is taken with respect to the same reference object (policy-to-policy, kernel-to-kernel, or path-measure-to-path-measure), and the exponential tilt can be applied either pointwise (statewise / timewise) or globally (on path space), yielding equivalent characterizations under standard factorization assumptions. When the baseline is Markovian, the path-space KL decomposes as a sum of one-step KL terms, which is the algebraic reason that KL-regularized dynamic programming admits tractable recursions.*

Remark 2654. *The theorem-like environments below are intentionally lightweight and computational: they are meant to be invoked as algebraic subroutines (e.g., "apply the exponential-tilt lemma" or "use the log-partition identity") rather than as standalone conceptual milestones. Where relevant, we will also highlight the role of normalization constants (log-partition functions), since they encode both the optimal value and the induced "soft" potentials that appear in Bellman and Schrödinger systems.*

47.1 One-step wu wei (Gibbs tilting) as a reusable inference rule

Helper Theorem 47.1 (Gibbs variational identity with exact optimality gap)**.** *Fix a state x, a passive distribution $P_0(\cdot \mid x)$ with full support, a cost $c : X \to \mathbb{R}$, and $\lambda > 0$. Define the one-step regularized objective*

$$J_x(P) \;:=\; \mathbb{E}_{x' \sim P(\cdot|x)}[c(x')] + \lambda\,\mathrm{KL}\big(P(\cdot \mid x) \,\|\, P_0(\cdot \mid x)\big).$$

Let

$$Z(x) \;:=\; \sum_{y \in X} P_0(y \mid x)\exp(-c(y)/\lambda), \qquad P^\star(y \mid x) \;:=\; \frac{P_0(y \mid x)\exp(-c(y)/\lambda)}{Z(x)}.$$

Then:

1. *(Minimum value)* $\min_P J_x(P) = -\lambda \log Z(x)$.

2. *(Exact gap) For every P, $J_x(P) = -\lambda \log Z(x) + \lambda \,\mathrm{KL}(P \,\|\, P^\star)$.*

In particular, $J_x(P) \geq -\lambda \log Z(x)$ with equality iff $P = P^\star$.

Remark 2655. ***Notation and conventions.*** *Here $P(\cdot \mid x)$ ranges over probability distributions on X (the next-state law given current state x). The symbol $\mathbb{E}_{x' \sim P(\cdot|x)}[\cdot]$ denotes expectation with respect to that distribution (Hyperseed-Concept 139). The divergence $\mathrm{KL}(P\|Q)$ is the Kullback–Leibler divergence, measuring how many "nats" of information are spent to deform Q into P; it is always ≥ 0 and vanishes exactly when $P = Q$. The parameter $\lambda > 0$ plays the role of a temperature or softness parameter: small λ makes the optimizer more sharply concentrated on cost minimizers; large λ makes it stay close to P_0.*

Remark 2656. ***Intuitive content.*** *The theorem says: if you minimize "expected cost + (effort to deviate from baseline)," then the optimal choice is not an arbitrary distribution but a* Gibbs tilt *of the passive distribution P_0 by $\exp(-c/\lambda)$. The normalizer $Z(x)$ is a partition function: it measures, in aggregate, how much low-cost mass is available under P_0. The "exact optimality gap" identity is especially useful for engines: it gives a quantitative certificate of suboptimality, namely the KL distance to the optimum.*

Remark 2657. ***Simple example.*** *Let $X = \{0,1\}$, $P_0(0 \mid x) = P_0(1 \mid x) = 1/2$, and costs $c(0) = 0$, $c(1) = 1$. Then*

$$P^\star(1 \mid x) = \frac{e^{-1/\lambda}}{1 + e^{-1/\lambda}}, \qquad P^\star(0 \mid x) = \frac{1}{1 + e^{-1/\lambda}}.$$

As $\lambda \to 0^+$ the policy becomes nearly deterministic on the cheaper outcome 0; as λ grows, it returns toward the unbiased baseline $1/2$.

Proof sketch. Compute $\mathrm{KL}(P\|P^\star)$ using $P^\star \propto P_0 \exp(-c/\lambda)$:

$$\lambda \mathrm{KL}(P\|P^\star) = \lambda \mathrm{KL}(P\|P_0) + \mathbb{E}_P[c] + \lambda \log Z(x).$$

Rearrange to obtain $J_x(P) = -\lambda \log Z(x) + \lambda \mathrm{KL}(P\|P^\star)$. Nonnegativity of KL gives the inequality and uniqueness. $\square$

Remark 2658. ***Commentary on the key steps.*** *The entire argument is an "algebraic completion of the square," except the square is replaced by KL divergence. One rewrites the objective in terms of KL to the candidate optimizer $P^\star$. The partition function $Z(x)$ appears because probabilities must normalize: $P^\star$ is defined only up to proportionality until $Z(x)$ is introduced.*

Remark 2659. ***Geometric intuition.*** *The set of distributions is a curved space; KL divergence behaves like a directed distance on it. This theorem shows the objective J_x is (up to an additive constant) exactly λ times the KL distance to a distinguished point $P^\star$. Thus minimizing J_x is literally moving as little as possible (in KL geometry) while still biasing toward low-cost outcomes. This is a formal rendering of "least forcing" (Hyperseed-Concept 206, 100).*

Corollary 47.2 (Easy bounds on the optimal cost)**.** *With the same setup,*

$$\min_{y \in X} c(y) \;\leq\; -\lambda \log Z(x) \;\leq\; \mathbb{E}_{y \sim P_0(\cdot|x)}[c(y)].$$

Remark 2660. ***Intuitive content and importance.*** *The optimal regularized value $-\lambda \log Z(x)$ is a "soft minimum" of the cost landscape seen through P_0. The corollary brackets this soft minimum between two familiar quantities: the hard minimum cost and the baseline expected cost. It reassures us that regularization does not invent values outside the meaningful range: one cannot do better than the best achievable cost, and one can always fall back to acting passively.*

Proof sketch. Lower bound: $Z(x) \le \exp(-\min c/\lambda)$ so $-\lambda \log Z(x) \ge \min c$. Upper bound: choose $P = P_0$ so $J_x(P_0) = \mathbb{E}_{P_0}[c]$ and $\min_P J_x(P) \le J_x(P_0)$. $\square$

Remark 2661. ***Why the inequalities work.*** *For the lower bound, the exponential weights never exceed the weight of the minimum-cost element, hence the sum $Z(x)$ cannot exceed what you would get if every term had that maximal weight. For the upper bound, we use the minimal principle itself: any candidate policy (in particular, the baseline) upper-bounds the minimum.*

Lemma 47.3 (Soft-min limits (temperature limits))**.** *Assume X is finite. Then:*

$$\lambda \to 0^+ \implies -\lambda \log Z(x) \to \min_{y \in X} c(y), \qquad \lambda \to \infty \implies P^\star(\cdot \mid x) \to P_0(\cdot \mid x).$$

Remark 2662. ***Intuition.*** *This lemma formalizes the two extreme temperaments of control. At low temperature ($\lambda \to 0^+$), the system becomes ruthlessly cost-minimizing: only the minimizers of c matter, and the value becomes the hard minimum. At high temperature ($\lambda \to \infty$), the exponential tilt flattens, and the optimal behavior becomes indistinguishable from passivity. In Wu Wei language, large λ corresponds to maximal non-forcing, while small λ corresponds to decisive forcing. A useful quantitative mnemonic is the "soft minimum" identity*

$$-\lambda \log \sum_x P_0(x) \exp\Big(-\frac{c(x)}{\lambda}\Big),$$

which interpolates between $\min_x c(x)$ as $\lambda \to 0^+$ and the passive baseline (up to an additive normalization determined by P_0) as $\lambda \to \infty$. In KL-regularized control, λ thus plays the role of a tradeoff parameter: it sets how expensive it is (in relative-entropy units) to deviate from P_0 in order to reduce expected cost.

Proof sketch. As $\lambda \to 0^+$, $Z(x)$ is dominated by minimizers of c (Laplace principle / softmin). As $\lambda \to \infty$, $\exp(-c/\lambda) \to 1$ pointwise so $P^\star \propto P_0$ and normalizes to P_0. More explicitly, writing the one-step optimizer in the Gibbs form (as in the preceding lemma)

$$P^\star(x) \;=\; \frac{P_0(x) \exp(-c(x)/\lambda)}{\sum_y P_0(y) \exp(-c(y)/\lambda)},$$

one sees that as $\lambda \to 0^+$ the denominator is asymptotically controlled by the set $\arg\min c$, so $P^\star$ concentrates its mass there (with relative weights proportional to P_0 restricted to the minimizers). Conversely, as $\lambda \to \infty$, the expansion $\exp(-c/\lambda) = 1 - \frac{c}{\lambda} + o(\lambda^{-1})$ shows the tilt becomes negligible, so the normalized distribution approaches P_0. $\square$

Remark 2663. ***Proof strategy (high-level).*** *The key is to observe which terms dominate a sum of exponentials. As λ shrinks, differences in cost are amplified exponentially, so the lowest-cost terms dominate. As λ grows, cost differences are suppressed, so the weighting becomes nearly uniform and thus returns to the baseline. Equivalently, one can view the normalizer $\sum_x P_0(x) e^{-c(x)/\lambda}$ as a partition function: at low temperature it is governed by ground states (minimum-cost states), while at high temperature it becomes insensitive to energetic differences and primarily reflects the baseline measure.*

47.2 Multi-step wu wei: desirability recursion and path-integral form

Helper Theorem 47.4 (Feynman–Kac / path-integral unrolling of desirability)**.** *Assume the finite-horizon KL-regularized control setup of Defs. 407–410 and Thm. 23, with desirability $z_t(x) =$*

$\exp(-V_t(x)/\lambda)$ *and terminal* $z_T(x) = \exp(-q_T(x)/\lambda)$*. Then* z_t *admits the passive-trajectory expectation form:*

$$z_t(x) = \mathbb{E}\Big[\exp\Big(-\frac{1}{\lambda}\sum_{s=t}^{T-1} q(x_s)\Big)\, z_T(x_T) \;\Big|\; x_t = x,\ x_{s+1} \sim P_0(\cdot \mid x_s)\Big].$$

In particular, in the finite-state case this conditional expectation is an explicit finite sum over all length-$(T-t)$ *paths starting at* x*, with the product of transition probabilities* $\prod_{s=t}^{T-1} P_0(x_{s+1} \mid x_s)$ *and the multiplicative weight* $\exp(-\sum q/\lambda)$ *appearing as factors in each term. This is exactly the discrete-time analogue of a Feynman–Kac representation: a linear evolution (for* z_t*) can be expressed as an average over random trajectories under a reference (passive) process with an exponential running weight.*

Remark 2664. ***Notation and meaning.*** *The sequence* $(x_t, x_{t+1}, \ldots, x_T)$ *is a random trajectory generated by repeatedly sampling from the passive kernel* $P_0(\cdot \mid x_s)$*. The term*

$$\exp\Big(-\frac{1}{\lambda}\sum_{s=t}^{T-1} q(x_s)\Big)$$

is a multiplicative weight (a Boltzmann factor) penalizing trajectories that incur large cumulative running cost q*. The theorem asserts that the desirability* $z_t(x)$ *is exactly the expectation of this weight times the terminal desirability* $z_T(x_T)$ *under passive dynamics. It is often helpful to read this as a "soft survival" quantity: trajectories that accumulate large cost are exponentially downweighted, and the remaining weighted mass is summarized by* $z_t(x)$*. Because* $z_T(x_T) = \exp(-q_T(x_T)/\lambda)$*, the terminal cost enters the same multiplicative structure, so both running and terminal costs contribute additively in the exponent along the entire path.*

Remark 2665. ***Intuitive content and importance.*** *This is the bridge from dynamic programming to "path integrals." Instead of solving a nonlinear Bellman recursion for* V_t*, one solves a* linear *recursion for* z_t *and can interpret* $z_t(x)$ *as a passive average over exponentially reweighted futures. For an automated reasoner, this is a powerful inference rule: it allows one to substitute reasoning about controlled trajectories with reasoning about passive trajectories plus explicit weights, aligning with the Wu Wei perspective [21]. A further conceptual benefit is that linearity unlocks standard tools (e.g. matrix products in finite state spaces, spectral viewpoints in infinite-horizon limits, and unbiased Monte Carlo estimation under* P_0 *with importance weights). In practice, the expectation form suggests simulation-based approximations: sample passive rollouts from* x*, compute the weight* $\exp(-\sum q/\lambda)z_T(x_T)$*, and average, which directly estimates* $z_t(x)$ *without explicitly enumerating actions.*

Proof sketch. Induct backward on t using the linear recursion $z_t(x) = \exp(-q(x)/\lambda)\sum_{x'} P_0(x' \mid x)z_{t+1}(x')$ and tower property of conditional expectation. Concretely, conditioning on the first passive step x_{t+1} gives

$$\mathbb{E}\Big[\exp\Big(-\frac{1}{\lambda}\sum_{s=t}^{T-1} q(x_s)\Big)z_T(x_T) \;\Big|\; x_t = x\Big] = \exp\Big(-\frac{q(x)}{\lambda}\Big)\sum_{x'} P_0(x' \mid x)\,\mathbb{E}\Big[\exp\Big(-\frac{1}{\lambda}\sum_{s=t+1}^{T-1} q(x_s)\Big)z_T(x_T) \;\Big|\; x_{t+1} = x'\Big],$$

and the inductive hypothesis identifies the inner conditional expectation with $z_{t+1}(x')$. ☐

Remark 2666. ***Proof sketch (strategy).*** *One first recognizes that the desirability recursion is linear in* z_{t+1}*. Then, by repeatedly substituting the recursion forward (or inducting backward), one* *obtains an iterated sum over paths. The tower property packages that iterated sum into a single conditional expectation over passive trajectories. Another way to view the same step is as an application of iterated conditioning: "peel off" one time step at a time, factor out the current-stage weight* $\exp(-q(x_t)/\lambda)$*, and propagate the remaining expected future weight through* P_0*. This is exactly the mechanism by which products of random weights along a Markov chain become expectations of exponentials of additive functionals.*

Remark 2667. ***Visual intuition.*** *Imagine all passive trajectories fan out from* x *like a tree. Each path gets a weight that shrinks exponentially with accumulated cost. The desirability is the total weighted mass reaching time* T*. High desirability means "many reasonably low-cost futures exist under the passive flow," which is precisely the sense in which forcing is unnecessary. Equivalently,* $-\lambda \log z_t(x) = V_t(x)$ *can be read as a "soft" cost-to-go: if* $z_t(x)$ *is large, then even without steering the dynamics aggressively, the passive process already tends to drift toward low-cost regions; if* $z_t(x)$ *is small, then most passive futures are costly, so meaningful improvement typically requires a sharper tilt (stronger forcing).*

Proposition 47.5 (Doob h-transform form of the optimal controlled kernel)**.** *Let* z_{t+1} *be as above and define*

$$P_t^\star(x' \mid x) \;:=\; \frac{P_0(x' \mid x)\, z_{t+1}(x')}{\sum_{y\in X} P_0(y \mid x)\, z_{t+1}(y)}.$$

Then $P_t^\star(\cdot \mid x)$ *is a Markov kernel with:*

1. *Normalization:* $\sum_{x'} P_t^\star(x' \mid x) = 1$.
2. *Absolute continuity:* $P_0(x' \mid x) = 0 \Rightarrow P_t^\star(x' \mid x) = 0$.

The denominator is exactly the one-step prediction of desirability under the passive dynamics,

$$\sum_{y\in X} P_0(y \mid x)\, z_{t+1}(y) = \mathbb{E}\big[z_{t+1}(x_{t+1}) \mid x_t = x,\ x_{t+1} \sim P_0(\cdot \mid x)\big],$$

so the formula can be read as a normalized reweighting of passive next-state proposals by their expected future "goodness".

Remark 2668. ***Intuitive content.*** *The optimal controlled kernel* $P_t^\star$ *is obtained by reweighting the passive kernel* P_0 *by the "promise of the future" encoded in* z_{t+1}*. Transitions leading to states with high* z_{t+1} *are amplified. This is the multi-step analogue of one-step Gibbs tilting: the immediate action is chosen so as to align with a future-looking desirability potential. The name "Doob* h*-transform" emphasizes that this reweighting preserves the Markov structure while conditioning the process toward favorable regions. One can also regard this as a Bayesian-looking update:* $P_0(\cdot \mid x)$ *plays the role of a proposal distribution over next states, while* $z_{t+1}(x')$ *is an (unnormalized) "likelihood" score for how desirable it is to land in* x'*. The controlled kernel* $P_t^\star$ *is then the corresponding normalized posterior over* x_{t+1}*.*

Proof sketch. Normalization is by construction. Absolute continuity follows because $P_t^\star$ is P_0 times a nonnegative weight, divided by a positive normalizer (full support ensures positivity). In addition, to see positivity of the denominator, note that if $P_0(\cdot \mid x)$ has full support and z_{t+1} is not identically zero, then there exists at least one y with $z_{t+1}(y) > 0$ and thus $P_0(y \mid x)z_{t+1}(y) > 0$, implying $\sum_y P_0(y \mid x)z_{t+1}(y) > 0$. □

Remark 2669. ***Commentary.*** *The nonnegativity of z_{t+1} is essential: it ensures we do not create negative transition weights. Full support of $P_0(\cdot \mid x)$ (as assumed in the one-step identity) ensures the denominator is strictly positive whenever z_{t+1} is not identically zero, so the formula defines a legitimate probability distribution. From the control perspective, absolute continuity encodes a "non-teleportation" principle: the controller cannot assign positive probability to transitions that are impossible under the passive physics. The only freedom is to* reallocate *probability mass among feasible next states, paying KL cost for deviating from P_0; the h-transform makes this reallocation explicit and computable from z_{t+1}.*

47.3 Resistance, acceptance, and opening: algebra useful for engines

Lemma 47.6 (Acceptance is an exponential similarity (and is lambda-free))**.** *Let* $\mathrm{Resist}_\lambda(\pi; x) = \lambda \mathrm{KL}(P_\pi(\cdot \mid x) \| P_0(\cdot \mid x))$ *and* $\mathrm{Accept}_\lambda(\pi; x) = \exp(-\mathrm{Resist}_\lambda(\pi; x)/\lambda)$ *as in Def. 414. Then*

$$\mathrm{Accept}_\lambda(\pi; x) = \exp\Big(-\mathrm{KL}(P_\pi(\cdot \mid x) \| P_0(\cdot \mid x))\Big) \in (0, 1],$$

so $\mathrm{Accept}_\lambda(\pi; x) = 1$ *iff* $P_\pi(\cdot \mid x) = P_0(\cdot \mid x)$*. In particular,* Accept_λ *does not depend on* λ*.*

Remark 2670. ***Intuition and usefulness.*** *"Resistance" is the λ-scaled KL cost of deviating from the passive kernel; "acceptance" is a similarity score obtained by exponentiating the negative KL. This lemma notes a pleasing cancellation: acceptance depends only on the* shape *of the deviation (the KL), not on the temperature/regularization scale λ. For an engine, this means acceptance can serve as a stable, scale-free diagnostic of non-forcing (Hyperseed-Concept 158, 206).*

Remark 2671. ***Operational reading.*** *The quantity* $\mathrm{Accept}_\lambda(\pi; x)$ *can be interpreted as a multiplicative penalty attached to the entire next-state distribution under π relative to the passive dynamics: a small change in KL produces a proportional change in* $\log \mathrm{Accept}$ *since*

$$\log \mathrm{Accept}_\lambda(\pi; x) \;=\; -\mathrm{KL}(P_\pi(\cdot \mid x) \| P_0(\cdot \mid x)).$$

Thus acceptance is naturally a "log-linear" score: differences in acceptance are easiest to compare on the log scale, where they coincide with differences in KL divergence.

Remark 2672. ***Range and edge cases.*** *The inclusion* $\mathrm{Accept}_\lambda(\pi; x) \in (0, 1]$ *uses that* $\mathrm{KL} \geq 0$*, hence* $\exp(-\mathrm{KL}) \leq 1$*. When* KL *is finite but large, acceptance can be extremely small, which is often desirable in diagnostics: a small acceptance cleanly flags that $P_\pi(\cdot \mid x)$ has become highly concentrated on events that are improbable under $P_0(\cdot \mid x)$. If* $\mathrm{KL}(P_\pi \| P_0) = +\infty$ *(e.g. P_π assigns positive probability to an event of P_0-probability 0), then* $\mathrm{Accept}_\lambda(\pi; x) = 0$ *in the extended-real sense; in many engine designs this corresponds to "hard incompatibility" with the passive flow and is treated as disallowed forcing.*

Remark 2673. ***Simple example.*** *If $P_\pi(\cdot \mid x)$ and $P_0(\cdot \mid x)$ are identical, then* $\mathrm{KL} = 0$ *and* $\mathrm{Accept} = 1$*. If P_π concentrates on outcomes that are unlikely under P_0, KL becomes large and* Accept *decays rapidly toward 0, reflecting that the policy is "fighting the flow."*

Remark 2674. ***Two-outcome sanity check.*** *Consider a binary next-state outcome with $P_0(\cdot \mid x) = (q, 1-q)$ and $P_\pi(\cdot \mid x) = (p, 1-p)$. Then*

$$\mathrm{KL}(P_\pi \| P_0) = p \log \frac{p}{q} + (1-p) \log \frac{1-p}{1-q},$$

so acceptance is $\exp(-\mathrm{KL})$*, a smooth function peaked at $p = q$ and decreasing as p deviates from q. This makes explicit that acceptance is not a linear penalty in $p - q$ but a curvature-sensitive penalty that grows sharply as p approaches 0 or 1 while q stays away from that boundary.*

Proof sketch. KL is nonnegative and equals 0 iff the two distributions coincide. The displayed expression cancels λ. $\square$

Remark 2675. ***Key step.*** *The proof is essentially dimensional analysis:* Resist_λ *is defined as* λ *times KL, while acceptance exponentiates* $-\mathrm{Resist}_\lambda/\lambda$*, so the scale* λ *drops out, leaving a pure KL-based similarity.*

Remark 2676. ***Consequences for optimization.*** *Because* $\log \mathrm{Accept}_\lambda(\pi; x)$ *is exactly* $-\mathrm{KL}(P_\pi(\cdot \mid x)\|P_0(\cdot \mid x))$*, maximizing acceptance is equivalent to minimizing the KL deviation from the passive kernel at each state. In constrained or regularized control problems, acceptance can therefore be used as a proxy constraint (e.g. enforce* $\mathrm{Accept}_\lambda(\pi; x) \geq \alpha$*) that is independent of the particular numerical choice of* λ*.*

Lemma 47.7 (Factorization rule: resistance adds, acceptance multiplies)**.** *Suppose the next-state distribution factors over independent components:* $P_0(x_1', x_2' \mid x_1, x_2) = P_0^1(x_1' \mid x_1)P_0^2(x_2' \mid x_2)$ *and similarly* $P_\pi = P_\pi^1 \otimes P_\pi^2$*. Then*

$$\mathrm{KL}(P_\pi\|P_0) = \mathrm{KL}(P_\pi^1\|P_0^1) + \mathrm{KL}(P_\pi^2\|P_0^2),$$

hence Resist_λ *is additive and* Accept *is multiplicative across components.*

Remark 2677. ***Intuition and importance.*** *Independence means "separable worlds" incur separable forcing costs: deviating from the baseline in subsystem* 1 *does not interact (in KL) with deviation in subsystem* 2*. Consequently, acceptance behaves like a product of similarities, mirroring how independent evidences combine multiplicatively. This add/multiply duality is often the algebraic backbone behind modular control architectures.*

Remark 2678. ***Explicit acceptance factorization.*** *Under the stated product assumptions,*

$$\mathrm{Accept}(\pi; x_1, x_2) = \exp\big(-\mathrm{KL}(P_\pi^1\|P_0^1) - \mathrm{KL}(P_\pi^2\|P_0^2)\big) = \mathrm{Accept}(\pi^1; x_1)\,\mathrm{Accept}(\pi^2; x_2),$$

so one can read acceptance as a "probabilistic compatibility" score that composes exactly like independent likelihood factors. This is often more numerically stable than working directly with KL sums when many components are present, since products can be accumulated via logs.

Remark 2679. ***Modularity caveat.*** *The lemma relies on true factorization of both* P_0 *and* P_π*. If the passive dynamics couple components (or the policy induces coupling), KL generally contains cross-terms and the forcing cost is no longer separable. In engine terms, coupling corresponds to "shared channels" through which forcing in one module can increase resistance in another, so the product rule is a diagnostic for when clean modularization is justified.*

Proof sketch. KL divergence is additive for product measures; substitute into definitions of Resist_λ and Accept. $\square$

Remark 2680. ***Geometric intuition.*** *Product structure corresponds to an orthogonality of coordinates in information geometry: one can move (in distribution space) along factor* 1 *and factor* 2 *independently, and the total "distance" (KL) is the sum of the factor distances. Exponentiating turns sums into products, hence acceptance multiplies.*

Remark 2681. ***Many-component extension.*** *The same calculation extends immediately to* n *independent components. If* $P_0 = \bigotimes_{i=1}^n P_0^i$ *and* $P_\pi = \bigotimes_{i=1}^n P_\pi^i$*, then*

$$\mathrm{KL}(P_\pi\|P_0) = \sum_{i=1}^n \mathrm{KL}(P_\pi^i\|P_0^i), \qquad \mathrm{Accept}(\pi; x) = \prod_{i=1}^n \mathrm{Accept}(\pi^i; x_i).$$

This "sum/product" structure is what enables distributed control laws to track a global forcing budget by tracking local forcing budgets and aggregating them additively.

Lemma 47.8 (Entropy bounds and KL-to-uniform identity for opening)**.** *Let* $\mathrm{Open}(\pi; x)$ *be Shannon entropy on a finite action set* A *(Def. 415). Then*

$$0 \leq \mathrm{Open}(\pi; x) \leq \log |A|,$$

and if Unif *is the uniform distribution on* A *then*

$$\mathrm{Open}(\pi; x) = \log |A| - \mathrm{KL}(\pi(\cdot \mid x) \,\|\, \mathrm{Unif}).$$

Remark 2682. ***Notation and meaning.*** $\mathrm{Open}(\pi; x)$ *is an "opening" measure: the entropy of the action distribution at state* x *(Hyperseed-Concept* **??***, 125). The bounds express that entropy is minimized by determinism (value* 0*) and maximized by the uniform distribution (value* $\log |A|$*). The KL-to-uniform identity says that being open is exactly being close to uniform, quantitatively.*

Remark 2683. ***Concrete extremizers.*** *The lower bound* 0 *is attained when* $\pi(\cdot \mid x)$ *is a point mass (choose one action with probability* 1*), while the upper bound* $\log |A|$ *is attained exactly at* $\pi(\cdot \mid x) = \mathrm{Unif}$*. The identity with* $\mathrm{KL}(\pi \| \mathrm{Unif})$ *makes these extremizers immediate: KL is minimized at* 0 *only when the two distributions coincide, so maximal opening occurs only under uniform randomized choice.*

Remark 2684. ***Why this is useful for engines.*** *In a Wu Wei-oriented controller, opening can be used as a knob to avoid brittle overcommitment: it measures how much the policy keeps possibilities alive. The identity expresses opening as a constant minus a KL term, so many monotonicity facts about KL immediately translate into monotonicity facts about opening.*

Remark 2685. ***Interpretation as a deficit-from-max formula.*** *The equality*

$$\log |A| - \mathrm{Open}(\pi; x) = \mathrm{KL}(\pi(\cdot \mid x) \,\|\, \mathrm{Unif})$$

can be read as: the gap *between maximal opening and current opening is exactly the information divergence from uniformity. Thus, opening is not merely a heuristic exploration score; it is a calibrated measure whose shortfall from* $\log |A|$ *has a precise information-theoretic meaning.*

Proof sketch. Standard entropy bounds. For the identity: $\mathrm{KL}(\pi \| \mathrm{Unif}) = \sum_a \pi(a) \log(\pi(a)/(1/|A|)) = \sum_a \pi(a) \log \pi(a) + \log |A|$. Rearrange. □

Remark 2686. ***Key step.*** *The proof uses the definition of KL divergence and the fact that* $\mathrm{Unif}(a) = 1/|A|$*. The term* $\log |A|$ *appears as the logarithm of the reciprocal of uniform probability, and the remaining term is (minus) the Shannon entropy.*

Remark 2687. ***Common corollaries.*** *Since* $\mathrm{KL}(\pi \| \mathrm{Unif}) \geq 0$*, the identity immediately yields* $\mathrm{Open}(\pi; x) \leq \log |A|$ *without separate bounding arguments. Moreover, if a sequence of policies* $\pi_k(\cdot \mid x)$ *converges to uniform in KL (i.e.* $\mathrm{KL}(\pi_k \| \mathrm{Unif}) \to 0$*), then* $\mathrm{Open}(\pi_k; x) \to \log |A|$*. Conversely, any systematic reduction in opening corresponds to an increase in KL-to-uniform, i.e. a quantitative move toward concentration.*

47.4 Resonance reward: algebraic expansions and bounds

Lemma 47.9 (Amplitude magnitude bounds)**.** *With $z_k(a \mid x) = (2E_k^+(a \mid x)-1)+i(2E_k^-(a \mid x)-1)$ as in Def. 416, we have $|z_k(a \mid x)| \le \sqrt{2}$ for all k, a, x. Consequently, with weights $w_k \ge 0$ and $z_{\text{tot}} = \sum_k w_k z_k$,*

$$0 \le r_{\text{res}}(a \mid x) = |z_{\text{tot}}(a \mid x)|^2 \le 2\Big(\sum_k w_k\Big)^2.$$

Remark 2688. ***Intuition and context.*** *The complex quantity z_k encodes, in its real and imaginary parts, two signed "evidence" coordinates derived from $(E_k^+, E_k^-) \in [0,1]^2$. Each coordinate is rescaled to lie in $[-1,1]$, so z_k lies in the square $[-1,1] \times [-1,1]$ in the complex plane. The lemma simply states the Euclidean radius of that square is $\sqrt{2}$, hence the magnitude bound. The resulting reward $r_{\text{res}} = |z_{\text{tot}}|^2$ is a nonnegative scalar measuring the strength of coherent summed resonance (Hyperseed-Concept 159, 160).*

Remark 2689. ***Tightness and normalization.*** *The bound $|z_k| \le \sqrt{2}$ is tight: equality holds precisely when both coordinates hit an extreme, i.e. when $2E_k^+ - 1 \in \{\pm 1\}$ and $2E_k^- - 1 \in \{\pm 1\}$ (equivalently $E_k^\pm \in \{0,1\}$). In that case z_k sits on a corner of the square and has maximal magnitude. In contrast, if $(E_k^+, E_k^-) = (\frac{1}{2}, \frac{1}{2})$ then $z_k = 0$ and the channel contributes no resonance. If one desires a per-channel amplitude constrained by 1 rather than $\sqrt{2}$, a conventional alternative is to consider the normalized amplitude $\tilde{z}_k := z_k/\sqrt{2}$, which would rescale r_{res} by a factor of $1/2$; the present convention keeps the mapping $(E_k^+, E_k^-) \mapsto z_k$ affine with unit coordinate ranges.*

Remark 2690. ***Why this matters.*** *Upper bounds are essential for stability arguments and for safely combining resonance reward with other bounded utilities. The inequality*

$$r_{\text{res}}(a \mid x) \le 2\Big(\sum_k w_k\Big)^2$$

gives an explicit global cap determined only by the weights, independent of the particular evidences. This kind of "worst-case amplitude control" is also consonant with resonance-based constructions in paraconsistent settings [24].

Remark 2691. ***Immediate corollaries for weight choices.*** *If the weights are normalized so that $\sum_k w_k = 1$ (a common choice when w_k represent a convex mixture of channels), then the lemma yields the simple global bound $r_{\text{res}}(a \mid x) \le 2$. More generally, if only an ℓ_1-budget is imposed, $\sum_k w_k \le W$, then $r_{\text{res}} \le 2W^2$. These restatements are often the form used in later control arguments because they separate (i) the design-time weight budget from (ii) the run-time evidence values.*

Proof sketch. Each real/imag part of z_k lies in $[-1,1]$, so $|z_k|^2 \le 1^2 + 1^2 = 2$. Then $|z_{\text{tot}}| \le \sum_k w_k |z_k| \le \sqrt{2} \sum_k w_k$ by triangle inequality. Square to get the bound. $\square$

Remark 2692. ***Proof strategy.*** *First bound each component amplitude, then bound the weighted sum by the triangle inequality, and finally square. The step from a bound on $|z_{\text{tot}}|$ to a bound on r_{res} is immediate because r_{res} is defined as the squared magnitude.*

Remark 2693. ***Algebraic detail of the per-channel bound.*** *Writing $z_k = (2E_k^+ - 1) + i(2E_k^- - 1)$ gives*

$$|z_k|^2 = (2E_k^+ - 1)^2 + (2E_k^- - 1)^2.$$

Since each factor satisfies $(2E-1)^2 \le 1$ for $E \in [0,1]$, one has $|z_k|^2 \le 2$ and hence $|z_k| \le \sqrt{2}$. This makes explicit that no probabilistic or independence assumptions are required: the estimate is purely geometric and follows only from the range constraint $E_k^\pm \in [0,1]$.

Proposition 47.10 (Coherence decomposition of resonance reward)**.** *Let $\bar{z}$ denote complex conjugate. Then*

$$r_{\text{res}}(a \mid x) = \Big|\sum_k w_k z_k(a \mid x)\Big|^2 = \sum_k w_k^2 |z_k(a \mid x)|^2 + 2\sum_{i<j} w_i w_j \Re\big(z_i(a \mid x)\, \bar{z}_j(a \mid x)\big).$$

Thus the cross-terms $\Re(z_i \bar{z}_j)$ encode agreement (positive) vs cancellation/conflict (negative).

Remark 2694. ***Intuitive content.*** *This is the familiar "sum of squares plus interference" decomposition. The diagonal terms $\sum_k w_k^2 |z_k|^2$ measure how strong each resonance channel is on its own. The off-diagonal terms measure how channels combine: if two channels point in the same direction in the complex plane, the real part $\Re(z_i \bar{z}_j)$ is positive and the total reward grows superadditively; if they point oppositely, the term is negative and they cancel.*

Remark 2695. ***Signed coherence as an angle.*** *For nonzero z_i, z_j, one may write*

$$\Re(z_i \bar{z}_j) = |z_i|\,|z_j|\, \cos(\theta_{ij}),$$

where θ_{ij} is the oriented angle between the two complex vectors. In this form, $\cos(\theta_{ij})$ acts as a signed coherence coefficient: it equals 1 for perfect alignment, -1 for perfect opposition, and 0 for orthogonality. This makes it clear that the reward can increase either by increasing per-channel magnitudes $|z_k|$ or by increasing alignment among channels.

Remark 2696. ***Why it connects.*** *In the subsequent Gibbs policy, resonance enters inside an exponential. There, constructive interference increases utility and hence probability mass; destructive interference suppresses it. This proposition is therefore the algebraic hinge between multi-channel evidence and action selection (Hyperseed-Concept 159, 59).*

Remark 2697. ***Bounding the interference contribution.*** *The cross-term always satisfies the sharp inequality*

$$-\,|z_i|\,|z_j| \;\le\; \Re(z_i \bar{z}_j) \;\le\; |z_i|\,|z_j|,$$

since $\Re(u) \le |u|$ and $|z_i \bar{z}_j| = |z_i|\,|z_j|$. Combined with $|z_k| \le \sqrt{2}$, this yields the uniform bound

$$\Re(z_i \bar{z}_j) \in [-2, 2],$$

and therefore each weighted interference term obeys

$$2w_i w_j\, \Re(z_i \bar{z}_j) \in [-4w_i w_j,\ 4w_i w_j].$$

These estimates clarify how negativity can enter r_{res} only through cancellation at the level of the inner sum z_{tot}; the final quantity $r_{\text{res}} = |z_{\text{tot}}|^2$ remains nonnegative, but destructive interference can substantially reduce it relative to the sum of diagonal contributions.

Proof sketch. Expand $|z_{\text{tot}}|^2 = z_{\text{tot}} \bar{z}_{\text{tot}}$ and collect diagonal and off-diagonal terms. □

Remark 2698. ***Expansion spelled out.*** *Writing $z_{\text{tot}} = \sum_k w_k z_k$ gives*

$$|z_{\text{tot}}|^2 = \Big(\sum_i w_i z_i\Big)\Big(\sum_j w_j \bar{z}_j\Big) = \sum_i w_i^2 z_i \bar{z}_i + \sum_{i \ne j} w_i w_j z_i \bar{z}_j.$$

Since $z_i \bar{z}_i = |z_i|^2$ and the $i \ne j$ terms can be paired as $z_i \bar{z}_j + z_j \bar{z}_i = 2\Re(z_i \bar{z}_j)$, the stated decomposition follows by grouping $i < j$.

Remark 2699. ***Geometric intuition.*** *Think of each z_k as a vector in the plane; z_{tot} is the weighted vector sum. The squared norm of a vector sum equals the sum of squared norms plus twice the pairwise dot products. Here $\Re(z_i \bar{z}_j)$ is exactly that dot product in complex notation.*

47.5 Resonance-modulated wu wei: Gibbs form, gap, and sensitivity

Helper Theorem 47.11 (Resonant Gibbs policy and exact optimality gap)**.** *Fix state x, baseline action distribution $\pi_0(\cdot \mid x)$ with full support, bounded cost $c(a \mid x)$, resonance weight $\beta \geq 0$, and $\lambda > 0$. Define utility*

$$u(a \mid x) := \beta\, r_{\mathrm{res}}(a \mid x) - c(a \mid x),$$

and the regularized objective

$$F_x(\pi) := \mathbb{E}_{a\sim\pi(\cdot|x)}[u(a \mid x)] - \lambda\, \mathrm{KL}(\pi(\cdot \mid x) \,\|\, \pi_0(\cdot \mid x)).$$

Let

$$Z_x := \sum_{b\in A} \pi_0(b \mid x) \exp(u(b \mid x)/\lambda), \qquad \pi^\star(a \mid x) := \frac{\pi_0(a \mid x)\exp(u(a \mid x)/\lambda)}{Z_x}.$$

Then:

1. *(Maximum value)* $\max_\pi F_x(\pi) = \lambda \log Z_x$*.*
2. *(Exact gap) For every π, $F_x(\pi) = \lambda \log Z_x - \lambda\, \mathrm{KL}(\pi \,\|\, \pi^\star)$.*

Hence $\pi^\star$ is the unique maximizer.

Remark 2700. ***Notation and sign conventions.*** *Compared to the earlier one-step theorem, we now* maximize *an objective $F_x(\pi)$, and the KL term appears with a negative sign. Thus KL penalizes deviation from the baseline π_0, while the utility u rewards resonance and penalizes cost. The normalizer Z_x is again a partition function, now over actions A rather than next-states X.*

Remark 2701. ***Intuitive content and importance.*** *The theorem says the optimal policy is again a Gibbs tilt, now favoring actions with high $(\beta\, r_{\mathrm{res}} - c)$. The exact gap identity provides a rigorous notion of "how far from wu wei" a candidate policy is: the performance loss is exactly λ times a KL divergence to the optimal policy. This makes the result especially suitable for meta-control and learning loops: it yields a scalar certificate that is both computable and interpretable.*

Remark 2702. ***Connection to earlier results.*** *This is the action-space analogue of the one-step kernel tilt: the algebra is identical once one recognizes the structural pattern "linear term in expectation plus KL regularizer." The resonance bounds and coherence decomposition above feed into this theorem by ensuring u is well-controlled and interpretable in terms of constructive/destructive interference.*

Proof sketch. Same algebra as the one-step control case, but for maximization: write $\mathrm{KL}(\pi\|\pi^\star)$ using $\pi^\star \propto \pi_0 \exp(u/\lambda)$ and rearrange to isolate $F_x(\pi)$. □

Remark 2703. ***Proof strategy.*** *One guesses the Gibbs form by analogy, then verifies it by rewriting* $\mathrm{KL}(\pi\|\pi^\star)$ *and solving for $F_x(\pi)$. The sign flip (minimization vs maximization) only changes whether $-\lambda \log Z$ or $+\lambda \log Z$ appears.*

Lemma 47.12 (Monotonicity of forcing-deviation with temperature)**.** *Let $\pi^\star_\lambda(a) \propto \pi_0(a)\exp(u(a)/\lambda)$ on a finite A with full-support π_0. Then* $\mathrm{KL}(\pi^\star_\lambda\|\pi_0)$ *is nonincreasing in λ. Equivalently, with $s = 1/\lambda$,* $\mathrm{KL}(\pi^\star_{1/s}\|\pi_0)$ *is nondecreasing in s.*

Remark 2704. ***Intuition.*** *As temperature λ increases, the Gibbs policy becomes less sharp and stays closer to the baseline π_0. Therefore the KL divergence to π_0 should drop. This lemma makes that intuition exact, and thereby justifies reading* $\mathrm{KL}(\pi^\star_\lambda\|\pi_0)$ *as an "amount of forcing" that is controlled monotonically by the temperature knob (Hyperseed-Concept 100, 88).*

Remark 2705. ***Why it connects.*** *Together with the KL-to-uniform identity for opening, this lemma yields monotonicity of openness under temperature changes (next corollary). Thus a single analytic inequality about* KL *propagates into a behavioral principle about exploration vs commitment.*

Proof sketch. Let $\pi_s(a) \propto \pi_0(a)\exp(su(a))$. Then $\mathrm{KL}(\pi_s\|\pi_0) = s\,\mathbb{E}_{\pi_s}[u] - \log Z(s)$ with $Z(s) = \sum_a \pi_0(a)\exp(su(a))$. Differentiate w.r.t. s and use $\frac{d}{ds}\mathbb{E}_{\pi_s}[u] = \mathrm{Var}_{\pi_s}(u) \geq 0$ to get $\frac{d}{ds}\mathrm{KL}(\pi_s\|\pi_0) = s\,\mathrm{Var}_{\pi_s}(u) \geq 0$. □

Remark 2706. ***Key step commentary.*** *The identity $\frac{d}{ds}\mathbb{E}_{\pi_s}[u] = \mathrm{Var}_{\pi_s}(u)$ is the classical exponential-family calculus: differentiating the log-partition function yields moments, and differentiating again yields variances. The inequality then becomes almost tautological: variance is non-negative, hence KL increases with sharpness $s = 1/\lambda$.*

Corollary 47.13 (If baseline is uniform, opening increases with lambda for Gibbs policies)**.** *If* $\pi_0 = \mathrm{Unif}$ *(uniform on A), then for $\pi^\star_\lambda$ as above,*

$$\mathrm{Open}(\pi^\star_\lambda; x) = \log|A| - \mathrm{KL}(\pi^\star_\lambda\|\mathrm{Unif})$$

is nondecreasing in λ.

Remark 2707. ***Intuition.*** *With a uniform baseline, "openness" is literally the complement of KL-to-uniform. Since higher temperature reduces KL-to-baseline, it increases openness. This expresses, in a clean inequality, the common-sense idea that softer control keeps more options available (Hyperseed-Concept 125, 195).*

Proof sketch. Combine the KL-to-uniform identity for Open with the monotonicity of $\mathrm{KL}(\pi^\star_\lambda\|\pi_0)$. □

Remark 2708. ***Proof strategy.*** *This is a direct substitution: rewrite opening in terms of KL, then apply the previous lemma and note that subtracting a nonincreasing function yields a nondecreasing one.*

Lemma 47.14 (Sensitivity of the optimal value to resonance weight)**.** *Let* $\Phi(\beta) := \max_\pi F_x(\pi) = \lambda \log Z_x(\beta)$ *with* $Z_x(\beta) = \sum_a \pi_0(a \mid x)\exp((\beta\, r_{\mathrm{res}}(a \mid x) - c(a \mid x))/\lambda)$*. Then*

$$\frac{d}{d\beta}\Phi(\beta) = \mathbb{E}_{a\sim\pi^\star(\cdot|x)}[r_{\mathrm{res}}(a \mid x)].$$

Remark 2709. ***Intuition and usefulness.*** *This is an envelope-theorem style statement: the derivative of the optimal value with respect to the resonance weight β equals the expected resonance reward under the* optimal *policy. It provides an interpretable gradient for meta-optimization: increasing β increases the optimum value at a rate equal to "how much resonance the current optimum is already harvesting." This is precisely the kind of sensitivity rule an automated reasoner can reuse to tune hyperparameters.*

Proof sketch. Differentiate $\lambda\log Z_x(\beta)$: $\frac{d}{d\beta}\log Z_x = (1/\lambda)\mathbb{E}_{\pi^\star}[r_{\mathrm{res}}]$, then multiply by λ. □

Remark 2710. ***Key step.*** *Differentiating $\log Z_x$ brings down the inside term r_{res}/λ and simultaneously normalizes by Z_x, which is exactly what constructs the Gibbs distribution $\pi^\star$. Thus the gradient naturally appears as an expectation under $\pi^\star$.*

47.6 Continuous-time wu wei (Schrodinger bridge): monotone knobs

Proposition 47.15 (WSB value is nondecreasing in epsilon)**.** *Let* $\mathrm{WSB}_\epsilon[\rho, v] = \iint \rho\big(\frac{1}{2}\|v\|^2 + \epsilon \log(\rho/p)\big)\, dx\, dt$ *as in Def. 411, with a fixed feasible set (continuity equation + boundary densities). Let* $J^\star(\epsilon)$ *be the minimal value over feasible* (ρ, v)*. Then for* $0 \le \epsilon_1 \le \epsilon_2$*,*

$$J^\star(\epsilon_1) \le J^\star(\epsilon_2).$$

Remark 2711. ***Intuition and conceptual role.*** *In the continuous-time Wu Wei Schrödinger bridge (WSB) formulation [21],* ϵ *scales the entropic regularization term* $\iint \rho \log(\rho/p)$*, i.e. the penalty for deviating from a reference path measure encoded by* p*. Increasing* ϵ *means "charging more" for informational deviation. It is therefore unsurprising, yet important to state explicitly, that the best achievable objective value cannot decrease as* ϵ *increases.*

Remark 2712. ***Connection to discrete time.*** *This monotonicity is the continuous analogue of how, in discrete-time Gibbs tilting, increasing* λ *makes control softer and reduces forcing; here, increasing* ϵ *increases the cost of deviation and thus weakly worsens the optimal value. Both are instances of the same structural principle: enlarging a penalty coefficient cannot improve the penalized optimum when the feasible set is fixed.*

Proof sketch. For any fixed feasible (ρ, v), $\mathrm{WSB}_{\epsilon_2}[\rho, v] \ge \mathrm{WSB}_{\epsilon_1}[\rho, v]$ because the only difference is $(\epsilon_2 - \epsilon_1) \iint \rho \log(\rho/p)$. Taking minima over the same feasible set preserves the inequality. □

Remark 2713. ***Proof strategy.*** *This is a pointwise comparison: for each feasible candidate, the objective increases with* ϵ*. The minimum over candidates therefore also increases (or stays the same). No deeper structure is required beyond feasibility not depending on* ϵ*.*

Lemma 47.16 (Cognitive Reynolds knob correspondence)**.** *In Def. 413,* $\mathrm{Re}_c = \|v\|_{\mathrm{typ}} L/\epsilon$ *decreases as* ϵ *increases. In discrete-time KL control, the analogous "low-regularization" knob is* $1/\lambda$*: larger* $1/\lambda$ *corresponds qualitatively to larger* Re_c *(sharper commitment / more brittle forcing).*

Remark 2714. ***Intuition.*** *The cognitive Reynolds number* Re_c *is a metaphorical measure of how inertial/ballistic the cognitive flow is compared to the smoothing effect of entropic regularization. When* ϵ *is small, the regularization is weak,* Re_c *is large, and the optimizer can form sharp, high-velocity "jets" of behavior (strong forcing). When* ϵ *is large, regularization dominates and the flow becomes smooth and conservative. Discrete-time temperature* λ *plays the same qualitative role: small* λ *(large* $1/\lambda$*) yields sharp Gibbs tilts, hence strong forcing.*

Remark 2715. ***Why this correspondence is helpful.*** *It allows one to transfer intuitions and even heuristics between the discrete-time inference rule (Gibbs tilting with* λ*) and the continuous-time bridge (WSB with* ϵ*), aligning two computational regimes under a single interpretive knob (Hyperseed-Concept* **??***, 207).*

Proof sketch. Immediate from the definitions: Re_c is inversely proportional to ϵ, and one-step/multi-step Gibbs tilting becomes sharper as λ decreases (equivalently $1/\lambda$ increases). □

Remark 2716. ***Commentary.*** *While the lemma is algebraically immediate, its conceptual content is not: it asserts that two superficially different regularization parameters (*ϵ *in a continuum variational problem,* λ *in a discrete KL control problem) should be read through the same lens of "how much the system is permitted to force." This is one of the reasons the Wu Wei formalism is a coherent unification rather than a mere collection of tricks [21].*

Part III
Theoretical Developments Regarding Hyperseed Concepts

=== BLOCK 2: JSON REPORT === “‘json

48 A Fixed Point + Selection Meta-Theorem Schema

Many constructions in compositional ontologies (including Hyperseed-style stacks) define “stable regimes” as fixed points of monotone operators on complete lattices: closures, viability kernels, mutually predictive reality-systems, workspace stabilization, etc. A reasoning engine typically needs more than existence: it must also *select* a specific stable regime using coherence/utility scores, projectors/regularizers, or meta-control policies. This note packages a reusable proof schema: (i) a fixed-point existence theorem and (ii) a selection principle that itself can be encoded as a monotone operator.

Concretely, the ambient order structure is meant to capture “informativeness” or “constraint”: elements higher in the order represent stronger commitments (e.g. larger closures, tighter invariant sets, more determinate world-models), and the join/meet operations of a complete lattice represent aggregation of compatible commitments and extraction of common content. The monotone operator then formalizes one step of a stabilization procedure: given a provisional regime, apply an update map that (by design) does not reverse the underlying notion of commitment. In many applications, the operator is built from compositional pieces (e.g. a perception update, a predictive closure, and a consistency filter), and monotonicity is precisely the algebraic condition that makes those pieces compatible with order-theoretic convergence arguments.

The fixed-point layer can be read as a pure existence-and-structure claim: under completeness and monotonicity, the set of fixed points is itself well-behaved (in particular, closed under meets and joins in standard settings), and there are canonical extremal stable regimes (least and greatest fixed points) corresponding to “minimal” and “maximal” consistent solutions. This is the level at which Knaster–Tarski style arguments typically enter: instead of analyzing a dynamical trajectory, one reasons about the order structure of post-fixed points and pre-fixed points, and obtains stable regimes as lattice-theoretic limits. In engineering terms, this tells us that if the update rule is order-preserving and the state space is closed under the relevant combinations of information, then some stable operating points *must* exist, even when they are not unique.

The selection layer is a distinct requirement: when multiple fixed points exist (as is typical in highly compositional systems), the mere existence of equilibria is not yet a usable specification. Selection can be implemented by introducing an auxiliary ordering on “candidates” (for example, a preference preorder derived from coherence scores, cost functionals, resource bounds, or safety constraints) and then building an operator that maps a set (or ideal/filter) of candidates to the subset that survive a selection rule. The key technical move in this note is that the selection rule itself can often be expressed as a monotone operator on an appropriate complete lattice of *collections* of regimes (e.g. subsets ordered by inclusion, down-sets ordered by inclusion, or pairs consisting of a regime and a certificate ordered componentwise). In that way, selecting a particular stable regime becomes another fixed-point problem: one seeks a fixed point of the selection operator that represents a self-consistent “chosen” candidate (or a minimal/maximal choice set) under the policy encoded by the selection map.

This separation—first prove that stable regimes exist as fixed points of an update operator, then prove that a choice mechanism exists as a fixed point of a selection operator—is intended as a reusable meta-theorem schema. It allows one to swap in different domain theories (different lattices and update operators) while reusing the same abstract proof skeleton, and it also makes explicit which assumptions belong to "physics" (the update dynamics) versus "governance" (the selection policy). In particular, by requiring monotonicity for both layers, the schema keeps the reasoning purely order-theoretic: existence, extremality, and (when present) canonicality of the selected regime are derived from lattice properties rather than from metric convergence or probabilistic mixing.

Remark 2717. *One can read the present section as a small piece of "mathematical political philosophy" for formal systems: we do not merely ask whether equilibria exist, but how a system may come to* legitimately settle *on one equilibrium among many. In Hyperseed-style compositional stacks, this corresponds to the engineering question of how an ontology, a workspace, or a goal-system stabilizes* and *how it breaks symmetry among multiple stable regimes [1]. The abstract results here are also the canonical tools used when fixed points are invoked to model meta-goal and self-modification stability [10].*

One may also view "legitimacy" here in a narrowly formal sense: the selection outcome should be *internally certified* by the same order-theoretic constraints that define stability, rather than imposed as an external ad hoc choice. For example, a meta-control policy may be required to be invariant under refinements of information (monotonicity), or to respect a dominance order induced by safety constraints; in such cases, the selected equilibrium is not merely a picked element, but a fixed point of a policy operator that can be audited against explicit axioms. This makes it possible to separate questions of value (which policy operator is endorsed) from questions of correctness (what fixed points that operator entails), while still working in a uniform mathematical idiom.

Remark 2718. *Conceptually, "stability" is being represented in the most austere Russellian way: as a fixed point of an order-preserving transformation. Yet the "selection" layer gestures toward the more process-oriented sensibility of Whitehead, in which actuality is not merely what is consistent, but what is* selected *by a process of concrescence; and toward Peirce's emphasis on habits (regularities) as the outcome of lawful formation [15, 14]. The mathematics itself, however, remains purely order-theoretic.*

In practical terms, the austerity is a feature: by working only with order structure, the schema applies equally to symbolic closures, semantic entailment operators, constraint propagation on workspaces, and abstract viability constructions, without committing to a particular notion of distance, probability, or gradient. When additional structure is available (e.g. topology, convexity, or metrics), it can often be layered on top to obtain stronger uniqueness or continuity properties; but the baseline fixed-point-plus-selection pattern already delivers a robust, compositional way to argue that "a stable regime exists" and that "a principled choice among stable regimes exists" under assumptions that are easy to state and easy to preserve under composition.

48.1 Standing assumptions

Definition 447 (Complete lattice, monotone map)**.** *A* complete lattice *is a poset $(L, \leq)$ in which every subset $A \subseteq L$ has a meet $\bigwedge A$ and a join $\bigvee A$. A map $F : L \to L$ is* monotone *if $x \leq y$ implies $F(x) \leq F(y)$.*

Remark 2719. *A useful immediate consequence of completeness is that L has distinguished extremal elements: the meet of the empty set $\bigwedge \varnothing$ is the* top *element (often written $\top$), and the join* *of the empty set $\bigvee \varnothing$ is the* bottom *element (often written $\bot$). Thus completeness is stronger than merely having binary meets/joins; it asserts that arbitrary intersections and unions (in the powerset case), or arbitrary infima and suprema (in the real-interval case), exist inside L without leaving the universe of admissible states.*

Remark 2720. *Intuitively, a complete lattice is a space of "states" where one can always form the* most conservative common refinement *(the meet, $\bigwedge A$) and the* least conservative common generalization *(the join, $\bigvee A$) of any collection of states, even an infinite one. The order $\le$ is the comparison of information, constraint, or commitment: $x \le y$ often reads as "y contains (at least) as much commitment/information/structure as x" depending on the application. In this reading, meets correspond to combining constraints (keeping only what all states in A jointly enforce), while joins correspond to relaxing constraints just enough to cover all states in A.*

Remark 2721. *Monotonicity is the minimal structural hypothesis one typically needs to make order-theoretic iteration meaningful: if $x \le y$ represents "y is at least as informative as x," then monotonicity says that applying the update rule does not invert information ordering. In particular, it allows one to compare runs started from different initial states, and it is exactly the hypothesis under which classical fixed-point theorems (e.g. Knaster–Tarski) apply in complete lattices.*

Remark 2722. *Two standard examples help fix ideas. (1) The powerset lattice $(\mathcal{P}(U), \subseteq)$ is complete, with $\bigwedge A = \bigcap A$ and $\bigvee A = \bigcup A$. Monotone maps here include closure operators, forward/backward reachability maps, and the mutual-prediction closure operators used to define reality-systems (cf. Hyperseed-Concept 149). A common pattern is that $F(S)$ is obtained from S by adding all elements forced by some rule; monotonicity then says that starting from a larger set cannot lead to fewer forced consequences. (2) Any interval like $([0,1], \le)$ is a complete lattice where $\bigwedge A = \inf A$ and $\bigvee A = \sup A$. In such a setting, monotone maps include many "update rules" for bounded confidence or graded evidence. The completeness assumption is precisely what prevents the pathological situation in which a limiting process has nowhere to go. One should keep in mind that completeness here refers to order-theoretic completeness (existence of all $\inf / \sup$), not necessarily metric completeness; the point is that order-limits of increasing/decreasing families remain representable as elements of the same state space.*

Remark 2723. *On notation: $\bigwedge A$ and $\bigvee A$ denote meet/join of an* arbitrary subset *$A \subseteq L$. When we write expressions like $x \wedge \alpha$ or $x \vee \beta$ later, these are the* binary *meet/join, i.e. $x \wedge \alpha := \bigwedge\{x, \alpha\}$ and $x \vee \beta := \bigvee\{x, \beta\}$. In particular, binary meets/joins are just a special case of arbitrary meets/joins, and the latter are the ones that enable taking "limits" of potentially infinite collections of approximants in a purely order-theoretic sense.*

Definition 448 (Prefix/postfix points, fixed points)**.** *Let $F : L \to L$.*

$$\begin{aligned}
\mathrm{Pre}(F) &:= \{x \in L : F(x) \le x\} \quad \textit{(prefix points)},\\
\mathrm{Post}(F) &:= \{x \in L : x \le F(x)\} \quad \textit{(postfix points)},\\
\mathrm{Fix}(F) &:= \{x \in L : F(x) = x\} \quad \textit{(fixed points)}.
\end{aligned}$$

Remark 2724. *A prefix point is a state x that is "already at least as strong as what F would produce from it": applying F does not add anything beyond x itself. A postfix point is the dual notion: x is "not stronger than its own update," i.e. F moves x upward (or at least not downward). A fixed point is where these two meet: the update rule leaves the state unchanged. Equivalently, $\mathrm{Fix}(F) = \mathrm{Pre}(F) \cap \mathrm{Post}(F)$, so fixed points are precisely the states that are simultaneously stable against strengthening (prefix) and stable against weakening (postfix) under the action of F.*

Remark 2725. *In the "information order" reading, the inequalities in* $\mathrm{Pre}(F)$ *and* $\mathrm{Post}(F)$ *can be interpreted as one-step invariants. For* $x \in \mathrm{Pre}(F)$*, the state already entails all consequences that the update rule would infer (so* F *is conservative relative to* x*); for* $x \in \mathrm{Post}(F)$*, the update rule can only add information to* x *(so* x *is an under-approximation of its own update). These two notions are especially useful when* F *is used to define a notion of consistency or closure: prefix points act like candidates that are closed "from above," while postfix points act like candidates that are closed "from below."*

Remark 2726. *Simple examples clarify the three sets. If* $L = \mathcal{P}(U)$ *and* F *is a closure operator (e.g. reachability closure, or mutual predictive closure), then* $\mathrm{Fix}(F)$ *is the family of closed sets;* $\mathrm{Pre}(F)$ *are sets that already contain their closure (which is the same as being closed if* F *is extensive), and* $\mathrm{Post}(F)$ *are sets whose closure contains them (which is always true for extensive* F*). In many applications,* F *is not necessarily extensive or contractive, so separating* $\mathrm{Pre}(F)$ *and* $\mathrm{Post}(F)$ *is not pedantry: it is exactly what allows the order-theoretic machinery to work without extra assumptions. In particular, one can reason about* upper bounds *on fixed points via prefix points and about* lower bounds *via postfix points, even when* F *does not behave like a classical closure (extensive and idempotent) or like a contraction.*

Remark 2727. *A key motivation for recording* $\mathrm{Pre}(F)$ *and* $\mathrm{Post}(F)$ *explicitly is that, under the standing assumptions (complete lattice and monotone* F*), the collection of fixed points is itself well-behaved: Knaster–Tarski implies that* $\mathrm{Fix}(F)$ *forms a complete lattice, with the least fixed point given by* $\bigwedge \mathrm{Pre}(F)$ *and the greatest fixed point given by* $\bigvee \mathrm{Post}(F)$*. Even when one does not immediately invoke the theorem, these formulas serve as a guiding heuristic for how "maximally conservative" and "maximally liberal" solutions are extracted from families of one-step invariants.*

48.2 Fixed points as a complete "solution space"

Theorem 58 (Knaster–Tarski package)**.** *Let* $(L, \leq)$ *be a complete lattice and let* $F : L \to L$ *be monotone. Define*

$$\mu := \bigwedge \mathrm{Pre}(F), \qquad \nu := \bigvee \mathrm{Post}(F).$$

Then:

1. μ *and* ν *are fixed points:* $F(\mu) = \mu$ *and* $F(\nu) = \nu$*.*
2. μ *is the least fixed point and* ν *is the greatest fixed point: for all* $x \in \mathrm{Fix}(F)$*,* $\mu \leq x \leq \nu$*.*
3. $\mathrm{Fix}(F)$ *is a complete lattice under the inherited order. Moreover, for any nonempty* $S \subseteq \mathrm{Fix}(F)$*, if we set*

   $$\alpha := \bigwedge S, \qquad \beta := \bigvee S,$$

   and define two auxiliary monotone maps

   $$H_\alpha(x) := F(x) \wedge \alpha, \qquad K_\beta(x) := F(x) \vee \beta,$$

   then:

   $$\bigwedge_{\mathrm{Fix}(F)} S \;=\; \mathrm{gfp}(H_\alpha), \qquad \bigvee_{\mathrm{Fix}(F)} S \;=\; \mathrm{lfp}(K_\beta).$$

   (Here $\bigwedge_{\mathrm{Fix}(F)}$ *and* $\bigvee_{\mathrm{Fix}(F)}$ *denote meet/join computed* inside $\mathrm{Fix}(F)$*.)*

Remark 2728. *For clarity of notation:* $\mathrm{Pre}(F) := \{x \in L : F(x) \le x\}$ *is the set of* pre-fixed points *(also called* prefixpoints*),* $\mathrm{Post}(F) := \{x \in L : x \le F(x)\}$ *is the set of* post-fixed points *(or* postfixpoints*), and* $\mathrm{Fix}(F) := \{x \in L : F(x) = x\}$ *is the set of fixed points. In a complete lattice* $\mathrm{Pre}(F)$ *and* $\mathrm{Post}(F)$ *are automatically nonempty:* $\top \in \mathrm{Pre}(F)$ *because* $F(\top) \le \top$*, and* $\perp \in \mathrm{Post}(F)$ *because* $\perp \le F(\perp)$*. Thus the meets/joins defining* μ *and* ν *are always defined.*

Remark 2729. *One useful way to read the theorem is as a "three-layer package": (i) fixed points exist (indeed, extremal ones exist), (ii) all fixed points are trapped between the extremal ones, and (iii) the collection of fixed points inherits enough structure to support arbitrary meets/joins* internally*. The third item is stronger than mere existence: it says the space of solutions is closed under the natural lattice operations once those operations are interpreted inside* $\mathrm{Fix}(F)$*.*

Remark 2730. *In plain language, the theorem says: if your update rule* F *never reverses the order of states, then there is always a* smallest *stable regime* μ *and a* largest *stable regime* ν*, and all other stable regimes sit between them. Moreover, the* set of all stable regimes *is itself structured as a complete lattice, meaning that stable regimes can be combined (by meet/join) and the combination is still stable when computed in the right way.*

Remark 2731. *This result is important because it turns existence of equilibria from a fragile analytic question into a structural certainty: no metric, no convexity, no continuity are required—only completeness of the state-space and monotonicity of the update rule. In systems terms, this is why fixed-point reasoning appears so pervasively when defining closures ("what is implied by what we already have"), viability kernels ("what can remain viable under constraints"), and mutually predictive closures (cf. reality-systems as fixed points, Hyperseed-Concept 149). In the Hyperseed context, this style of reasoning is explicitly leveraged in the analysis of stable goal configurations and self-modification [10].*

Remark 2732. *A small notational comment for later use:* $\mathrm{lfp}(\cdot)$ *and* $\mathrm{gfp}(\cdot)$ *denote the least and greatest fixed points of a monotone operator, respectively, computed in the ambient complete lattice. The theorem shows how to compute* meets/joins internal to $\mathrm{Fix}(F)$ *using* lfp/gfp *of auxiliary operators that force the result to stay below (or above) a target bound.*

Remark 2733. *The auxiliary operators in (3) can be viewed as "clamped" versions of* F*. The map* $H_\alpha(x) = F(x) \wedge \alpha$ *runs one step of* F *and then caps the result at* α*; fixed points of* H_α *are precisely fixed points of* F *that do not exceed* α*. Dually,* $K_\beta(x) = F(x) \vee \beta$ *runs one step of* F *and then enforces a floor at* β*; its fixed points are exactly fixed points of* F *that lie above* β*. This is why taking* $\mathrm{gfp}(H_\alpha)$ *and* $\mathrm{lfp}(K_\beta)$ *produces, respectively, the greatest fixed point below all of* S *and the least fixed point above all of* S*.*

Proof. (1) Let $\mu := \bigwedge \mathrm{Pre}(F)$. For any $p \in \mathrm{Pre}(F)$ we have $\mu \le p$, so by monotonicity $F(\mu) \le F(p) \le p$. Thus $F(\mu)$ is a lower bound of $\mathrm{Pre}(F)$, hence $F(\mu) \le \mu$. Now apply F again: since $F(\mu) \le \mu$, monotonicity implies $F(F(\mu)) \le F(\mu)$, i.e. $F(\mu) \in \mathrm{Pre}(F)$. Because μ is the greatest lower bound of $\mathrm{Pre}(F)$, we get $\mu \le F(\mu)$. So $F(\mu) = \mu$.

Similarly, let $\nu := \bigvee \mathrm{Post}(F)$. For any $q \in \mathrm{Post}(F)$ we have $q \le \nu$, so $F(q) \le F(\nu)$ by monotonicity, i.e. $q \le F(\nu)$ because $q = F(q)$ need not hold but $q \le F(q)$ does. Hence $F(\nu)$ is an upper bound of $\mathrm{Post}(F)$, so $\nu \le F(\nu)$. Also, since ν is an upper bound of $\mathrm{Post}(F)$, it is itself in $\mathrm{Post}(F)$: indeed, for each $q \in \mathrm{Post}(F)$, $q \le \nu$, and therefore $q \le F(\nu)$, so $\nu \le F(\nu)$. Then applying F to $\nu \le F(\nu)$ gives $F(\nu) \le F(F(\nu))$, i.e. $F(\nu) \in \mathrm{Post}(F)$. Since ν is the least upper bound of $\mathrm{Post}(F)$, we obtain $F(\nu) \le \nu$. Thus $F(\nu) = \nu$.

To make the "$q \le F(\nu)$" step fully explicit: $q \in \mathrm{Post}(F)$ means $q \le F(q)$, and $q \le \nu$ implies $F(q) \le F(\nu)$ by monotonicity, hence $q \le F(q) \le F(\nu)$. This is the only place where we use post-fixedness rather than fixedness.

(2) If $x \in \mathrm{Fix}(F)$, then $F(x) = x$ implies both $F(x) \le x$ and $x \le F(x)$, so $x \in \mathrm{Pre}(F) \cap \mathrm{Post}(F)$. Therefore $\mu = \bigwedge \mathrm{Pre}(F) \le x$ and $x \le \bigvee \mathrm{Post}(F) = \nu$. In particular, μ and ν are respectively the bottom and top elements of the poset $(\mathrm{Fix}(F), \le)$, so every fixed point is "sandwiched" between them. (This is often how one proves bounds on equilibria: show a candidate is pre-fixed or post-fixed to trap it between μ and ν.)

(3) We sketch the completeness construction with the stated formulas. Fix nonempty $S \subseteq \mathrm{Fix}(F)$ and put $\alpha := \bigwedge S$ (meet in L). First observe $F(\alpha) \le \alpha$: for each $s \in S$ we have $\alpha \le s$, hence $F(\alpha) \le F(s) = s$ by monotonicity. So $F(\alpha)$ is a lower bound of S, hence $F(\alpha) \le \alpha$.

Now define $H_\alpha(x) = F(x) \wedge \alpha$. This map is monotone (meet with a constant preserves monotonicity). Any fixed point y of H_α satisfies $y \le \alpha$, hence $F(y) \le F(\alpha) \le \alpha$, so

$$y = H_\alpha(y) = F(y) \wedge \alpha = F(y).$$

Thus every fixed point of H_α is a fixed point of F lying below α, hence below every element of S. Conversely, if $y \in \mathrm{Fix}(F)$ and $y \le \alpha$, then $H_\alpha(y) = F(y) \wedge \alpha = y \wedge \alpha = y$, so $y \in \mathrm{Fix}(H_\alpha)$. Therefore $\mathrm{Fix}(H_\alpha) = \{y \in \mathrm{Fix}(F) : y \le \alpha\}$, and its greatest element $\mathrm{gfp}(H_\alpha)$ is exactly the meet of S computed inside $\mathrm{Fix}(F)$.

Equivalently (spelling out the "internal meet" viewpoint), $\bigwedge_{\mathrm{Fix}(F)} S$ is characterized as the *greatest* fixed point that is a lower bound of S within $\mathrm{Fix}(F)$. Since $\alpha = \bigwedge S$ is the greatest lower bound in the ambient lattice L, the condition "y is a lower bound of S" is exactly $y \le \alpha$, so taking the greatest fixed point among those y is precisely the gfp of the clamped operator H_α. This is why the formula uses $\mathrm{gfp}(H_\alpha)$ rather than simply α (which may fail to be a fixed point of F).

The join formula is dual. Let $\beta := \bigvee S$ (join in L). For each $s \in S$, $s \le \beta$ implies $F(s) = s \le F(\beta)$, so $F(\beta)$ is an upper bound of S. By minimality of β as the least upper bound, $\beta \le F(\beta)$, i.e. $\beta \in \mathrm{Post}(F)$. Define $K_\beta(x) = F(x) \vee \beta$, which is monotone. Any fixed point y of K_β satisfies $y \ge \beta$, hence $F(y) \ge F(\beta) \ge \beta$, so

$$y = K_\beta(y) = F(y) \vee \beta = F(y).$$

Thus fixed points of K_β are exactly fixed points of F lying above β, and the least such point $\mathrm{lfp}(K_\beta)$ is the join of S inside $\mathrm{Fix}(F)$.

As with meets, the point is that $\beta = \bigvee S$ computed in L need not itself be fixed; instead, $\mathrm{lfp}(K_\beta)$ selects the *least* fixed point that still dominates all of S. The restriction to nonempty S in the statement is only to avoid notational distraction: completeness of $\mathrm{Fix}(F)$ also covers the empty meet/join, yielding the top and bottom elements of $\mathrm{Fix}(F)$, namely ν and μ from (1)–(2), respectively. □

Remark 2734. Proof sketch (high level). *The least fixed point μ is obtained by taking the "most informative" state that is still below* every *prefix point; monotonicity then forces $F(\mu)$ to be both below and above μ, hence equal. The greatest fixed point ν is dual. For completeness of* Fix(F), *the idea is that the naive meet $\alpha = \bigwedge S$ might fail to be a fixed point; one therefore applies a constrained fixed-point computation: iterate F while never exceeding the bound α (via H_α), and take the greatest fixed point compatible with the bound. The join construction is the same story with an upward bound.*

Remark 2735. *A useful geometric intuition is to picture L as a landscape of partially ordered regimes, and F as a "flow" that can only move points upward when inputs move upward. Prefix points are those above their image, postfix points below their image. The meet of prefix points is the lowest "ceiling" compatible with all ceilings; applying F cannot jump above any ceiling, so it must land under that ceiling, and then the self-referential step closes the trap.*

48.3 Selection as an operator: "stable after dynamics + projection"

Definition 449 (Selection projector)**.** *A* selection projector *is a map $S : L \to L$ such that:*

1. *S is monotone;*
2. *S is idempotent: $S \circ S = S$.*

Intuition: S maps arbitrary states to a "selected" subset of states, and idempotence means selected states are already stable under selection.

Remark 2736. *Philosophically, S formalizes a familiar move: from the profusion of possible states, we admit only those states that satisfy some criterion of admissibility, coherence, feasibility, or economy. The monotonicity requirement says that if a state becomes "stronger" in the order-theoretic sense, then selection does not behave perversely with respect to this strengthening. Idempotence says selection is not an endless ritual: once a state has been brought into the selected form, re-selecting changes nothing.*

Remark 2737. *Examples. (1) Feasibility projection: if $A \subseteq L$ is a set of admissible states and $S(x)$ is the least element of A above x (when it exists), then S is idempotent and monotone. (2) Normalization/projection for resource-bounded reasoning: S may delete components exceeding a budget, or collapse distinctions deemed too costly. This connects directly to the use of weakness/simplicity normalization (Hyperseed-Concept 202 and Hyperseed-Concept 143) as an operator that enforces cognitive economy [3, 2].*

Remark 2738. *In applications, S can model: coherence regularization, simplicity/weakness normalization, budget-feasible projection, policy-class restriction, "make explicit" compilation, etc. Nothing here requires S to be extensive or contractive.*

Theorem 59 (Existence of selected equilibria)**.** *Let $(L, \leq)$ be a complete lattice, $F : L \to L$ monotone, and $S : L \to L$ a selection projector. Define the combined update*

$$T := S \circ F.$$

Then:

1. *T is monotone and therefore has a least and a greatest fixed point in L.*
2. *Every fixed point of T is automatically a fixed point of S:*

$$x \in \mathrm{Fix}(T) \;\Rightarrow\; x \in \mathrm{Fix}(S).$$

3. *Any state that is simultaneously F-stable and selected is T-stable:*

$$\mathrm{Fix}(F) \cap \mathrm{Fix}(S) \subseteq \mathrm{Fix}(T).$$

Remark 2739. *This theorem says that if you first apply dynamics (F) and then apply selection (S), the composite update rule T is still monotone, hence still possesses extremal equilibria by the Knaster–Tarski package (Theorem 58). Moreover, any equilibrium of the composite is necessarily already "in selected form," and any state that is both dynamically stable and already selected is an equilibrium of the composite. In other words: "stability after projection" is itself a stable regime.*

Remark 2740. *This is the basic bridge between existence and design: it legitimizes the common engineering move of taking a system with messy dynamics and then repeatedly projecting back to a manageable subspace (feasible, coherent, simple, budgeted). In AGI architecture language, it is a formal template for repeatedly applying a cognitive update and then applying a meta-control or resource-allocation constraint (cf. Hyperseed-Concept 87 and Hyperseed-Concept 60), a theme recurring in cognitive synergy approaches [19].*

Proof. (1) T is a composition of monotone maps, hence monotone. Apply Theorem 58(1).

(2) If $x \in \mathrm{Fix}(T)$, then $x = T(x) = S(F(x))$ lies in the image of S. Apply idempotence:

$$S(x) = S(S(F(x))) = S(F(x)) = x.$$

So $x \in \mathrm{Fix}(S)$.

(3) If $x \in \mathrm{Fix}(F) \cap \mathrm{Fix}(S)$, then

$$T(x) = S(F(x)) = S(x) = x,$$

so $x \in \mathrm{Fix}(T)$. □

Remark 2741. Proof sketch (high level). *The only substantive ingredient is that monotonicity is preserved under composition, so Theorem 58 applies to T. The rest is algebraic: if x is fixed by T, then x is literally of the form $S(\cdot)$, and idempotence of S forces $S(x) = x$; conversely, if x is fixed by both F and S, then substituting these equalities into $T(x) = S(F(x))$ yields $T(x) = x$.*

Remark 2742. *A helpful picture is to imagine F as moving points around and S as a "snap-to-grid" operator. A T-fixed point is a point that, after being moved and snapped, lands back on itself. The theorem says such a point must already lie on the grid (be S-fixed), and that any point that is simultaneously unmoved by F and already on the grid is also a T-fixed point.*

48.4 Meta-selection: selecting the update rule (policy/parameter) and the state together

Theorem 60 (Self-consistent selection fixed point on a product lattice)**.** *Let $(P, \preceq)$ and $(L, \leq)$ be complete lattices. Assume:*

- *$F : P \times L \to L$ is monotone in both arguments;*
- *$S : L \to L$ is a selection projector (monotone, idempotent);*
- *$G : L \to P$ is monotone (a "policy/parameter selection" map).*

Define $H : P \times L \to P \times L$ by

$$H(p, x) := \big(G(x),\, S(F(p, x))\big).$$

Then H has a least and a greatest fixed point (p^*, x^*), and any fixed point satisfies:

$$p^* = G(x^*), \qquad x^* = S(F(p^*, x^*)), \qquad x^* \in \mathrm{Fix}(S).$$

Moreover, the fixed point condition $H(p^*, x^*) = (p^*, x^*)$ is exactly the coupled "simultaneous equation" system consisting of a meta-selection equation for the update rule ($p^* = G(x^*)$) together with a selected equilibrium condition for the state ($x^* = S(F(p^*, x^*))$). In particular, the result is not merely an existence statement for equilibria in L for a given *p, but an existence statement for equilibria of the* joint *closed-loop map that chooses p from x and then updates x using that p.*

Remark 2743. *The theorem expresses a clean notion of* self-consistency*: the "policy/parameter" p^* is exactly what the policy-selection map G would choose when observing the resulting stable state x^*, and the state x^* is stable under the dynamics induced by that very policy (with selection applied). This is a formal schema for feedback loops in which the system chooses how it will update itself based on its current condition, and then settles into a regime compatible with that choice (Hyperseed-Concept 110 and Hyperseed-Concept 203). One useful way to read the equations is as a closure condition: starting from x^*, the system "reads" a policy p^* via G, then applies the corresponding update $F(p^*, \cdot)$, and finally enforces admissibility via S, landing back on the same x^*. The extra statement $x^* \in \mathrm{Fix}(S)$ emphasizes that the stabilized state lies in the selected (admissible) region, so that selection is not merely applied once but is consistent with the fixed point.*

Remark 2744. *Why this matters: without such a product fixed point, one could have an endless regress in which the system's state determines its policy, which changes its state, which changes its policy, and so on, without convergence. The theorem guarantees that, at least at the level of order-theoretic abstraction, there are extremal self-consistent solutions. This is one of the clean mathematical backbones behind fixed-point analyses of meta-goal stability in self-modifying agents [10], and it resonates with the broader theme that "least-effort" or constraint-regularized selection rules can be treated as operators in their own right [21]. Concretely, the existence of a* least *and* greatest *fixed point provides two canonical boundaries for the space of self-consistent regimes: one can interpret the least fixed point as the most conservative (least committing) self-consistent configuration compatible with the order, and the greatest fixed point as the most expansive one. Even when intermediate fixed points exist, these extremal fixed points supply well-defined endpoints for comparative statics (e.g., how changing F, G, or S shifts the minimal or maximal stable closed-loop behavior).*

Proof. The product poset $(P \times L, \preceq \times \leq)$ is a complete lattice with coordinatewise meets and joins. Explicitly, if $\{(p_i, x_i)\}_{i\in I} \subseteq P \times L$, then

$$\bigvee_{i\in I}(p_i, x_i) = \Big(\bigvee_{i\in I} p_i,\ \bigvee_{i\in I} x_i\Big), \qquad \bigwedge_{i\in I}(p_i, x_i) = \Big(\bigwedge_{i\in I} p_i,\ \bigwedge_{i\in I} x_i\Big),$$

which exist by completeness of P and L. The map H is monotone because G, S, and F are monotone and products preserve monotonicity. More explicitly, if $(p, x) \preceq \times \leq (p', x')$ (i.e. $p \preceq p'$ and $x \leq x'$), then monotonicity of G gives $G(x) \preceq G(x')$, and monotonicity of F in both arguments gives $F(p, x) \leq F(p', x')$, hence monotonicity of S yields $S(F(p, x)) \leq S(F(p', x'))$. Thus $H(p, x) \preceq \times \leq H(p', x')$. By Theorem 58(1), H has least and greatest fixed points, and any fixed point satisfies the displayed equalities by unwinding $H(p^*, x^*) = (p^*, x^*)$. Finally, $x^* = S(F(p^*, x^*))$ implies $x^* \in \mathrm{Fix}(S)$ by the same idempotence argument as in Theorem 59(2): applying S to both sides gives $S(x^*) = S(S(F(p^*, x^*))) = S(F(p^*, x^*)) = x^*$, so indeed $S(x^*) = x^*$. □

Remark 2745. Proof sketch (high level). *The core move is to shift perspective: instead of treating "policy choice" and "state update" as two separate processes, we bundle them into a single update on the product space $P \times L$. Completeness and monotonicity then re-enter exactly as in Theorem 58.*

The self-consistency equalities are not extra work: they are simply what it means to be a fixed point of H. Equivalently, one can think of the coupled iteration

$$(p_{t+1}, x_{t+1}) = \big(G(x_t),\ S(F(p_t, x_t))\big)$$

as a single monotone dynamical system on a complete lattice; Tarski's theorem guarantees extremal stationary points for this iteration even when no metric contraction or continuity assumptions are available.

Remark 2746. *Visually, one can imagine x living in a landscape of states and p as choosing which "vector field" on that landscape applies. The map G reads off from the current position which vector field to use next; F moves under the chosen field; S projects the result into a selected subspace. The theorem says there exist equilibria of this coupled system: a point on the landscape together with a choice of vector field that mutually sustain one another. In settings where S represents feasibility (hard constraints) or attention (projection to a subspace of represented features), the condition $x^* \in \mathrm{Fix}(S)$ can be read as "the equilibrium is internally representable/admissible": re-applying the feasibility/attention filter does not further change the equilibrium.*

Remark 2747 (Hyperseed reading)**.** *This theorem captures the "fixed point + selection" picture where the system selects an intervention, attention regime, or update-operator parameter* as a function of its own current state*, and then stabilizes under the resulting dynamics + selection. It is a direct abstract analog of "reflective will as meta-selection". The product structure is doing the conceptual work: it lets one treat "choosing how to update" as part of the state to be stabilized, rather than as an external controller. In particular, the meta-level variable p is not assumed fixed during convergence; it is itself subject to a monotone self-consistency constraint mediated by G.*

Remark 2748. *In Hyperseed terms, one may view G as a meta-level attentional or policy-selection habit, hence a Peircean "Third" organizing a family of possible updates; while S plays the role of the admissibility filter that keeps the resulting state within a coherent sub-ontology or feasible workspace [14, 15]. The point is not to import metaphysics into the proof, but to clarify why this particular abstract pattern recurs so widely in cognitive and ontological engineering [1, 19]. From a purely mathematical standpoint, the same pattern also appears whenever one has (i) a family of monotone operators $x \mapsto F(p, x)$ indexed by a parameter p, (ii) a monotone "index selection" rule $x \mapsto G(x)$, and (iii) a monotone projection enforcing a constraint set $\mathrm{Fix}(S)$. The theorem isolates exactly the minimal order-theoretic hypotheses under which the closed-loop operator admits extremal equilibria.*

48.5 Comparative statics: how selected equilibria move when the dynamics are strengthened

Definition 450 (Pointwise order on operators)**.** *For $F, G : L \to L$, write $F \leq_{\mathrm{pt}} G$ if $F(x) \leq G(x)$ for all $x \in L$.*

Remark 2749. *The pointwise order $\leq_{\mathrm{pt}}$ is the natural way to say "G is everywhere at least as strong as F." In many applications F and G are closure-like updates, reachability operators, or inference operators; then $F \leq_{\mathrm{pt}} G$ expresses that G adds (weakly) more consequences than F from any starting point. This definition is useful because it allows comparative statics arguments without committing to any metric notion of distance between operators.*

Remark 2750. *Two small but useful clarifications about $\leq_{\mathrm{pt}}$: (i) it is itself a partial order on the set of all endomaps $L \to L$ (reflexive, antisymmetric, transitive), inherited pointwise from $\leq$ on L;*

(ii) it is tailored to order-theoretic iteration arguments because it interacts well with composition by monotone maps: if $F \le_{\mathrm{pt}} G$ and S is monotone, then $S \circ F \le_{\mathrm{pt}} S \circ G$, exactly the comparison needed below. In particular, no continuity, contractiveness, or topology on L is required for these comparisons.

Theorem 61 (Monotone comparative statics for extremal selected equilibria)**.** *Let $(L, \le)$ be a complete lattice, let $S : L \to L$ be monotone, and let $F, G : L \to L$ be monotone. Assume $F \le_{\mathrm{pt}} G$. Define $T_F := S \circ F$ and $T_G := S \circ G$. Then:*

$$\mathrm{lfp}(T_F) \le \mathrm{lfp}(T_G), \qquad \mathrm{gfp}(T_F) \le \mathrm{gfp}(T_G).$$

Remark 2751. *This theorem says: if you strengthen the underlying dynamics from F to G (in the sense that G produces larger updates at every point), and you keep the same monotone selection layer S, then both the least and the greatest selected equilibria can only move upward. It is a formal version of a common-sense principle: more supportive/stronger dynamics cannot yield a smaller extremal stable regime when selection preserves order.*

Remark 2752. *It is worth noting what* moves upward *means here. Since L is an abstract complete lattice, "upward" is with respect to $\le$ and need not refer to any numerical increase. For example, on a powerset lattice $(\mathcal{P}(U), \subseteq)$, the conclusion reads* $\mathrm{lfp}(T_F) \subseteq \mathrm{lfp}(T_G)$ *and* $\mathrm{gfp}(T_F) \subseteq \mathrm{gfp}(T_G)$*, i.e., strengthening the dynamics can only enlarge the least and greatest selected invariant sets. On a product lattice of features ordered componentwise, it means every component of the extremal equilibria weakly increases.*

Remark 2753. *This result connects directly back to Theorem 58 via the characterization of* lfp *and* gfp *as meets of prefix points and joins of postfix points. It also underwrites the practical methodology of parameter sweeps: when a reasoning engine strengthens couplings, adds evidence, increases communication, or broadens admissible inferences, one obtains monotone bounds on how equilibria can shift. In the language of cognitive architectures, it gives a rigorous backbone to "turn the knob and see how the stable workspace grows" arguments [19].*

Remark 2754. *A standard comparative-statics perspective is to view F and G as two parameter values of a family $(F_\theta)_{\theta \in \Theta}$ ordered by strength. If $\theta \le \theta'$ implies $F_\theta \le_{\mathrm{pt}} F_{\theta'}$, then Theorem 61 implies that both $\theta \mapsto \mathrm{lfp}(S \circ F_\theta)$ and $\theta \mapsto \mathrm{gfp}(S \circ F_\theta)$ are monotone maps from $(\Theta, \le)$ into $(L, \le)$. This is exactly the order-theoretic analogue of "monotone policy functions" in parametric fixed-point problems, except that the present statement requires only lattice completeness and monotonicity.*

Proof. Because $F \le_{\mathrm{pt}} G$ and S is monotone, we have $T_F \le_{\mathrm{pt}} T_G$. Let $\mathrm{Pre}(T) := \{x : T(x) \le x\}$ as before. If $x \in \mathrm{Pre}(T_G)$ then $T_G(x) \le x$, and since $T_F(x) \le T_G(x)$ we also get $T_F(x) \le x$. Hence $\mathrm{Pre}(T_G) \subseteq \mathrm{Pre}(T_F)$, so

$$\mathrm{lfp}(T_F) = \bigwedge \mathrm{Pre}(T_F) \le \bigwedge \mathrm{Pre}(T_G) = \mathrm{lfp}(T_G).$$

Similarly, if $x \in \mathrm{Post}(T_F)$ then $x \le T_F(x) \le T_G(x)$, so $x \in \mathrm{Post}(T_G)$. Thus $\mathrm{Post}(T_F) \subseteq \mathrm{Post}(T_G)$ and therefore

$$\mathrm{gfp}(T_F) = \bigvee \mathrm{Post}(T_F) \le \bigvee \mathrm{Post}(T_G) = \mathrm{gfp}(T_G).$$

□

Remark 2755. *The proof uses only order-theoretic comparisons of sets of prefix/postfix points, so it is robust to substantial changes in interpretation. In particular, the argument does not require* *that F or G be inflationary ($x \leq F(x)$) or deflationary ($F(x) \leq x$) in general; it only uses monotonicity plus the pointwise comparison $F \leq_{\mathrm{pt}} G$. If, in an application, one does have inflationarity (typical for closure-like "add information" updates), then* $\mathrm{Post}(T)$ *is automatically nonempty (e.g. it contains $\perp$), which can make the existence of* $\mathrm{gfp}(T)$ *feel especially concrete, but the theorem does not rely on such additional structure.*

Remark 2756. Proof sketch (high level). *The strategy is to compare the sets of prefix points and postfix points. If $T_F \leq_{\mathrm{pt}} T_G$, then it is* easier *to satisfy $T_G(x) \leq x$ than to satisfy $T_F(x) \leq x$, so* $\mathrm{Pre}(T_G) \subseteq \mathrm{Pre}(T_F)$*; taking meets reverses inclusions into inequalities. Dually, it is* easier *to satisfy $x \leq T_F(x)$ than $x \leq T_G(x)$ when $T_F(x) \leq T_G(x)$, so postfix points include the other way; taking joins again yields the desired inequality.*

Remark 2757. *One can picture* $\mathrm{Pre}(T)$ *as a family of "upper barriers" and* $\mathrm{Post}(T)$ *as "lower supports" for the dynamics. Strengthening the dynamics shrinks the set of barriers and expands the set of supports; the extremal equilibria, defined as the tightest barrier and the loosest support, therefore move monotonically.*

Remark 2758. *A concrete mental model is: if x is an "upper barrier" for T_G (meaning $T_G(x) \leq x$), then it is automatically an upper barrier for any weaker update T_F because $T_F(x) \leq T_G(x)$. Thus, as the dynamics become stronger, some previously valid barriers cease to be barriers, so the meet of all barriers can only increase. Conversely, if x is a "lower support" for T_F (meaning $x \leq T_F(x)$), then it remains a support for T_G, so supports become more abundant and their join can only increase. This restates the same inclusions but emphasizes why the direction of the inequalities in the theorem is the "same" for* lfp *and* gfp *even though meets and joins react oppositely to set inclusion.*

Remark 2759. *For reasoning engines, this is the basic "if you strengthen supports/couplings/inputs, the least stable selected regime can only increase" principle. It is often the engine-level justification for doing parameter sweeps and sensitivity bounds.*

Remark 2760. *An illustrative example on a powerset lattice: let $L = \mathcal{P}(U)$, let S be a monotone "selection" operator (e.g. enforcing admissibility constraints), and let $F(X)$ be the set of states reachable from X under some transition relation. If G corresponds to adding transitions (or adding inference rules), then $F \leq_{\mathrm{pt}} G$ holds as $\subseteq$-inclusion for every starting set X. Theorem 61 then states that both the least and greatest S-selected invariant regions under reachability expand when transitions are added: one cannot obtain a smaller extremal stable region by allowing more reachability, provided the selection stage respects inclusion.*

48.6 Score-based selection among selected equilibria (existence of an optimizer)

Theorem 62 (Existence of score-maximizing selected equilibria under compactness)**.** *Let L be a compact Hausdorff topological space and let $T : L \to L$ be continuous. Assume* $\mathrm{Fix}(T) \neq \emptyset$. *Then* $\mathrm{Fix}(T)$ *is compact. In particular, for any continuous score function $J : L \to \mathbb{R}$, there exists $x^\star \in \mathrm{Fix}(T)$ such that*

$$J(x^\star) = \max\{J(x) : x \in \mathrm{Fix}(T)\}.$$

Moreover, the set of maximizers

$$\arg\max_{\mathrm{Fix}(T)} J \ := \ \{x \in \mathrm{Fix}(T) : J(x) = \max_{y \in \mathrm{Fix}(T)} J(y)\}$$

is a nonempty compact subset of $\mathrm{Fix}(T)$ *(and hence of L).*

Remark 2761. *Up to this point, selection has been treated as an* operator *(S) whose fixed points define what is admissible. But in many applications one also wants an* optimizer *among admissible equilibria: maximize coherence, utility, elegance, stability margin, or some other score. This theorem says that when the state space is compact and the update map is continuous, the set of equilibria is itself compact, hence any continuous score function achieves a maximum on it. A further modeling takeaway is that the maximizer need not be unique: the theorem guarantees existence, not single-valuedness. When multiple equilibria share the top score, the "selected-by-score" outcome is naturally a set-valued choice (the argmax set above), which is still well-behaved topologically due to compactness.*

Remark 2762. *This result is not order-theoretic but topological: it complements Knaster–Tarski rather than competing with it. Knaster–Tarski guarantees extremal fixed points under monotonicity and completeness; the present theorem guarantees existence of a score-maximizing fixed point under compactness and continuity. In practice, a system designer may use the order-theoretic results to prove that equilibria exist robustly, and then use compactness to justify a subsequent maximization step as well-posed. One can view these as two different "existence engines": order-theoretic hypotheses often align with comparative statics and monotone updates, while compactness/continuity hypotheses align with geometric or analytic models where scores and equilibria vary continuously with state.*

Remark 2763. *The assumption* $\mathrm{Fix}(T) \neq \emptyset$ *is logically independent of compactness and continuity: compactness alone does not force a fixed point to exist without additional structure (e.g. a convexity hypothesis as in Schauder-type theorems). Here the role of compactness is not to* create *fixed points but to make the set of already-existing fixed points closed and hence compact, so that maximization over them is meaningful and attained.*

Proof. Consider the continuous map $h : L \to L \times L$ defined by $h(x) = (x, T(x))$. In a Hausdorff space, the diagonal $\Delta := \{(x, x) : x \in L\}$ is closed in $L \times L$. We have

$$\mathrm{Fix}(T) = \{x : T(x) = x\} = h^{-1}(\Delta),$$

so $\mathrm{Fix}(T)$ is closed in L. Since L is compact, $\mathrm{Fix}(T)$ is compact. A continuous real-valued function on a compact set attains its maximum, so J has a maximizer on $\mathrm{Fix}(T)$. For the additional claim about $\arg\max_{\mathrm{Fix}(T)} J$, note that $\mathrm{Fix}(T)$ is compact and $J|_{\mathrm{Fix}(T)}$ is continuous, so the maximum value $m := \max_{x\in\mathrm{Fix}(T)} J(x)$ is finite and the level set

$$\arg\max_{\mathrm{Fix}(T)} J = \{x \in \mathrm{Fix}(T) : J(x) = m\} = (J|_{\mathrm{Fix}(T)})^{-1}(\{m\})$$

is closed in $\mathrm{Fix}(T)$; hence it is compact, and it is nonempty because m is attained. □

Remark 2764. Proof sketch (high level). *The fixed point set is the preimage of the diagonal under the graph map $x \mapsto (x, T(x))$. In Hausdorff spaces the diagonal is closed, so continuity makes the fixed point set closed; compactness of L then forces compactness of* $\mathrm{Fix}(T)$*. Finally, the Weierstrass maximum principle gives existence of a maximizer for J. Equivalently, one can say that the graph of a continuous map T is closed in $L \times L$ and fixed points are exactly the intersection of this graph with the diagonal; the Hausdorff hypothesis is what ensures the diagonal is closed, making the intersection behave cleanly.*

Remark 2765. *A visual intuition: draw the graph of T inside $L \times L$; fixed points are where that graph intersects the diagonal. Compactness prevents "escaping to infinity" and ensures the* *intersection structure behaves well enough that closedness and maximum-attainment follow. One can also interpret the score J as a "height function" on the equilibrium locus: compactness prevents taking an improving sequence of equilibria whose scores increase without limit while the equilibria themselves drift toward a non-equilibrium boundary point.*

Remark 2766 (Hyperseed reading)**.** *When L is a finite product of $[0,1]^k$ (e.g. a p-bit evidence state space for a finite language), L is compact. If the combined "dynamics + selection" operator T is continuous (often true when built from joins/meets and continuous t-norm-like operations), then there exists a coherence-maximizing selected stable state, formalizing "resonance/coherence selects among fixed points". In such cases, compactness is typically inherited from the product topology, and continuity can often be checked componentwise (e.g. if each coordinate update is a continuous formula in the coordinates). This makes the theorem a convenient "plug-in" lemma: once fixed points have been established by other means, optimizing a continuous coherence functional over them requires no additional existence work.*

Remark 2767. *In contexts where "selection" is interpreted as a tendency toward least-effort trajectories or geodesic-like regularization (Hyperseed-Concept 206 and Hyperseed-Concept 207), continuity is not merely a technical assumption but a modeling claim: small changes in state produce small changes in the selected update, allowing a score landscape to be meaningfully optimized [21]. From this perspective, discontinuities in T can be read as "phase transitions" in the update rule; the present theorem clarifies that if such transitions occur, maximization over equilibria may fail to be attained unless one adds further structure (for instance, by enlarging the state space to a compactification, or by relaxing the score from continuous to upper semicontinuous while retaining compactness).*

49 Coarse-Graining and Refinement as Monotone Inference Principles

This section collects several related theorems: invariance/monotonicity principles for passing between fine and coarse descriptions (contexts, resolutions, coarse-grainings). The key construction is a sup-pushforward (a left Kan extension in a thin/posetal setting), which yields sound "fine-to-coarse" inference rules. We then show monotone consequences for (i) pattern intensity, (ii) weakness/simplicity as failed distinctions, and (iii) effability/ineffability as resource-bounded fidelity under indistinction.

Concretely, the guiding picture is that a *fine* description distinguishes more cases (more states, more features, more measurement outcomes), whereas a *coarse* description identifies some of those cases. An assertion verified at the fine level can be transported to the coarse level by asking for the *least* coarse assertion that is implied by it (or, dually, the *greatest* coarse assertion consistent with it, depending on the direction of inference under study). In an order-theoretic setting this transport is most naturally expressed by adjoint-style constructions; the "sup-pushforward" mentioned above is the order-enriched analogue of taking an image along a map by collecting evidence via a supremum over fibers.

The phrase "left Kan extension in a thin/posetal setting" is meant literally: if one regards a preorder as a category with at most one morphism between any two objects, then many categorical universal properties reduce to order-theoretic ones. In particular, left Kan extension becomes a pointwise supremum formula, and the soundness of "forgetting details" becomes an instance of monotonicity together with the fact that suprema compute least upper bounds. This is the technical mechanism behind the invariance/monotonicity principles collected here.

Remark 2768. *The philosophical motive is straightforward: whenever our epistemic access is limited, we work with coarse descriptions. The central question is then: which inferences remain valid when details are forgotten? The results below answer this by giving* order-theoretic *conditions under which truths established at a fine resolution remain true (or become easier to satisfy) at a coarser one. In Hyperseed terms, this is precisely the kind of "safe abstraction" one wants when moving between* Contexts and Aspects *(Hyperseed-Concept 86) and when reasoning under limited* Effort *(Hyperseed-Concept 100) about* Patterns *(Hyperseed-Concept 130); see also [1, 5, 19].*

A useful way to keep the direction of "safety" in mind is the following. If x is a fine-grained claim and $\gamma(x)$ is its coarse-grained counterpart, then "safe abstraction" typically means that whenever x holds, $\gamma(x)$ also holds, i.e. $x \le \gamma(x)$ in an information order where larger elements represent weaker (or less informative) conditions. Many of the results below can be read as systematic ways of producing such γ (often as a left adjoint / left Kan extension), together with monotonicity statements ensuring that increasing coarseness cannot invalidate what has already been established at finer resolution.

49.1 Standing assumptions

Definition 451 (Quantale-lite assumptions)**.** *Fix a complete lattice $(V, \le)$ with joins of all subsets. We write $\oplus$ for joins. Assume also a monotone binary operation $\otimes : V \times V \to V$ (monotone in each argument).*

In particular, completeness means that for every subset $S \subseteq V$ the element $\oplus S \in V$ exists and is characterized by the usual universal property: (a) $s \le \oplus S$ for all $s \in S$, and (b) if $u \in V$ satisfies $s \le u$ for all $s \in S$, then $\oplus S \le u$. Dually, because V is a complete lattice (not merely a complete join-semilattice), arbitrary meets also exist; while meets will typically remain in the background in what follows, they are available whenever a dual formulation is convenient (e.g. when expressing "must hold under all refinements" rather than "holds under some refinement").

Remark 2769. *This definition deliberately asks for less than a full quantale: we do* not *assume associativity, commutativity, a unit, or distributivity of $\otimes$ over joins. The proofs below only need: (i) we can form a join $\oplus S$ for* any *subset $S \subseteq V$ (so V is complete as a join-semilattice, indeed a complete lattice), and (ii) if $a \le a'$ and $b \le b'$ then $a \otimes b \le a' \otimes b'$. In particular, $\oplus\{\cdots\}$ denotes the least upper bound (supremum) of the displayed set, and the symbol $\perp$ (used later) denotes the least element of V (the join of the empty set).*

Intuitively, one may read V as a space of "degrees" (truth degrees, intensities, plausibilities, costs-as-ordered, etc.), and $\otimes$ as some way of composing two degrees. The link to the Hyperseed notion of Quantale Weakness *(Hyperseed-Concept 143) and* Weakness *(Hyperseed-Concept 202) is conceptual rather than syntactic here: we are using the minimal order-theoretic skeleton that makes the later monotonicity arguments go through; compare [3, 2].*

It is worth emphasizing what monotonicity of $\otimes$ gives (and what it does not). Monotonicity guarantees that if one replaces an input degree by a weaker/greater one (depending on the chosen interpretation of $\le$), then the composed degree cannot become strictly stronger/smaller; this is precisely the kind of "no miracles under weakening" property needed when transporting statements along coarse-grainings. By contrast, associativity or distributivity would enable algebraic reshuffling of multi-step compositions or commuting joins past $\otimes$; these are powerful but unnecessary for the basic fine-to-coarse soundness arguments, which rely only on order and supremum constructions.

Remark 2770. *Nothing below uses special properties of the canonical p-bit quantale beyond: (1) joins exist; (2) monotonicity of $\otimes$.*

One can read this as a robustness claim: the monotone inference principles proved later are not artifacts of a particular numerical scale (such as probabilities, p-bits, or log-odds), but follow from much weaker structural assumptions. In practice, this flexibility lets one instantiate V by a variety of ordered domains (e.g. bounded truth degrees, resource bounds, or penalty scores) as long as "combining evidence/resources" is monotone. This is also why the section speaks of "quantale-lite" rather than committing to a fully quantalic semantics at the outset: the later constructions are meant to apply uniformly across many choices of degree domain, provided only that the relevant suprema and monotone compositions exist.

49.2 Coarse-graining as sup-pushforward

Definition 452 (Coarse-graining data)**.** *Let X be a set of fine states and X_0 a set of coarse states. A coarse-graining map is a surjection $\alpha : X \to X_0$.*

Let P be a set of fine patterns and P_0 a set of coarse patterns, with an arbitrary map $\beta : P \to P_0$. An intensity is any function $I : P \times X \to V$.

Remark 2771. *Although the definition above treats V as an arbitrary codomain, the constructions below use $\oplus$ (and a bottom element $\perp$ for empty joins). Thus, minimally, one may take V to be a poset equipped with the relevant joins of subsets that arise as fibers*

$$\{ I(p, x) : \beta(p) = p_0,\ \alpha(x) = x_0 \}.$$

In many applications it is convenient to assume V is a complete join-semilattice (or a complete lattice), so that every *subset has a join. This ensures that the sup-pushforward is always defined without side conditions, and it clarifies why the empty-fiber value is naturally $\perp$ (the join of the empty set).*

Remark 2772. *The picture is: X is the world described in high resolution, while X_0 is what remains after we "forget" some distinctions (Hyperseed-Concept 98). The surjection $\alpha : X \to X_0$ identifies many fine states with a single coarse state; surjectivity ensures every coarse state is genuinely represented by at least one fine state. Likewise, $\beta : P \to P_0$ allows us to map fine-grained pattern descriptions to coarser pattern descriptions (or to merge multiple fine patterns into one coarse label). The intensity function $I(p, x) \in V$ may be read as "how strongly pattern p applies to state x," generalizing the scalar intensities used earlier for patterns and emergence (Hyperseed-Concept 130,* **??***; see [5]).*

A simple example: let X be pixel images and X_0 be their downsampled versions; α is the downsampling. Let P be a set of fine edge-detectors, and P_0 a set of coarse edge-detectors; β maps each fine detector to its coarse "family." Then $I(p, x)$ could be a graded edge strength. The point of the formalism is that it does not depend on the particulars of images or edges: it is a general abstraction mechanism.

Remark 2773. *It is useful to keep two kinds of "many-to-one" effects distinct. The surjection α guarantees that every coarse state x_0 has at least one fine representative x (so every x_0 corresponds to a nonempty fiber $\alpha^{-1}(x_0)$). In contrast, β is not required to be surjective: some coarse pattern labels $p_0 \in P_0$ may have no fine patterns mapping to them, in which case the coarse intensity at (p_0, x_0) will typically collapse to $\perp$ under sup-pushforward. This is often desirable: it records that the coarse label is* unrealized *(or unsupported) by the current fine vocabulary.*

Definition 453 (Sup-pushforward intensity)**.** *Given (α, β) and $I : P \times X \to V$, define $I_0 : P_0 \times X_0 \to V$ by*

$$I_0(p_0, x_0) \ :=\ \oplus\{ I(p, x) \ :\ \beta(p) = p_0,\ \alpha(x) = x_0 \}.$$

(If the constraint set is empty, interpret the join as $\perp$.)

Remark 2774. *This is the central construction. The set*

$$\{\, I(p,x) \;:\; \beta(p) = p_0,\ \alpha(x) = x_0 \,\}$$

collects all *fine-level intensities consistent with the coarse labels (p_0, x_0). Taking their join (supremum) makes $I_0(p_0, x_0)$ the* best-case *intensity available among the fine witnesses.*

Two small examples clarify the semantics.

- *If $V = [0,1]$ ordered by $\leq$ and $\oplus$ is* sup*, then $I_0(p_0, x_0)$ is the maximum fine intensity compatible with (p_0, x_0). Thus coarse intensity records that "there exists a refinement where the pattern is this strong."*

- *If $V = \{0,1\}$ with $\oplus = \vee$, then $I_0(p_0, x_0) = 1$ iff there exists some refinement (p, x) mapping to (p_0, x_0) with $I(p,x) = 1$. This is the ordinary existential pushforward of a predicate along a map.*

This "$\oplus$-over-fibers" operation is the posetal analogue of a left Kan extension: we extend the fine intensity along the coarse identification by taking the least upper bound compatible with the coarse data. In a reasoning engine, this is the canonical way to compute a coarse observable that is sound for existential-style inferences (and is aligned with the general Hyperseed ontology stance that many statements are resolution-relative; compare [1, 19]).

Remark 2775. *One can also read sup-pushforward as an "existential quantification" over refinements, generalized from booleans to an arbitrary join-structure: fixing (p_0, x_0), we range over all (p, x) that refine it, and aggregate their contributions by $\oplus$. In particular, when V supports graded notions of evidence, $I_0(p_0, x_0)$ expresses the strongest evidence achievable by choosing an appropriate fine witness consistent with the coarse observation.*

Concretely, if one forms the relation (or correspondence)

$$R \subseteq (P \times X) \times (P_0 \times X_0), \qquad ((p,x),(p_0,x_0)) \in R \iff \beta(p) = p_0 \ \wedge\ \alpha(x) = x_0,$$

then the definition is exactly "push I forward along R by taking joins along the R-fibers." This viewpoint often makes later monotonicity statements feel like familiar facts about existential images.

Remark 2776. *The choice of $\oplus$ encodes an* optimistic *(best-case, witness-based) abstraction principle. Other choices are possible in other inference regimes: for instance, an $\bigwedge$-over-fibers construction would encode a* pessimistic *(worst-case, all-refinements) principle, corresponding to universal rather than existential reasoning. The present section focuses on $\oplus$ because it is the one that preserves witnesses under forgetting, which is the monotone inference behavior used repeatedly later.*

Theorem 63 (Dominance of sup-pushforward)**.** *For all $p \in P$ and $x \in X$,*

$$I_0(\beta(p), \alpha(x)) \ \geq\ I(p,x).$$

Remark 2777. *Intuitively, the theorem says:* coarsening by sup-pushforward can only increase (or preserve) intensity*. Whatever strength a pattern has at a fine state remains attainable when we forget detail, because the coarse value is defined by taking a join over all consistent fine values and therefore cannot fall below any one of them.*

This is the basic "soundness" guarantee that underwrites later monotonicity results: once we accept that coarse intensity is defined by a supremum over fine witnesses, then any fine witness remains a witness after coarsening. This connects directly to the later "threshold persistence" corollary and, in a different guise, to the effability and registration results, which are also essentially "witness persistence under forgetting."

Remark 2778. *It can also be helpful to view the inequality as a form of* extensiveness *of an abstraction operator: starting from a particular fine datum (p, x), mapping it to the coarse pair $(\beta(p), \alpha(x))$ and then evaluating I_0 yields a value that dominates the original intensity. Equality holds exactly when the chosen witness (p, x) already attains the fiber-maximum, i.e. when $I(p, x)$ is a join-maximal element among all $I(p', x')$ with the same coarse image. Thus the strictness of the inequality measures how much "hidden headroom" is present inside the coarse equivalence class.*

Proof. Fix $p \in P$ and $x \in X$. In the defining join for $I_0(\beta(p), \alpha(x))$, the pair (p, x) is a valid witness because $\beta(p) = \beta(p)$ and $\alpha(x) = \alpha(x)$. Therefore the join is at least $I(p, x)$. □

Remark 2779. Proof sketch. *The proof uses only one idea: a join is an upper bound for each element being joined. Since (p, x) itself appears among the candidates for $I_0(\beta(p), \alpha(x))$, the supremum cannot be smaller than $I(p, x)$.*

The key step is recognizing that the "fiber constraints" $\beta(p) = p_0$ and $\alpha(x) = x_0$ are satisfied tautologically when $p_0 = \beta(p)$ and $x_0 = \alpha(x)$. Visually, if one imagines α and β as partitioning X and P into coarse equivalence classes, the point is that each fine element sits inside its own class, so it is always available as a representative when we compute the coarse supremum.

Remark 2780. *Categorically inclined readers may recognize the same mechanism in the adjunction between pullback and $\oplus$-pushforward for V-valued relations: precomposition along (β, α) (a pullback of intensities from coarse to fine) has a left adjoint given by $\oplus$ over the fibers. The dominance inequality is then the unit inequality of that adjunction specialized to the posetal setting. This perspective is optional here, but it helps explain why the construction is "canonical": it is forced by the requirement that the coarse observable be the least one that still soundly supports existential witness-lifting.*

Corollary 31 (Threshold persistence (sound fine-to-coarse rule))**.** *Fix any threshold $\theta \in V$. If $I(p, x) \geq \theta$, then $I_0(\beta(p), \alpha(x)) \geq \theta$.*

Remark 2781. *This corollary is the operational form of the previous theorem: it tells a reasoning engine that "if I can certify intensity $\geq \theta$ at the fine level, then I may assert intensity $\geq \theta$ at the coarse level." In many applications, θ encodes an activation threshold or a decision boundary, so this is precisely a* sound abstraction rule*. One may read it as a formal instance of "truth persists under forgetting" when truth is expressed as crossing an order-threshold.*

Remark 2782. *From the standpoint of automated reasoning, threshold persistence is a "monotone compilation" principle: any rule or classifier validated at fine resolution remains valid after abstraction, provided it is phrased in terms of inequalities that are preserved by $\geq$-monotonicity. In particular, when V is numeric and θ is tuned to control false positives/false negatives, this corollary explains why coarse-grained systems often become* more permissive*: they can inherit any strong fine witness hidden inside the coarse bin, but they cannot distinguish whether that witness is typical or exceptional without additional structure.*

Proof. By the previous theorem, $I_0(\beta(p), \alpha(x)) \geq I(p, x) \geq \theta$. □

Remark 2783. Proof sketch. *This is a one-line transitivity argument: dominance gives $I_0 \geq I$, and the assumption gives $I \geq \theta$, hence $I_0 \geq \theta$. In other words, the order $\geq$ on V is being used only through its transitivity: if an abstracted quantity sits above the concrete one, and the concrete one sits above a fixed threshold, then the abstracted quantity must also sit above that same threshold. No additional algebraic structure (beyond the order) is needed for this step.*

The conceptual point is that thresholds behave well with respect to monotone maps and joins: once we have $a \leq b$, any lower bound $\theta \leq a$ is also a lower bound for b. Equivalently, the set of elements above θ is upward closed: enlarging information (moving upward in the order) cannot invalidate a previously satisfied lower-bound constraint. This upward-closedness viewpoint is what later makes it natural to speak of "safe abstraction" under coarse-graining: we may lose distinctions, but we do not lose the validity of monotone consequences expressible as lower bounds.

49.2.1 Compositionality

Definition 454 (Successive coarse-grainings). *Let $X \xrightarrow{\alpha_1} X_0 \xrightarrow{\alpha_2} X_{00}$ be surjective maps. Let $P \xrightarrow{\beta_1} P_0 \xrightarrow{\beta_2} P_{00}$ be any maps. The surjectivity assumption on the α_i emphasizes that every coarse state has at least one refinement; this is the typical situation when α_i is a "forgetful" map induced by a partition of X. (If one drops surjectivity, one must adopt a convention for joins over empty fibers, e.g. taking them to be a bottom element when it exists.)*

Given $I : P \times X \to V$, define:

- *I_1 = sup-pushforward of I along (α_1, β_1),*
- *I_2 = sup-pushforward of I_1 along (α_2, β_2),*
- *I_{12} = sup-pushforward of I along $(\alpha_2 \circ \alpha_1, \beta_2 \circ \beta_1)$.*

Here the phrase "sup-pushforward" implicitly assumes that the relevant joins exist in V for the fibers determined by the constraints $\alpha_i(x) = x_i$ and $\beta_i(p) = p_i$; in many applications V is a complete lattice or at least admits the required (possibly finite) joins. Note also that we do not require the β_i to be surjective: parameter reindexing may collapse or discard parameters, and the compositionality statement below only compares the values at (p_{00}, x_{00}) where the defining joins are taken over whatever preimages exist.

Remark 2784. *This definition formalizes the idea that coarsening can happen in stages: perhaps we first forget fine pixel-level detail, and later forget color channels; or first aggregate individuals into households, then households into regions. The two procedures for producing a twice-coarsened intensity are:*

(a) push forward once, then push forward again; or

(b) push forward directly along the composite forgetting map.

The theorem below says these agree exactly, which is a kind of associativity law for abstraction. This is the reason one may regard sup-pushforward as a genuine "inference principle": it composes cleanly, like a functorial construction in a posetal/categorical setting (compare the thin Kan-extension remark above, and the general compositional stance of [1]). From the poset viewpoint, the content is that taking a left Kan extension along a composite map agrees with composing the corresponding left Kan extensions; in the thin (order-enriched) setting the proof reduces to manipulating joins and index sets. Concretely, this compositionality is what allows one to build multi-resolution pipelines without having to re-justify each new "level" as an ad hoc construction: the same abstraction operator can be iterated without changing its meaning.

Theorem 64 (Sup-pushforward is compositional). *For all $p_{00} \in P_{00}$ and $x_{00} \in X_{00}$,*

$$I_2(p_{00}, x_{00}) \;=\; I_{12}(p_{00}, x_{00}).$$

Remark 2785. *In plain terms:* it does not matter whether we coarse-grain in one step or many; the resulting coarse intensity is the same. *This is important because practical systems often maintain multiple levels of representation and may switch between them dynamically. Without compositionality, the meaning of a coarse statement would depend on the path taken to get there, which would be an undesirable kind of epistemic relativity. One can also read the equation $I_2 = I_{12}$ as a path-independence property on the "abstraction graph" of representations: any two routes that forget the same information yield the same abstracted value when the forgetting maps agree on the nose.*

This theorem connects back to "dominance" because dominance is what makes each pushforward a safe abstraction; compositionality is what makes sequences of safe abstractions themselves coherent. In particular, dominance is a pointwise inequality that ensures no coarse value undershoots any of its refinements, while compositionality ensures that repeatedly taking such safe upper envelopes does not accidentally introduce extra slack beyond what the final forgetting map already enforces.

Proof. Fix (p_{00}, x_{00}). By definition,

$$I_2(p_{00}, x_{00}) = \oplus_{\substack{\beta_2(p_0)=p_{00} \\ \alpha_2(x_0)=x_{00}}} I_1(p_0, x_0).$$

Expand I_1:

$$I_1(p_0, x_0) = \oplus_{\substack{\beta_1(p)=p_0 \\ \alpha_1(x)=x_0}} I(p, x).$$

Substitute into the expression for $I_2(p_{00}, x_{00})$ and use associativity/idempotence of joins (joining over a join) to get a single join over all (p, x) satisfying $\beta_2(\beta_1(p)) = p_{00}$ and $\alpha_2(\alpha_1(x)) = x_{00}$, i.e. $(\beta_2 \circ \beta_1)(p) = p_{00}$ and $(\alpha_2 \circ \alpha_1)(x) = x_{00}$. But this is exactly the definition of $I_{12}(p_{00}, x_{00})$. More explicitly, one is using the elementary fact that for a family $\{a_{i,j}\}$ indexed by pairs (i, j) in some relation $R \subseteq I \times J$, one has

$$\oplus_{i\in I} \oplus_{\substack{j\in J \\ (i,j)\in R}} a_{i,j} = \oplus_{(i,j)\in R} a_{i,j},$$

provided the relevant joins exist; this is precisely the "flattening" of a nested join into a join over a combined indexing set. No distributivity assumptions are invoked: only the universal property of $\oplus$ as the least upper bound (and hence its associativity/commutativity/idempotence as an n-ary operation on finite index sets, or the corresponding coherence for the existing joins in the general case). $\square$

Remark 2786. Proof sketch. *The strategy is "flattening": write I_2 as a join of I_1's, then write each I_1 as a join of I's. A join of joins can be flattened into a single join over the combined index set; this uses only the universal property of joins (equivalently, that taking joins is associative and idempotent at the level of indexing). One can also regard this as a Fubini-type principle for suprema: iterated suprema over successive fibers coincide with a single supremum over the total fiber of the composite map.*

The key step is matching the indexing constraints: the nested constraints

$$\beta_2(p_0) = p_{00},\ \beta_1(p) = p_0 \quad \textit{and} \quad \alpha_2(x_0) = x_{00},\ \alpha_1(x) = x_0$$

are equivalent to the single composite constraints

$$(\beta_2 \circ \beta_1)(p) = p_{00}, \qquad (\alpha_2 \circ \alpha_1)(x) = x_{00}.$$

This equivalence is simply the elimination of the intermediate variables p_0 and x_0: choosing an intermediate representative and then requiring consistency is the same as directly requiring that the *coarse labels match after both forgetting steps. In relational terms, the set of admissible pairs* (p, x) *is the pullback of the singleton* $\{(p_{00}, x_{00})\}$ *along* $(\beta_2 \circ \beta_1, \alpha_2 \circ \alpha_1)$*, and the nested join computes the supremum over that pullback by first grouping elements according to their intermediate images.*

Geometrically, one can picture the refinement maps as partitions: refining in two stages means first grouping fine elements into intermediate blocks, then grouping those blocks into larger blocks. The theorem says that taking a supremum over fine elements inside the final large block can be done either directly or by first taking suprema inside intermediate blocks and then taking the supremum over those intermediate suprema. In particular, the intermediate blocks function only as a book-keeping device: they may be convenient computationally or conceptually, but they do not alter the final abstract value determined by the coarsest partition.

49.3 Weakness under coarse-graining

Definition 455 (Crisp indistinction relation and weakness)**.** *Let* $H \subseteq X \times X$ *be a (crisp) indistinction relation (failed distinctions). Let* $\mu : X \to V$ *be an importance weight.*

Define the weakness of H *(relative to* μ*) by*

$$w_X(H) \ := \ \oplus_{(u,v)\in H}\ \mu(u) \otimes \mu(v).$$

Remark 2787. *Here* H *encodes which pairs of states the system fails to distinguish; this is an explicit formal avatar of the Hyperseed notion of* Distinction *and its failure (Hyperseed-Concept 98). Calling* H *"crisp" means membership is Boolean (either a pair is indistinct or not), in contrast to a graded indistinction weight used later.*

It is intentional that no further axioms are imposed on H *here:* H *need not be an equivalence relation, need not be symmetric, and need not include the diagonal. In applications one often considers symmetric* H *(mutual confusion) or reflexive* H *(each state is trivially indistinct from itself), but the definition of weakness does not require these. Notably, whether* $(u, u) \in H$ *is included affects whether "self-confusions" contribute to weakness; excluding the diagonal focuses the measure on* failures to separate distinct states*, while including it can be used to model degenerate sensors that sometimes fail even to stably identify a state with itself.*

The weakness $w_X(H)$ *aggregates the "importance" of indistinguishable pairs. If* $\mu(u)$ *measures how consequential state* u *is (in attention, reward, probability mass, salience, etc.), then* $\mu(u)\otimes\mu(v)$ *measures the combined seriousness of failing to distinguish* u *from* v*, and the join over* H *reports the overall weakness level. In many quantale-weakness instantiations (Hyperseed-Concept 143),* $\oplus$ *is a supremum and* $\otimes$ *behaves like a conjunction or product; but theorems below only require monotonicity. This aligns with the stance in [3, 2] that "weakness" is a structurally robust notion across many concrete choices of semantics.*

The definition also makes sense for edge cases: if $H = \varnothing$*, then* $w_X(H)$ *is the join over an empty set, i.e. the bottom element of the* V*-order (when such a bottom exists, as in standard complete lattices). Thus "no failed distinctions recorded" corresponds to minimal weakness, which matches the intended reading.*

A toy example: let $V = [0, 1]$ *with* $\oplus = \sup$ *and* $\otimes = \min$*. Then* $w_X(H)$ *is simply the maximum, over indistinct pairs, of* $\min(\mu(u), \mu(v))$*; so it reports whether there exists a highly important pair that is being conflated. If instead* $\otimes$ *were taken as ordinary multiplication, then* $\mu(u) \otimes \mu(v) = \mu(u)\mu(v)$ *would penalize confusions between two simultaneously high-importance states more sharply, while still preserving the monotonicity-based arguments used below.*

Definition 456 (Pushforward of weights and relations)**.** *Let* $\alpha : X \to X_0$ *be surjective. Define pushed-forward importance* $\mu_0 : X_0 \to V$ *by*

$$\mu_0(x_0) \ := \ \oplus\{\mu(x) : \alpha(x) = x_0\}.$$

Define pushed-forward indistinction $H_0 \subseteq X_0 \times X_0$ by:

$$(x_0, y_0) \in H_0 \iff \exists (x, y) \in H \text{ with } \alpha(x) = x_0,\ \alpha(y) = y_0.$$

Equivalently, $H_0 = (\alpha \times \alpha)[H]$.

Remark 2788. *The pushforward μ_0 is the same "sup over fibers" idea used for intensities: the importance of a coarse state x_0 is taken as the join of the importances of its fine refinements. This is a natural choice when one wants the coarse system to remain conservative: if any fine refinement is important, then the coarse representative should be regarded as important too.*

Surjectivity of α makes X_0 genuinely a quotient/coarsening of X: every coarse state has at least one fine representative, so the fiber join is always taken over a nonempty set. If α were not surjective, one would have to decide what importance to assign to coarse states with empty fibers (typically the bottom of V), but the intended "coarse-graining by forgetting distinctions" picture is clearest in the surjective case.

The use of $\oplus$ rather than, say, addition or averaging is deliberate: it produces an upper envelope *abstraction. In probabilistic interpretations this is not the usual marginalization (which would sum probabilities), but it is the right operation for worst-case/conservative propagation of importance and for monotone inference principles: the coarse system is required not to understate the importance of any fine possibility that it collapses.*

The pushed-forward relation H_0 says that two coarse states are indistinct if they have some *indistinct fine representatives. This is again an existential definition: coarse indistinction holds whenever the fine system contains a witness of indistinction that survives forgetting. In terms of* Self vs. Other *boundaries and perceptual confusions (Hyperseed-Concept 165), this is the minimal condition under which a confusion at high resolution still counts as a confusion after merging states.*

It is also worth noting what information is intentionally discarded by this pushforward: multiple distinct fine witnesses of indistinction between the same coarse pair (x_0, y_0) do not accumulate as multiple counts; H_0 only records that indistinction is possible*. This choice aligns with the subsequent weakness functional, which already aggregates contributions via $\oplus$ rather than by counting or summing occurrences.*

Theorem 65 (Coarse-graining does not decrease weakness)**.** *With $w_X(H)$ and $w_{X_0}(H_0)$ computed using μ and μ_0 as above,*

$$w_X(H) \ \leq \ w_{X_0}(H_0).$$

Remark 2789. *The theorem states:* when we coarse-grain by taking joins over refinements, the measured weakness cannot go down*. This matches intuition: forgetting distinctions cannot make you* less *weak with respect to the distinctions you were already failing to draw. If anything, coarsening tends to make weakness more visible, because more fine importance mass is aggregated into fewer coarse bins, and indistinction witnesses are preserved.*

One can also read this as a "soundness under abstraction" statement: $w_{X_0}(H_0)$ is a safe upper bound on the fine weakness $w_X(H)$ computed before forgetting detail. Thus any downstream principle that enforces a bound on weakness at the coarse level (e.g. "keep weakness $\leq \theta$") is automatically conservative with respect to the fine level.

A concrete micro-example: suppose $X = \{a, b, c\}$, $X_0 = \{A, C\}$ with $\alpha(a) = \alpha(b) = A$ and $\alpha(c) = C$. Let $H = \{(a, c)\}$ record a single failed distinction between a and c. Then $H_0 = \{(A, C)\}$. If $\mu(a)$ is small but $\mu(b)$ is large, the pushforward makes $\mu_0(A) = \mu(a) \oplus \mu(b)$, so the coarse weakness for the pair (A, C) can become large even though the original witness involved only a rather than b. This captures the intended conservatism: after merging a and b, any confusion between some *representative of A and C becomes a potential confusion involving the whole coarse bin A, and the bin inherits the maximum importance among its refinements.*

This is a monotonicity fact of the same logical type as the dominance theorem for intensities. It also connects to the later effability monotonicity theorem: there, coarsening the indistinction weight makes fidelity easier *to achieve, hence effability sets grow; here, coarsening states makes weakness* larger*, hence weakness bounds become more conservative. Both are instances of the general principle: "sup-pushforward turns fine information into coarse information by taking an upper envelope." See [3] for broader discussion of weakness under abstraction.*

Finally, observe that the inequality direction depends on two design choices acting together: (i) μ_0 uses a join over fibers (so importance can only increase when passing to the quotient), and (ii) H_0 uses existential pushforward (so indistinction witnesses can only be added, not removed). Changing either choice changes which quantities become monotone under coarse-graining.

Proof. Fix any $(u, v) \in H$. Then by definition $(\alpha(u), \alpha(v)) \in H_0$. Also by construction of μ_0, $\mu_0(\alpha(u)) \geq \mu(u)$ and $\mu_0(\alpha(v)) \geq \mu(v)$. By monotonicity of $\otimes$,

$$\mu(u) \otimes \mu(v) \ \leq\ \mu_0(\alpha(u)) \otimes \mu_0(\alpha(v)).$$

Now take joins. The left join ranges over all $(u, v) \in H$. The right join ranges over all pairs in H_0, which in particular includes all $(\alpha(u), \alpha(v))$ with $(u, v) \in H$. Therefore

$$\oplus_{(u,v)\in H}\mu(u) \otimes \mu(v) \ \leq\ \oplus_{(x_0,y_0)\in H_0}\mu_0(x_0) \otimes \mu_0(y_0).$$

□

Remark 2790. Proof sketch. *The proof transports each fine indistinction witness $(u, v) \in H$ to a coarse witness $(\alpha(u), \alpha(v)) \in H_0$, and shows its contribution can only increase because $\mu_0(\alpha(u))$ and $\mu_0(\alpha(v))$ are defined as joins that dominate $\mu(u), \mu(v)$. Monotonicity of $\otimes$ then propagates this domination to the pairwise combined importance, and taking joins preserves the inequality.*

The key step is that the definition of H_0 is existential: every fine indistinction produces a coarse indistinction. If H_0 were defined universally (e.g. requiring all *representatives to be indistinct), the inequality could fail. So the theorem is also a lesson in how the choice of pushforward definition encodes a philosophy of abstraction: existential pushforward yields safe upper bounds on weakness.*

Technically, the argument uses only three monotonicity facts: (1) each fiber join satisfies $\mu(x) \leq \mu_0(\alpha(x))$, (2) $\otimes$ is monotone in each argument, and (3) $\oplus$ is monotone with respect to enlarging the index set (here, H mapping into H_0). No commutativity or associativity properties of $\otimes$ are needed for this particular inequality, and no algebraic properties of H beyond being a subset are required. This minimality is important for later reuse when H is replaced by more structured, graded, or context-dependent notions of indistinction.

Corollary 32 (Iterated coarse-graining yields a nondecreasing weakness chain)**.** *For a chain of surjections $X \to X_0 \to X_{00} \to \cdots$ with corresponding pushed-forward relations and pushed-forward weights, the sequence of weaknesses is nondecreasing.*

Remark 2791. *This corollary says that as we ascend a hierarchy of ever coarser descriptions (Hyperseed-Concept* **??***), the weakness measure forms an ascending chain. In decision terms, once a weakness bound is exceeded at some coarse level, it will remain exceeded at all coarser levels. This is useful for pruning: one can detect unacceptable weakness early without needing to compute fine-grained details.*

Proof. Apply the previous theorem at each step and compose the inequalities. □

Remark 2792. Proof sketch. *Each coarse-graining step yields an inequality $w_{fine} \le w_{coarse}$. Chaining these inequalities yields monotonicity along the entire tower.*

Conceptually, this is the order-theoretic analogue of a renormalization flow that is monotone in a chosen statistic: weakness is a quantity that cannot be "improved" merely by forgetting structure.

49.4 Effability monotonicity under coarsening

Definition 457 (Fidelity under indistinction weights)**.** *Let X be finite. An indistinction weight function is any $\iota : X \times X \to [0,1]$. Given a target $x \in X$ and a distribution $q \in \Delta(X)$, define fidelity:*

$$\mathrm{Fid}_\iota(x, q) \;:=\; \sum_{y \in X} q(y)\, \iota(x, y).$$

Remark 2793. *This definition introduces a* graded *notion of indistinction, in contrast to the crisp relation H above. The function $\iota(x, y)$ quantifies how acceptable it is to confuse y with x at a given resolution: $\iota(x, y) = 1$ means "y is indistinguishable from x" (perfectly acceptable), and $\iota(x, y) = 0$ means "completely wrong." This corresponds directly to the Hyperseed idea that* Ineffability *(Hyperseed-Concept* **??***) is not absolute but resolution- and resource-relative.*

The distribution $q \in \Delta(X)$ represents what an observer's description decodes to: it is a probabilistic hypothesis over fine states. The fidelity $\mathrm{Fid}_\iota(x, q)$ *is then the expected indistinction weight under q. Two simple examples:*

- *If $\iota(x, y) = \mathbf{1}[x = y]$, then* $\mathrm{Fid}_\iota(x, q) = q(x)$*, the ordinary probability of being exactly correct.*
- *If $\iota(x, y)$ is* 1 *whenever x and y share a coarse label (say $\alpha(x) = \alpha(y)$) and* 0 *otherwise, then fidelity measures the probability that q lands in the correct coarse class.*

Thus, ι formalizes a "metric of adequacy" for descriptions, connecting naturally with Perception *and* Presentational Immediacy *(Hyperseed-Concept 134, 138) insofar as these are always mediated by permissible confusions.*

Definition 458 ((epsilon,K)-effability)**.** *Fix an observer O equipped with: a description space D_O, a cost $\sigma_O : D_O \to [0, \infty)$, and a decoder* $\mathrm{dec}_O : D_O \to \Delta(X)$*.*

Fix $\epsilon \in (0, 1)$ and $K > 0$. An element $x \in X$ is (ϵ, K)-effable (relative to ι) iff there exists $d \in D_O$ such that $\sigma_O(d) \le K$ and $\mathrm{Fid}_\iota(x, \mathrm{dec}_O(d)) \ge 1 - \epsilon$*. Let* $\mathrm{Eff}_O(\epsilon, K; \iota) \subseteq X$ *denote the effable set.*

Remark 2794. *This definition makes* effability *explicitly a function of two constraints:*

- *an error tolerance ϵ (how close we must get), and*
- *a resource budget K (how costly a description we are allowed).*

In Hyperseed language, this is a precise way to talk about Ineffability *and its negation under bounded* Effort *(Hyperseed-Concept* **??***, 100) and bounded representational capacity (Hyperseed-Concept 157). The observer model* $(D_O, \sigma_O, \mathrm{dec}_O)$ *is intentionally abstract; it can represent symbolic language, neural codes, scientific theories, or internal cognitive encodings (compare [19, 20]).*

A concrete example: let D_O be bitstrings, $\sigma_O(d)$ be length, and $\mathrm{dec}_O(d)$ *be a probabilistic decoder (e.g. a Bayesian posterior over X). Then (ϵ, K)-effable means: "there exists a K-bit message whose decoded hypothesis assigns at least $1 - \epsilon$ fidelity to x under the indistinction weighting ι." This resembles algorithmic information viewpoints ([16]) but with an explicitly resolution-relative success criterion.*

Theorem 66 (Monotonicity in resources and resolution)**.** *Let $K' \geq K$. Then*

$$\mathrm{Eff}_O(\epsilon, K; \iota) \subseteq \mathrm{Eff}_O(\epsilon, K'; \iota).$$

If ι and ι' satisfy $\iota(x, y) \leq \iota'(x, y)$ for all x, y (i.e. ι' is coarser), then

$$\mathrm{Eff}_O(\epsilon, K; \iota) \subseteq \mathrm{Eff}_O(\epsilon, K; \iota').$$

Remark 2795. *The theorem says two things, both unsurprising yet foundational for disciplined reasoning:*

1. *If you are allowed to spend more description cost, you can effably describe at least as many things.*
2. *If you relax the fidelity criterion by making more confusions acceptable (i.e. you coarsen the indistinction weights), then effability becomes easier, so the effable set can only grow.*

In short: more resources and lower resolution both increase effability*.*

This result complements the earlier weakness monotonicity result. There, coarsening increased a defect measure *(weakness). Here, coarsening increases a* capability set *(effability). Both are monotone phenomena, and both are indispensable if one wants stable meta-reasoning about what can or cannot be expressed under bounded resources (cf. [19]).*

Proof. (Resource monotonicity.) If x has a witnessing description d with $\sigma_O(d) \leq K$, then also $\sigma_O(d) \leq K'$.

(Resolution monotonicity.) Fix x and any distribution q. If $\iota \leq \iota'$ pointwise, then

$$\mathrm{Fid}_{\iota'}(x, q) = \sum_y q(y)\iota'(x, y) \;\geq\; \sum_y q(y)\iota(x, y) = \mathrm{Fid}_\iota(x, q),$$

since $q(y) \geq 0$ and sums preserve inequality. Therefore any d that meets the $1 - \epsilon$ threshold under ι also meets it under ι'. □

Remark 2796. Proof sketch. *For resource monotonicity, keep the same witness description: a larger budget cannot invalidate a previously affordable description. For resolution monotonicity, observe that fidelity is a nonnegative weighted sum of $\iota(x, y)$ values, so increasing ι pointwise can only increase fidelity.*

The key step is the use of pointwise order $\iota \leq \iota'$ and nonnegativity of q: this is exactly the kind of elementary inequality that underlies many "data processing" principles in information theory, but here it is presented in its bare order-theoretic form.

Corollary 33 (Safe contrapositive rule for reasoning engines)**.** *If $x \notin \mathrm{Eff}_O(\epsilon, K; \iota')$ for some coarser $\iota' \geq \iota$, then $x \notin \mathrm{Eff}_O(\epsilon, K; \iota)$. Equivalently: ineffability at an easier (coarser) resolution implies ineffability at a harder (finer) one.*

Remark 2797. *This corollary is often the form one actually uses: it gives a* safe negative inference*. If an entity cannot be described even when we permit generous confusions (coarse ι'), then it certainly cannot be described when we demand stricter fidelity (fine ι). For automated systems, this supports early stopping and conservative claims of ineffability (Hyperseed-Concept* **??***) without having to search at the finest resolution first.*

Proof. Contrapositive of $\mathrm{Eff}_O(\epsilon, K; \iota) \subseteq \mathrm{Eff}_O(\epsilon, K; \iota')$. □

Remark 2798. Proof sketch. *If $A \subseteq B$, then "not in B" implies "not in A"; apply this with $A = \mathrm{Eff}_O(\epsilon, K; \iota)$ and $B = \mathrm{Eff}_O(\epsilon, K; \iota')$.*

The deeper intuition is that effability sets are upward-closed with respect to both budgets and coarsening of indistinction: a failure at the top propagates downward.

49.5 Downward closure of registration (optional, but useful)

Definition 459 (Context refinement and forgetting)**.** *Let $\mathcal{C}$ be a poset of contexts, where $C \preceq D$ means "D refines C". Assume for each C a set U_C and a map $\mathrm{asp}_C : U \to U_C$. Write $x|_C := \mathrm{asp}_C(x)$.*

For $C \preceq D$, assume a forgetful map $\pi_{D\to C} : U_D \to U_C$ with $x|_C = \pi_{D\to C}(x|_D)$ for all $x \in U$.

Remark 2799. *This definition introduces a general apparatus for moving between contexts (Hyperseed-Concept 86). The poset $\mathcal{C}$ encodes a refinement order: D contains more distinctions than C. The map $\mathrm{asp}_C : U \to U_C$ extracts the "aspect" of a global entity $x \in U$ as seen in context C; notation $x|_C$ emphasizes that we are restricting attention.*

The coherence condition $x|_C = \pi_{D\to C}(x|_D)$ states that forgetting commutes with taking aspects: if you view x in the fine context D and then forget down to C, you get the same result as viewing x in C directly. This is the minimal algebra one needs for consistent multi-resolution reasoning, and it is one of the standard background assumptions in compositional ontologies (cf. [1]).

A simple example: U could be full physical world-histories; U_C could be coarse summaries such as "macrostates" in thermodynamics; and $\pi_{D\to C}$ could be marginalization/aggregation.

Definition 460 (Registration schema)**.** *Fix a system X and time t. In context C, assume: (i) an equivalence relation $\sim_C$ on U_C, (ii) a pattern set P_C, (iii) an intensity map $\mathrm{Int}_{C,t} : P_C \times U_C \to V$, (iv) a reference predicate $\mathrm{Ref}_C(\cdot,\cdot)$.*

Fix a threshold $\theta \in V$.

We say "X registers A at time t in context C" if there exist: an entity $A_0 \in U$ and a pattern $p_C \in P_C$ such that

$$A_0|_C \sim_C A|_C, \quad \mathrm{Int}_{C,t}(p_C, A_0|_C) \not\leq \theta, \quad \mathrm{Ref}_C(p_C, A|_C) \textit{ is nontrivial.}$$

Remark 2800. *This schema formalizes a familiar epistemic pattern: a system "registers" an entity A when it can bring to bear some pattern p_C that applies with intensity above threshold, and when that pattern actually* refers *to A in a nontrivial way (Hyperseed-Concept 153, 152). The auxiliary witness A_0 allows registration up to contextual equivalence: it may suffice to register something equivalent to A under $\sim_C$ (Hyperseed-Concept* **??***), rather than A itself with absolute precision.*

A basic example: in a visual context C, A is a person, $\sim_C$ identifies people up to clothing color, p_C is a face template, Int *measures match strength, and Ref_C encodes that the template genuinely tracks the person rather than some spurious correlation. The threshold θ is then an attention/recognition cutoff (Hyperseed-Concept 60, 151).*

The usefulness of the schema is that it separates three issues: (1) identity up to a chosen equivalence, (2) strength/intensity above a threshold, and (3) referential nontriviality. This separation is essential when one wants to transport registration statements across contexts, as done in the theorem below.

Theorem 67 (Registration is downward closed under forgetting, under coherence hypotheses)**.** *Let $C \preceq D$. Assume:*

1. *(Equivalence coherence) For all $u, v \in U_D$, $u \sim_D v \Rightarrow \pi_{D\to C}(u) \sim_C \pi_{D\to C}(v)$.*
2. *(Pattern map) A function $\beta : P_D \to P_C$.*
3. *(Intensity is sup-pushforward) For all $p_C \in P_C$ and $u_C \in U_C$,*

$$\mathrm{Int}_{C,t}(p_C, u_C) = \oplus\{\mathrm{Int}_{D,t}(p_D, u_D) : \beta(p_D) = p_C,\ \pi_{D\to C}(u_D) = u_C\}.$$

4. *(Reference coherence) For all $p_D \in P_D$,*

$$\mathrm{Ref}_D(p_D, A|_D) \textit{ nontrivial} \Rightarrow \mathrm{Ref}_C(\beta(p_D), A|_C) \textit{ nontrivial.}$$

Then:

If X registers A at time t in context D, then X registers A at time t in context C.

Remark 2801. *What the theorem asserts is a conservative stability principle:* if registration holds at a fine resolution, then it still holds after forgetting detail*, provided the ingredients of registration (equivalences, patterns, intensities, reference) cohere with forgetting in the stated ways.*

Why this matters is pragmatic and philosophical at once. Pragmatically, a system often proves a claim using detailed internal structures but must communicate or act using coarser summaries; the theorem guarantees it does not lose what it has already secured. Philosophically, it articulates a modest form of realism about registration: the act of "seeing that A is there" should not evaporate merely because we choose to speak in broader strokes, as long as our coarsening is coherent.

This connects directly to the earlier sup-pushforward dominance theorem: hypothesis (3) ensures that coarse intensities are defined by the same supremum-over-witnesses construction, so that a fine witness remains a coarse witness. The extra hypotheses (1) and (4) ensure that identity-up-to-equivalence and reference also survive forgetting. In the broader Hyperseed setting this is an instance of "downward closure" of cognitive commitments across contexts; compare [1, 19].

Proof. Assume X registers A at time t in context D. By the registration schema (in D), there exist $A_0 \in U$ and $p_D \in P_D$ such that

$$A_0|_D \sim_D A|_D, \quad \mathrm{Int}_{D,t}(p_D, A_0|_D) \not\leq \theta, \quad \mathrm{Ref}_D(p_D, A|_D) \text{ nontrivial.}$$

Define $p_C := \beta(p_D) \in P_C$ and $u_C := A_0|_C \in U_C$. By forgetting, $u_C = \pi_{D\to C}(A_0|_D)$ and also $A|_C = \pi_{D\to C}(A|_D)$. By equivalence coherence, $A_0|_D \sim_D A|_D$ implies $A_0|_C \sim_C A|_C$. In particular, the coarse identity/equivalence requirement is satisfied by the *same* underlying object A_0 after applying the restriction/forgetting map; no new matching argument is needed at level C beyond the coherence axiom.

By reference coherence, $\mathrm{Ref}_C(p_C, A|_C)$ is nontrivial. Here "nontrivial" is inherited rather than re-proved: the role of reference coherence is precisely to ensure that pushing a pattern forward along β does not collapse a previously meaningful reference relation into a degenerate one when the associated ambient content is forgotten to C.

Finally, apply sup-pushforward dominance: in the defining join for $\mathrm{Int}_{C,t}(p_C, u_C)$, the witness $(p_D, A_0|_D)$ is feasible since $\beta(p_D) = p_C$ and $\pi_{D\to C}(A_0|_D) = u_C$. Hence $\mathrm{Int}_{C,t}(p_C, u_C) \geq \mathrm{Int}_{D,t}(p_D, A_0|_D)$. The point of the feasibility check is that the supremum/join at the coarse level ranges over *fine-level* pairs that project to the prescribed coarse arguments; thus it is enough to exhibit a single fine pair lying above (p_C, u_C) under $(\beta, \pi_{D\to C})$. Since $\mathrm{Int}_{D,t}(p_D, A_0|_D) \not\leq \theta$, also $\mathrm{Int}_{C,t}(p_C, u_C) \not\leq \theta$ (monotonicity of $\leq$). Equivalently, if the coarse intensity were $\leq \theta$, then by transitivity with the displayed inequality one would obtain $\mathrm{Int}_{D,t}(p_D, A_0|_D) \leq \theta$, contradicting the fine-level registration hypothesis; this is the contrapositive form of the same order-theoretic monotonicity step. Thus A_0 and p_C witness registration in C. $\square$

Remark 2802. Proof sketch. *The proof transports the fine-level witnesses (A_0, p_D) down to the coarse context. For identity, it uses equivalence coherence: if A_0 matches A in D, then their forgotten images match in C. For reference, it uses reference coherence: nontrivial reference persists when patterns are mapped by β. For intensity, it uses the same dominance principle as earlier:*

since coarse intensity is a supremum over all fine witnesses, the specific fine witness we already have provides a lower bound on the coarse intensity. Put differently, the argument is modular: (i) identity compatibility is preserved by $\pi_{D\to C}$, (ii) reference compatibility is preserved by β (together with forgetting on the object side), and (iii) intensity compatibility is preserved because the coarse score is constructed to be an upper envelope of all consistent fine scores.

The key step is the last one: turning $\mathrm{Int}_{D,t}(p_D, A_0|_D) \not\leq \theta$ into $\mathrm{Int}_{C,t}(p_C, u_C) \not\leq \theta$ via the inequality $\mathrm{Int}_{C,t}(p_C, u_C) \geq \mathrm{Int}_{D,t}(p_D, A_0|_D)$. This is precisely where the choice of sup-pushforward matters: it is engineered to preserve witnesses. Intuitively, the coarse system is not allowed to "forget away" intensity evidence, because any piece of fine evidence compatible with the coarse description is still admissible in the coarse supremum. In that sense, the construction implements a monotone inference rule: projecting information downward cannot invalidate an above-threshold intensity that was already achieved by some compatible fine description.

One can visualize the situation as a commutative diagram: U_D maps down to U_C by forgetting, and P_D maps down to P_C by β. Registration at level D is a point in the product $P_D \times U_D$ above threshold; the theorem says its image in $P_C \times U_C$ remains above threshold. Concretely, the pair $(p_D, A_0|_D)$ sits over (p_C, u_C) in the fiber of the map $(\beta, \pi_{D\to C})\colon P_D \times U_D \to P_C \times U_C$, and the coarse intensity is evaluated by taking the join over that fiber. The proof therefore amounts to observing that the fiber is nonempty (witnessed by $(p_D, A_0|_D)$) and that taking a join cannot yield a value below one of its contributing elements.

Remark 2803 (Why this is useful)**.** *This theorem gives a safe inference rule: registration/perceptual claims proved at a detailed resolution remain valid at coarser resolutions, provided intensities and reference are defined by coherent pushforward/forgetting laws. This is a common need in resource-bounded reasoning. It is also useful for multi-scale modeling: one may establish registration in a fine model where the relevant discriminations are explicit, and then soundly reuse the conclusion in a reduced model (lower-dimensional, aggregated, or otherwise compressed) without re-running the full fine analysis. The proof shows exactly which axioms are doing the work: coherence for identity and reference, and supremum-based pushforward for intensity.*

50 Weakness/Effort/Pattern-Intensity Tradeoff Theorems as Decision Tools

Here we collect a small family of "tradeoff" theorems linking (i) effort/weakness monotonicity for distinction policies, (ii) effort-based simplicity, and (iii) pattern intensity as normalized compression gain. The results are stated so they can be used as decision tools: convert intensity thresholds into explicit effort budgets, bound sensitivity to modeling overhead, and justify Pareto-style pruning and "maximally open adequate" selection rules.

Concretely, the intended workflow is that a designer begins with operational constraints (available compute, limited supervision, bounded attention, restricted witness language) and expresses these as an *effort budget*; the theorems then give sufficient conditions ensuring that certain distinctions are infeasible, unstable under overhead, or dominated by other policies. Conversely, if a minimum pattern-intensity threshold is required for downstream use (e.g. to trigger memory consolidation, to justify adding a concept, or to promote a hypothesis into a reusable module), the tradeoffs provide a principled way to translate this threshold into a constraint on allowable weakness and on the complexity of the corresponding representations.

The decision-theoretic reading also clarifies why the statements are phrased as inequalities rather than as exact characterizations. In practice, the quantities being compared—effort, weakness, description length, and compression gain—are rarely measured in perfectly commensurate units, and they are often estimated with modeling-dependent slack. The goal, therefore, is to supply bounds that remain informative when the cost model is coarsened, when the witness language is refactored, or when a policy class is enlarged, while still supporting reliable choices such as "this family of distinctions is not worth paying for" or "any policy achieving this intensity must incur at least this much effort."

Remark 2804. *Philosophically, the guiding idea is that an ontology or inference engine is always bargaining with its own finitude: to draw more distinctions requires more effort, and to describe things more simply requires representational resources. The notion of "weakness" used here (Hyperseed-Concept 202) is a formal way to talk about deliberately* failing *to distinguish (Hyperseed-Concept 98) certain differences, a stance that appears in multiple places in the Hyperseed stack [1] and in quantale-based treatments of weakness [3, 2].*

This "bargaining" viewpoint is also meant to be operational rather than merely metaphorical. A policy that is weaker is not simply "less accurate"; it is a choice to refrain from spending effort on certain refinements, often because their expected return in compression, prediction, or control is low relative to the resources they consume. In this sense, weakness functions as a knob controlling granularity: turning the knob toward greater weakness collapses distinctions, reduces the burden on representation, and can improve robustness by ignoring brittle micro-differences; turning it toward greater strength resolves finer differences, but may demand more effort and may increase exposure to modeling overhead.

Remark 2805. *The emphasis on tradeoffs is aligned with the "route A / route B" perspective on managing dependency and modeling overhead in compositional reasoning [9]. The specific choice here is to keep the mathematics austere: we work with inequalities that are robust under changes of modeling assumptions, so that a system designer can rely on them even when the internal witness language, cost model, or policy space is being revised.*

In particular, the phrase "pattern intensity as normalized compression gain" is meant to signal a quantity that is comparable across domains and scales: it measures how much shorter (or simpler) a description becomes when a pattern is used, relative to a baseline that encodes the same data or task without that pattern. Normalization matters because raw compression gain can be inflated by trivial changes of units or by scaling the dataset, whereas an intensity-like ratio (or suitably offset-normalized difference) can be interpreted as a stable notion of "signal-to-overhead" for pattern utility. The tradeoff theorems in this section therefore aim to separate three effects that otherwise get conflated in informal reasoning: (a) genuine structure captured by a pattern, (b) the effort required to discover, maintain, or apply the pattern under a given distinction policy, and (c) modeling overhead due to the representational apparatus itself.

The references to "Pareto-style pruning" and "maximally open adequate" selection rules should be read as practical corollaries: once effort and intensity are placed in the same inequality framework, one can rule out policies that are jointly worse (higher effort and lower intensity) and prefer policies that remain as weak as possible while still meeting adequacy constraints (e.g. a minimum discrimination requirement for a task). This supports an engineering discipline in which policy classes are not only compared by objective value, but also organized by dominance relations, with explicit attention to the stability of these relations under reasonable changes in overhead assumptions.

50.1 Setup

50.1.1 Effort-based simplicity and pattern intensity

Definition 461 (Baseline cost, witnesses, and simplicity)**.** *Fix a context C and an entity x.*

A witness *of x is any description/representation w that decodes to x. Write $u(w;x) \in [0,\infty]$ for the cost of witness w (e.g. description cost or a compositional cost). Fix a* baseline *witness* $\mathrm{base}_C(x)$ *with baseline cost*

$$s_C^{\mathrm{base}}(x) := u(\mathrm{base}_C(x); x).$$

Define the (contextual) simplicity of x as the infimal witness cost

$$s_C(x) := \inf\{u(w;x) : w \text{ is a witness of } x\}.$$

Remark 2806. *The symbols in this definition play distinct conceptual roles. The object x is whatever the context C takes to be an "entity"; the witness w is a* representation *(Hyperseed-Concept 157) of x in some description language; and $u(w;x)$ is a cost (length, energy, time, number of primitives, etc.) assigned to using w to obtain x. Allowing the value ∞ makes it possible to treat "inapplicable" or "ill-formed" witnesses uniformly: they simply never matter to infima. The baseline witness* $\mathrm{base}_C(x)$ *is a conventional point of comparison: it is not assumed optimal, only available.*

Remark 2807. *Intuitively, $s_C(x)$ measures how simply x* can *be described within the representational resources of the context C (Hyperseed-Concept 169). In algorithmic information theory, a canonical example would be: x is a finite string, w is a program that prints x, and $u(w;x)$ is program length; then $s_C(x)$ is essentially Kolmogorov complexity [16]. In a more structural example aligned with pattern ontologies [5], x might be a composite object (a graph, a scene, an interaction trace), w a decomposition plus glue, and u the sum of part costs plus coordination overhead.*

Remark 2808. *This definition is useful because it lets later tradeoff theorems speak in the simplest possible currency:* cost. *Rather than trying to reason directly about the metaphysical status of patterns, we reason about whether a candidate pattern witness reduces description cost relative to a baseline. This is deliberately operational: an inference engine can compute or approximate costs and use them to make decisions.*

Remark 2809. *Note that $s_C(x)$ is defined via an infimum and therefore supports approximation: even when the true optimum witness is unknown, any candidate witness w with finite $u(w;x)$ provides an upper bound $s_C(x) \le u(w;x)$. Conversely, lower bounds on $s_C(x)$ (e.g. information-theoretic bounds, resource-bounded adversary arguments, or minimality certificates in a restricted witness language) translate directly into limits on attainable compression, which is precisely what later decision tools will need.*

Definition 462 (Scalar pattern intensity)**.** *Assume $s_C^{\mathrm{base}}(x) > 0$. Define the scalar intensity of witness w for x by*

$$I_C(w;x) := \max\left\{0,\ \frac{s_C^{\mathrm{base}}(x) - u(w;x)}{s_C^{\mathrm{base}}(x)}\right\} = \max\left\{0,\ 1 - \frac{u(w;x)}{s_C^{\mathrm{base}}(x)}\right\}.$$

If $s_C^{\mathrm{base}}(x) = 0$, set $I_C(w;x) = 0$ for all w by convention.

Remark 2810. *The expression $1 - u(w;x)/s_C^{\mathrm{base}}(x)$ is the* fractional savings *achieved by using w instead of the baseline witness. The outer* $\max\{0,\cdot\}$ *clamps negative savings to 0, which enforces a* *conceptual discipline: intensity is meant to measure the presence of a pattern (Hyperseed-Concept 130) as a* compression gain *relative to a chosen reference, not as a penalty for doing worse than baseline. Thus, intensity lives in* $[0,1]$ *and can be read as "how much of the baseline description has been made unnecessary by this witness."*

Remark 2811. *Two quick examples:*

- *(a) If* $u(w;x) = \frac{1}{2}s_C^{\text{base}}(x)$*, then* $I_C(w;x) = \frac{1}{2}$*: the witness compresses the baseline by 50%.*
- *(b) If* $u(w;x) \geq s_C^{\text{base}}(x)$*, then* $I_C(w;x) = 0$*: the witness has no positive intensity in this context (it may still be useful for other reasons, but not as a compression-based pattern witness).*

The definition is useful precisely because it translates the somewhat qualitative idea of "pattern strength" into a normalized quantity that supports thresholding and budgeting.

Remark 2812. *The normalization by* $s_C^{\text{base}}(x)$ *makes intensities comparable* within *a fixed baseline convention, but it also makes explicit that intensity is baseline-relative: changing* $\text{base}_C(x)$ *can change* $I_C(w;x)$ *even when* $u(w;x)$ *is unchanged. This is intentional, because later decision procedures will often be framed as "is this witness worth adopting relative to what we already do by default?" rather than "is this witness absolutely optimal?"*

Remark 2813. *For fixed* x *and* C *with* $s_C^{\text{base}}(x) > 0$*, the map* $u \mapsto \max\{0, 1 - u/s_C^{\text{base}}(x)\}$ *is monotone non-increasing in* u*. Thus, any improvement in witness cost (lower* $u(w;x)$*) can only increase intensity, and witnesses with the same cost have the same intensity regardless of their internal structure. This ensures that later theorems can treat intensity as a pure function of resource use, leaving representational details to the cost model* u*.*

Definition 463 (Optimal attainable intensity (supremum form))**.** *Assume* $s_C^{\text{base}}(x) > 0$*. Define the* attainable intensity bound *of* x *by*

$$I_C^\star(x) := \sup\{I_C(w;x) : w \text{ is a witness of } x\}.$$

Remark 2814. *The supremum* sup *is chosen instead of* max *because there need not exist a single best witness: a sequence of witnesses may approach the infimal cost without ever attaining it. In such cases* $I_C^\star(x)$ *expresses an idealized "capacity" for compression-based pattern intensity, given the representational regime of* C*. This quantity becomes a convenient upper bound for decision procedures: any concrete witness must lie below it.*

Remark 2815. *Conceptually,* $I_C^\star(x)$ *is to intensity what* $s_C(x)$ *is to simplicity: it is a best-possible value under the current rules of representation, and it changes when we expand the witness language. This fits neatly with the Hyperseed view that pattern and representation are co-constituted by a context [5]: change the context, and what counts as an intense (i.e. compressive) pattern can change as well.*

Proposition 77 (Attainable intensity in terms of simplicity)**.** *Assume* $s_C^{\text{base}}(x) > 0$*. Then*

$$I_C^\star(x) \;=\; \max\left\{0,\; 1 - \frac{s_C(x)}{s_C^{\text{base}}(x)}\right\}.$$

Remark 2816. *This identity unpacks the definitions: since* $I_C(w;x) = \max\{0, 1-u(w;x)/s_C^{\text{base}}(x)\}$*, taking a supremum over witnesses is equivalent to minimizing* $u(w;x)$ *over witnesses, i.e. passing to* $s_C(x)$*. In particular, whenever* $s_C(x) \geq s_C^{\text{base}}(x)$*, no witness can achieve positive compression relative to baseline and* $I_C^\star(x) = 0$*; and whenever* $s_C(x) \ll s_C^{\text{base}}(x)$*, the context admits high potential intensity. This is one reason the later tradeoff theorems can be stated either in the language of "simplicity gaps" (*$s_C^{\text{base}}(x) - s_C(x)$*) or in the normalized language of intensity without changing substantive content.*

50.1.2 Distinction policies, weakness, and effort

Definition 464 (Policies and opening/closing)**.** *Let H range over admissible indistinction policies (each H can be thought of as a set of undistinguished pairs). Write $H \subseteq H'$ to mean that H' is an* opening *of H (it collapses weakly more distinctions), and $H' \subseteq H$ to mean that H' is a* closing.

Remark 2817. *The inclusion order here is a convenient way to treat "how much the agent chooses to ignore" as a lattice-like control knob: moving upward (an opening) allows more pairs to be treated as the same, while moving downward (a closing) forces the agent to preserve more distinctions. In later sections, this order will serve as the formal backbone for statements of the form "if you open the policy, effort can decrease but weakness can increase," i.e. monotonic tradeoffs along the inclusion axis.*

Remark 2818. *It is often helpful to keep two extremes in mind. The minimal policy $H = \varnothing$ corresponds to collapsing no pairs (maximal discrimination), while a maximally open policy (when admissible) would collapse every pair the context allows, yielding a very coarse view of entities. Many practical settings restrict admissibility so that H must satisfy consistency constraints (for example, being symmetric, or being closed under some form of transitivity), but the definition intentionally does not bake in a particular constraint set: different applications (perception, clustering, theorem proving, abstraction in planning) impose different closure requirements on what counts as a permissible "indistinction."*

Remark 2819. *Thinking of H as a set of undistinguished pairs also anticipates quotient-style constructions: an opening $H \subseteq H'$ can be read as moving to a coarser quotient in which more items are identified. Even when H is not literally an equivalence relation, it can be completed to one (for instance by taking an admissible closure) and the resulting quotient intuition explains why openings typically reduce representational burden: fewer distinctions mean fewer bits, fewer cases, and fewer branches to handle, at the possible cost of conflating situations that matter downstream.*

Remark 2820. *Here H is an abstract stand-in for a "policy of indistinction": which pairs of fine-grained states or entities are treated as the same for current purposes. The partial order by inclusion captures a natural qualitative notion: an* opening *(Hyperseed-Concept 125) throws away more distinctions (Hyperseed-Concept 98) and thus yields a coarser view; a* closing *(Hyperseed-Concept 72) reinstates distinctions and yields a finer view. This is the same order-theoretic stance used in coarse-graining arguments: one can often reason monotonically as one moves from fine to coarse. In particular, thinking of H as a binary relation of "treated-as-equal" pairs, the condition $H \subseteq H'$ means that every identification licensed by H remains licensed by H', while H' may additionally identify pairs that H still keeps distinct. When H happens to be an equivalence relation (or a congruence in an algebraic setting), opening corresponds to passing to a coarser partition (or quotient) and closing corresponds to refining that partition. This makes the inclusion order a convenient proxy for the intuitive idea of "more or fewer distinctions enforced" without committing to a particular ontology of states, features, or representational primitives.*

Remark 2821. *A simple example is perceptual resolution: H might equate colors within 1 unit in RGB distance, whereas an opening H' equates colors within 5 units; the latter policy collapses more pairs, and hence $H \subseteq H'$. In a symbolic setting, H might declare two terms indistinguishable when they are alpha-equivalent, while H' also identifies terms under a wider congruence. One can also view these examples as moving from stricter to looser admissibility constraints on downstream judgments: under H', more stimuli count as "the same input," and more syntactic forms count as "the same expression," so fewer case distinctions must be carried through later steps. The intended* *reading is not that H' is "more correct," but that it is a deliberate relaxation whose costs and benefits can be reasoned about monotonically.*

Assumption 1 (Weakness and effort monotonicity)**.** *There is a weakness functional $w(H)$ and an effort functional $\mathrm{Eff}_C(H)$ such that:*

$$H \subseteq H' \implies w(H) \leq w(H') \quad \textit{and} \quad \mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(H').$$

That is: opening increases weakness and decreases policy effort.

Remark 2822. *This assumption formalizes a widely encountered engineering and epistemic motif: it is easier to act, compute, and decide when one is willing to lump more things together, and the corresponding "weakness" is precisely the degree to which distinctions are not enforced. The effort functional (Hyperseed-Concept 100) may represent time, energy, number of measurements, or attention allocation; the weakness functional (Hyperseed-Concept 202) may measure how much indistinction is permitted. The mathematical content is simply antitonicity of effort and monotonicity of weakness with respect to inclusion, which is the minimal structure needed for the later "open if you can" theorems. See [3] for quantale-centric variants and interpretations. A useful intuition is that $w(H)$ can be read as a "slack" or "tolerance" parameter attached to the policy: as H opens, the system tolerates more equivalences and therefore becomes less brittle to micro-variation, but also potentially less discriminative. Conversely, $\mathrm{Eff}_C(H)$ can be read as the cost of enforcing the policy—e.g. the cost of gathering the information needed to separate cases that H insists on separating, or the computational cost of maintaining invariants that are only meaningful at a finer granularity. The assumption deliberately avoids specifying any functional form (linearity, convexity, etc.); only the direction of change under opening is fixed, so later results can be stated without overfitting to a particular application domain.*

Assumption 2 (Representational monotonicity under opening)**.** *Each policy H induces an admissible witness family $\mathcal{W}_H(x)$ for each x, and opening weakly enlarges it:*

$$H \subseteq H' \implies \mathcal{W}_H(x) \subseteq \mathcal{W}_{H'}(x) \;\; \textit{for all } x.$$

Define the policy-indexed simplicity

$$s_{C,H}(x) := \inf\{u(w; x) : w \in \mathcal{W}_H(x)\},$$

and the policy-indexed attainable intensity bound

$$I^{\star}_{C,H}(x) := \sup\{I_C(w; x) : w \in \mathcal{W}_H(x)\}.$$

Remark 2823. *This is the representational counterpart of weakness/effort monotonicity: a coarser policy allows more descriptions to count as legitimate witnesses, because fewer distinctions need to be honored. Formally, $\mathcal{W}_H(x)$ is a* constrained *witness set; opening removes constraints and thus can only enlarge the set. The derived quantities $s_{C,H}(x)$ and $I^{\star}_{C,H}(x)$ let us talk about simplicity and intensity* under the policy*, rather than in the unconstrained ideal. Concretely, $\mathcal{W}_H(x)$ can be thought of as the set of admissible encodings, explanations, models, certificates, or constructions of x that are compatible with the equivalences imposed by H. When H is stricter, some candidate witnesses are disallowed because they implicitly rely on identifications that the policy forbids, or because verifying them would require resolving distinctions that the policy insists must remain explicit. When H opens, these requirements relax, so witnesses that were previously "invalid" (or too costly to validate under the stricter distinction regime) can become admissible. In this way, the enlargement $\mathcal{W}_H(x) \subseteq \mathcal{W}_{H'}(x)$ expresses a permissiveness ordering that mirrors the earlier ordering on effort and weakness.*

Remark 2824. *A concrete picture is: a stricter policy H might require a witness to preserve exact structure (e.g. exact graph isomorphism), while an opening H' permits approximate structure (e.g. graph edit distance within a threshold). Then $\mathcal{W}_{H'}(x)$ contains witnesses that would be rejected under H, so the infimal achievable cost can drop, and the achievable intensity can rise. This is one formal route to the idea that "letting go of distinctions" can unlock simpler representations, a recurring theme in pattern/emergence accounts [5]. It is also helpful to separate two effects that this example conflates: (i)* search *becomes easier because more candidates qualify as witnesses, and (ii)* validation *becomes easier because approximate constraints are cheaper to check than exact ones. Both effects are compatible with the single inclusion statement for witness families, because admissibility can be defined to include whatever verification obligations are part of the policy. In applications, the same opening may simultaneously lower description cost $u(w; x)$ (by permitting shorter or more compressive encodings) and raise attainable intensity $I_C(w; x)$ (by permitting witnesses that capture stronger regularities once irrelevant micro-structure is ignored).*

Remark 2825. *The inclusion $\mathcal{W}_H(x) \subseteq \mathcal{W}_{H'}(x)$ immediately yields monotonicity of the derived extrema: if $H \subseteq H'$, then*

$$s_{C,H'}(x) \leq s_{C,H}(x) \quad \textit{and} \quad I^{\star}_{C,H}(x) \leq I^{\star}_{C,H'}(x),$$

since the infimum is taken over a larger set and the supremum is taken over a larger set. Thus, opening weakly improves the best achievable simplicity (in the sense of lowering the minimal cost) and weakly improves the attainable intensity bound (in the sense of allowing higher intensity), even before invoking any additional properties of $u(\cdot; x)$ or $I_C(\cdot; x)$. These monotone relationships are the representational analogue of "opening reduces effort" and will be used later to compare decision quality across policies without requiring any explicit optimization algorithm.

50.2 Core intensity algebra: converting intensity into budgets

Lemma 154 (Intensity is truncated relative savings)**.** *Assume $s_C^{\text{base}}(x) > 0$ and let $s := s_C^{\text{base}}(x)$. For any witness w with cost $u := u(w; x)$,*

$$I_C(w; x) = \max\left\{0,\ 1 - \frac{u}{s}\right\}.$$

In particular, $I_C(w; x) > 0$ iff $u < s$ and $I_C(w; x) = 0$ iff $u \geq s$.

Remark 2826. *This lemma states that the intensity formula is nothing more (and nothing less) than a normalized notion of savings relative to baseline, truncated to avoid negative values. The key operational consequence is the "phase transition" at $u = s$: once a witness costs at least as much as the baseline, it is intensity-zero and can be ignored by any routine that is specifically searching for compressive patterns.*

Remark 2827. *A useful rearrangement (valid on the positive-intensity region $u < s$) is the inversion*

$$u = (1 - I_C(w; x))\, s_C^{\text{base}}(x).$$

Thus, once intensity is interpreted as "fraction of baseline saved," the witness cost is exactly "fraction of baseline not saved.*" This also makes clear why the truncation at 0 is natural: if $u > s$, then the formula $1 - u/s$ would correspond to a* negative *savings fraction, which is typically not treated as a separate regime but simply regarded as "no compression."*

Proof. Immediate algebra from the definition of $I_C(w; x)$ and the clamp at 0. □

Remark 2828. Proof sketch and intuition. *One expands the definition and notes that* $s_C^{\mathrm{base}}(x)$ *has been abbreviated as* s*. The "iff" statements are simply the observation that* $\max\{0, 1 - u/s\}$ *is positive exactly when its unclamped argument is positive, i.e. when* $u/s < 1$*. Geometrically,* $I_C(w; x)$ *is the line* $1 - u/s$ *as a function of* u*, chopped off at* 0*.*

Remark 2829. *Concrete calibration can be helpful. If* $s_C^{\mathrm{base}}(x) = 100$ *and a candidate witness has cost* $u = 30$*, then* $I_C(w; x) = 1 - 30/100 = 0.7$*, meaning it realizes* 70% *of the baseline cost as relative savings. If instead* $u = 120$*, then* $I_C(w; x) = \max\{0, 1 - 1.2\} = 0$*, so this candidate is treated identically (for compression purposes) to any even more expensive candidate.*

Theorem 68 (Intensity threshold $\Leftrightarrow$ explicit cost budget)**.** *Assume* $s_C^{\mathrm{base}}(x) > 0$ *and fix* $\tau \in (0, 1]$*. For a witness* w *of* x *with cost* $u := u(w; x)$*, the following are equivalent:*

$$I_C(w; x) \geq \tau \quad \Longleftrightarrow \quad u \leq (1 - \tau)\, s_C^{\mathrm{base}}(x).$$

Remark 2830. *In plain language, this theorem says:* having intensity at least τ is exactly the same as being below a linear cost budget*. The budget* $(1-\tau)s_C^{\mathrm{base}}(x)$ *is the baseline cost times the fraction of baseline you are still allowed to spend. Thus the theorem converts an epistemic or heuristic condition ("pattern intensity is high enough") into an explicit resource constraint (Hyperseed-Concept 100) on witness search.*

Remark 2831. *The parameter endpoints have clear interpretations. If* $\tau = 1$*, then the budget is* $(1-\tau)s_C^{\mathrm{base}}(x) = 0$*, so only witnesses of zero cost can meet the threshold, matching* $I_C(w; x) = 1 - u/s$ *on* $u < s$*. If* τ *is very small (approaching* 0 *from above), then the budget approaches* $s_C^{\mathrm{base}}(x)$*, meaning that even very mild compression counts as meeting the threshold, but still excluding witnesses that do not beat baseline. The exclusion of* $\tau = 0$ *in the statement is aligned with this: at* $\tau = 0$ *one would allow all* $u \leq s$*, but the "clamp is inactive" step used in the proof would no longer be forced by the inequality.*

Remark 2832. *This equivalence is important because it makes intensity thresholds actionable. Many systems can prune candidates quickly based on cost (e.g. partial evaluation, admissible heuristics, early termination), whereas intensity is often computed only after substantial semantic checking. Therefore the theorem gives a principled "do not even consider" cutoff that is guaranteed sound.*

Remark 2833. *Operationally, the theorem can be read as a compilation rule for search: replace the semantic predicate "*$I_C(w; x) \geq \tau$*" by the syntactic (or at least cheaper-to-check) predicate "*$u(w; x) \leq (1 - \tau)s_C^{\mathrm{base}}(x)$*," and postpone any expensive validation steps until after a candidate has passed this budget gate. This is precisely the kind of conversion needed to turn intensity from a descriptive statistic into a decision tool.*

Proof. Write $s := s_C^{\mathrm{base}}(x)$. Since $\tau > 0$, the inequality $I_C(w; x) \geq \tau$ forces $I_C(w; x) > 0$, hence the clamp is inactive and

$$I_C(w; x) = 1 - \frac{u}{s}.$$

Thus $I_C(w; x) \geq \tau$ iff $1 - u/s \geq \tau$ iff $u \leq (1 - \tau)s$. The converse is the same algebra. $\square$

Remark 2834. Proof sketch and intuition. *The proof consists of two moves. First, because* $\tau > 0$*, any witness meeting the threshold must lie in the region where the clamp* $\max\{0, \cdot\}$ *does nothing. Second, on that region the intensity is an affine function of the cost, so solving the inequality* $I_C(w; x) \geq \tau$ *is a single line of algebra. One may picture the graph of* $u \mapsto I_C(w; x)$ *as a line descending from* 1 *at* $u = 0$ *to* 0 *at* $u = s$*, and then staying flat at* 0 *thereafter; the threshold* τ *corresponds to a horizontal line cutting the descending segment at exactly* $u = (1 - \tau)s$*.*

Remark 2835. *It is sometimes convenient to express the same cutoff in relative terms by dividing through by baseline:*

$$I_C(w;x) \geq \tau \quad \Longleftrightarrow \quad \frac{u(w;x)}{s_C^{\text{base}}(x)} \leq 1-\tau.$$

That is, meeting intensity τ means the witness must cost at most a $(1-\tau)$ fraction of the baseline cost. This ratio form emphasizes that the criterion is scale-free in the baseline: if all costs are multiplied by a constant, the threshold decision is unchanged.

Corollary 34 (Decision tool: "intensity at least τ" becomes a hard budget)**.** *To guarantee $I_C(w;x) \geq \tau$, it suffices to search only among witnesses with $u(w;x) \leq (1-\tau)s_C^{\text{base}}(x)$. Equivalently: any candidate witness exceeding that budget can be discarded without further analysis.*

Remark 2836. *This corollary is the computational face of the previous theorem: it licenses a strict pruning rule in any witness-generation or pattern-mining loop. In particular, it supports beam search and A* style procedures in which cost bounds are maintained incrementally: once a partial witness already exceeds $(1-\tau)s_C^{\text{base}}(x)$, it cannot be completed into a witness of intensity at least τ.*

Remark 2837. *One can also view the pruning rule as enforcing a search invariant: throughout the computation, the current frontier of candidates is restricted to those whose* best possible completion cost *remains below the budget. Any admissible lower bound $\underline{u}$ on the final witness cost therefore yields a sound early rejection criterion $\underline{u} > (1-\tau)s_C^{\text{base}}(x)$, even when the exact $u(w;x)$ is not yet known. This is where the theorem interfaces naturally with standard branch-and-bound logic.*

Lemma 155 (Lipschitz sensitivity of intensity in witness cost)**.** *Assume $s_C^{\text{base}}(x) = s > 0$. For any two witnesses with costs $u, v \in [0, \infty]$,*

$$\big|I(u;x) - I(v;x)\big| \leq \frac{|u-v|}{s},$$

where $I(\cdot;x) := \max\{0, 1 - \cdot/s\}$.

Remark 2838. *This lemma quantifies robustness: small additive errors in cost estimation produce proportionally small errors in intensity, with proportionality constant $1/s$. It is particularly relevant when $u(w;x)$ is not computed exactly but approximated (e.g. by an estimator, a surrogate model, or a partial evaluation). The notation $I(u;x)$ is a deliberate abbreviation: once x and s are fixed, intensity depends on a witness only through its cost.*

Remark 2839. *The constant $1/s$ has an immediate interpretation: larger baselines make intensity* less *sensitive to absolute cost perturbations. For instance, an absolute error of ± 1 in the cost changes intensity by at most 0.01 when $s = 100$, but by at most 0.1 when $s = 10$. This helps separate two regimes: when the baseline is large, coarse cost approximations may be sufficient for stable thresholding; when the baseline is small, intensity-based decisions may require more precise cost accounting.*

Proof. The map $g(t) := 1 - t/s$ is $(1/s)$-Lipschitz. The clamp map $h(t) := \max\{0, t\}$ is 1-Lipschitz. Thus $I = h \circ g$ is $(1/s)$-Lipschitz. □

Remark 2840. Proof sketch and intuition. *The unclamped intensity $g(t) = 1 - t/s$ is a line of slope $-1/s$, so changing t by Δ changes $g(t)$ by exactly Δ/s in magnitude. The clamp $h(t)$ can only* reduce *variation (it never amplifies differences), which is captured by 1-Lipschitzness. Composing two Lipschitz maps multiplies the constants, giving $1/s$. Visually: away from the clamp point the graph is a straight line, and at the clamp point it "bends" into a flat segment, which cannot increase sensitivity.*

Remark 2841. *A complementary way to see the same bound is to consider cases. If both $u, v < s$, then $I(u;x) = 1 - u/s$ and $I(v;x) = 1 - v/s$, giving equality $\big|I(u;x) - I(v;x)\big| = |u-v|/s$. If both $u, v \geq s$, then both intensities are 0 and the left-hand side is 0. If one cost is below s and the other above, then the intensity difference is at most the below-s intensity, which is itself at most the normalized distance to the clamp point s; this is again bounded by $|u-v|/s$ because crossing the clamp requires $|u-v| \geq |s - \min\{u,v\}|$. This case analysis makes explicit how the truncation creates a "saturation" region in which changes in cost do not change intensity at all.*

50.3 Overhead and compositional witnesses: robustness bounds

Definition 465 (Compositional witness overhead)**.** *A compositional witness has the form $P = (y, z, t)$ with $t \geq 0$ and cost*

$$u(P;x) := h_C(P) := s_C(y) + s_C(z) + t,$$

so that increasing glue/interaction overhead t increases the witness cost additively.

Remark 2842. *This definition isolates a common structure in compositional description: one pays for the parts ($s_C(y)$ and $s_C(z)$) and for the "glue" t that binds them into x. The glue may represent alignment, interface constraints, communication bandwidth, synchronization, or any interaction term that is not reducible to the isolated part costs. In the language of pattern theory, P is a candidate* explanation *of x by subpatterns plus relations [5]. In particular, t is meant to capture any* nonseparable *burden that arises only when the parts are forced to cohere as a single description of x, even if each part is individually cheap.*

Remark 2843. *A simple example is a string x witnessed by concatenation of substrings y, z: the glue cost t might encode the boundary information and the instruction "concatenate." In a causal or combinatorial witness, t might encode the coupling rule that turns components into a whole. The definition is useful because it lets us reason cleanly about how modeling overhead degrades intensity, without needing to assume anything deep about $s_C(\cdot)$. One can also view t as a stand-in for "engineering overhead" in representation learning: even if two latent factors are cheap to encode, making them interact (e.g., via attention, cross-terms, or constraints) typically requires additional parameters, data, or coordination that should be accounted for explicitly.*

Remark 2844. *Although we write the witness as a pair (y, z) plus glue t, the same bookkeeping extends to a k-part decomposition $P = (y_1, \ldots, y_k, t)$ with cost $u(P;x) = \sum_i s_C(y_i) + t$; all bounds below continue to hold verbatim because they depend only on the fact that t enters additively. In this sense, the present two-part notation is a minimal template for compositionality rather than a restriction to binary factoring.*

Theorem 69 (Overhead penalty bound)**.** *Assume $s_C^{\mathrm{base}}(x) = s > 0$ and let $P = (y, z, t)$ be a compositional witness of x. For any $\Delta \geq 0$ let $P' = (y, z, t + \Delta)$ (same parts, larger overhead). Then*

$$I_C(P';x) \geq I_C(P;x) - \frac{\Delta}{s}.$$

In particular, increasing overhead by Δ cannot reduce intensity by more than Δ/s.

Remark 2845. *This theorem says that overhead hurts in a controlled way: intensity cannot collapse faster than linearly in the added overhead, and the scale factor is set by the baseline cost s. In practical terms, if the baseline cost is large, then modest overhead changes have little relative effect; if the baseline cost is small, overhead is proportionally more dangerous. This is exactly* *the kind of engineering heuristic one would like to promote from folklore to theorem. Note also that the assumption $s > 0$ is essential only to avoid division by zero; conceptually, s serves as the normalization that turns an absolute cost increase Δ into a dimensionless intensity drop Δ/s.*

Remark 2846. *The result connects directly to the Lipschitz lemma: overhead enters additively into witness cost, so the same Lipschitz constant yields the bound. It also anticipates later "tradeoff" uses: when an engine considers making a model more compositional (hence paying more glue), this inequality bounds how much intensity can be sacrificed for the compositional restructuring. Equivalently, it gives a simple sensitivity guarantee: if the glue term is uncertain up to $\pm\Delta$ due to implementation details, then the resulting intensity uncertainty is at most Δ/s.*

Remark 2847. *For the common linear intensity profile (as in earlier sections), $I(u;x)$ behaves like a clipped affine function of u (e.g., $I(u;x) = \max\{0, 1 - u/s\}$), in which case the bound is tight whenever both $u(P;x)$ and $u(P;x) + \Delta$ lie in the linear (unclipped) regime. When $u(P;x) + \Delta$ pushes the cost into the saturated regime where intensity is already near 0, the inequality remains valid but becomes conservative, reflecting the fact that intensity cannot fall below 0.*

Proof. We have $u(P';x) = u(P;x) + \Delta$. Apply the Lipschitz bound with $u = u(P;x)$ and $v = u(P;x) + \Delta$:

$$|I(u;x) - I(u + \Delta;x)| \le \Delta/s.$$

Since I is nonincreasing in cost, $I(u + \Delta;x) \le I(u;x)$, hence $I(u + \Delta;x) \ge I(u;x) - \Delta/s$, which is the stated inequality. Interpreting $I_C(P;x)$ as $I(u(P;x);x)$, the same one-dimensional cost perturbation argument applies because changing t by Δ leaves the part costs fixed and alters the total cost only through an additive shift. □

Remark 2848. Proof sketch and intuition. *The proof has two ingredients: (i) overhead Δ is exactly an additive increase in cost, and (ii) intensity changes at most Δ/s under a Δ change in cost (Lipschitz). The final step uses monotonicity of I in cost to remove absolute values and get a one-sided bound. One may imagine sliding along the descending segment of the intensity-vs-cost line: increasing cost by Δ slides rightward by Δ and therefore moves downward by at most Δ/s. In decision terms, this provides a "worst-case penalty" certificate: even if the glue turns out to be less efficient than expected by Δ, the intensity cannot be worse by more than Δ/s.*

Corollary 35 (Design inequality for keeping intensity above a threshold)**.** *Assume $s_C^{\mathrm{base}}(x) = s > 0$ and fix $\tau \in (0, 1]$. If a compositional witness $P = (y, z, t)$ satisfies*

$$t \le (1 - \tau)s - s_C(y) - s_C(z),$$

then $I_C(P;x) \ge \tau$.

Remark 2849. *This corollary is a direct "specification inequality": if you want intensity at least τ, then the admissible overhead is what remains of the budget after paying for the parts. It is useful in synthesis settings: one can select candidate components y, z and immediately see whether any glue budget remains, before attempting to construct the detailed coupling. When the right-hand side is negative, the inequality simply reports infeasibility under this two-part factoring: even with $t = 0$, the parts alone already exceed the $(1 - \tau)s$ budget, so no amount of clever interfacing can meet the target intensity without changing the parts (or the baseline scale s).*

Proof. The condition is exactly $u(P;x) = s_C(y) + s_C(z) + t \le (1 - \tau)s$. Apply the threshold–budget theorem. □

Remark 2850. Proof sketch and intuition. *The inequality on t is simply the rearranged statement "total cost is within the $(1-\tau)s$ budget." The earlier threshold theorem then converts that budget condition into the desired intensity condition. In other words: the corollary is not new algebra, but a useful way of presenting the same algebra in the language of "overhead capacity." One can also read it as a margin statement: the quantity $(1-\tau)s - s_C(y) - s_C(z)$ is the remaining slack available for interactions, and the corollary says that keeping glue within this slack is sufficient to preserve the desired intensity.*

Corollary 36 (Overhead robustness budget for a tolerated intensity drop)**.** *Assume $s_C^{\mathrm{base}}(x) = s > 0$ and let $P = (y, z, t)$ be a compositional witness of x. Fix $\varepsilon \geq 0$. If the glue overhead is increased by at most $\Delta \leq \varepsilon s$, then the resulting witness $P' = (y, z, t + \Delta)$ satisfies*

$$I_C(P'; x) \geq I_C(P; x) - \varepsilon.$$

Remark 2851. *This restates the overhead penalty bound in the most operational form: to guarantee that intensity degrades by at most ε, it suffices to bound unforeseen glue overhead by εs. In optimization or design loops, this gives a simple acceptance test for refactorings that incur additional interface machinery: if the added machinery is known (or bounded) to cost at most εs, then the refactoring is intensity-safe up to tolerance ε.*

50.4 Attainable intensity capacity and observer upgrades

Theorem 70 (Closed form for attainable intensity bound)**.** *Assume $s_C^{\mathrm{base}}(x) > 0$. Then*

$$I_C^{\star}(x) = \max\left\{0,\ 1 - \frac{s_C(x)}{s_C^{\mathrm{base}}(x)}\right\} = \max\left\{0,\ \frac{s_C^{\mathrm{base}}(x) - s_C(x)}{s_C^{\mathrm{base}}(x)}\right\}.$$

Moreover, for every witness w of x, one has $I_C(w; x) \leq I_C^{\star}(x)$.

Remark 2852. *The closed form makes explicit that $I_C^{\star}(x) \in [0, 1]$ whenever $s_C(x) \geq 0$ and $s_C^{\mathrm{base}}(x) > 0$: the outer $\max\{0, \cdot\}$ truncates negative values, and the ratio cannot exceed 1 when the infimal cost is nonnegative. In particular, the two boundary cases are conceptually important: (i) if $s_C(x) \geq s_C^{\mathrm{base}}(x)$, then $I_C^{\star}(x) = 0$, meaning that even the best witness does not beat the baseline in cost; and (ii) if $s_C(x) = 0$, then $I_C^{\star}(x) = 1$, meaning (on this scale) that one can in principle achieve full intensity relative to the baseline. This provides a direct way to interpret intensity as a* normalized cost savings *relative to the baseline, namely*

$$I_C^{\star}(x) = \frac{\text{(baseline cost)} - \text{(best achievable cost)}}{\text{(baseline cost)}} \quad \text{truncated below at } 0.$$

Remark 2853. *This theorem identifies the best possible intensity in terms of the best possible witness cost. Thus, intensity capacity is nothing but (truncated) normalized "compressibility gap" between the baseline and the simplest description. The result is important because it reduces a supremum over intensities to a single ratio involving $s_C(x)$, which is often the quantity one estimates or bounds in complexity arguments [16]. It also clarifies the role of the baseline: a poor baseline inflates the apparent available intensity, while a strong baseline makes high intensity harder to achieve.*

Remark 2854. *A practical corollary is that comparing attainable intensities across systems is only meaningful once the baseline choice is pinned down. For example, changing $s_C^{\mathrm{base}}(x)$ rescales the same underlying best cost $s_C(x)$ into a different normalized gap. This is exactly the same phenomenon one sees in approximation ratios in algorithms: the denominator sets the reference difficulty, and the numerator measures improvement relative to that reference.*

Remark 2855. *The connection to the broader Hyperseed pattern story [5] is that emergent or meaningful patterns are those that* explain *by compressing. Here the explanation is measured against an explicit baseline. The formula shows exactly what must be true for nonzero attainable intensity: we must have $s_C(x) < s_C^{\mathrm{base}}(x)$, i.e. some witness is strictly simpler than the baseline.*

Remark 2856. *It is also worth separating two notions that can otherwise be conflated: (a) the* existence *of a witness with high intensity, and (b) the* attainment *of the supremal intensity. The theorem gives the value of the supremum $I_C^\star(x)$ in closed form, but does not require that there is an actual witness $w^\star$ with $u(w^\star; x) = s_C(x)$ achieving it. In many complexity settings, the infimum is not necessarily a minimum; nonetheless, one can approximate the optimum cost arbitrarily well, which is sufficient to approximate the attainable intensity arbitrarily well.*

Proof. Write $s := s_C^{\mathrm{base}}(x) > 0$ and $m := s_C(x) = \inf_w u(w; x)$.

For any witness w, $u(w; x) \geq m$, and since $u \mapsto \max\{0, 1 - u/s\}$ is nonincreasing,

$$I_C(w; x) \leq \max\{0, 1 - m/s\}.$$

Hence $I_C^\star(x) \leq \max\{0, 1 - m/s\}$.

For the reverse inequality: by the definition of infimum, for each $n \in \mathbb{N}$ there exists a witness w_n with $u(w_n; x) \leq m + \frac{1}{n}$. Then

$$I_C(w_n; x) \geq \max\left\{0, 1 - \frac{m + 1/n}{s}\right\}.$$

Taking $n \to \infty$ shows $\sup_n I_C(w_n; x) \geq \max\{0, 1 - m/s\}$, hence $I_C^\star(x) \geq \max\{0, 1 - m/s\}$. ☐

Remark 2857. *The proof uses only two structural facts: (i) $I_C(w; x)$ depends on w only through the scalar cost $u(w; x)$, and (ii) the mapping from cost to intensity is monotone (and continuous from the right on $(0, \infty)$, with truncation at 0). This is why essentially the same reasoning applies to many alternative "intensity" parametrizations, as long as they are monotone transforms of cost relative to a fixed baseline.*

Remark 2858. Proof sketch and intuition. *The upper bound is monotonicity: since intensity decreases with cost, the best intensity cannot exceed what you would get if you could plug in the minimal possible cost m. The lower bound uses the defining property of an infimum: one can approximate m with witness costs $m + 1/n$. Applying the intensity function and taking $n \to \infty$ forces the supremum of intensities up to the same value. Visually, one is pushing the witness costs leftward toward the point $u = m$ on the intensity graph.*

Remark 2859. *A concrete sanity check is the "do-nothing" witness: if the witness class contains a baseline-like encoding whose cost is exactly $s_C^{\mathrm{base}}(x)$, then one always has at least intensity 0, and one only gains positive intensity by finding witnesses that reduce cost below the baseline. This aligns with the interpretation that intensity measures* improvement *rather than absolute simplicity.*

Theorem 71 (Representation expansion improves simplicity and intensity capacity)**.** *Fix x and assume $s_C^{\mathrm{base}}(x) > 0$. If $\mathcal{W}(x) \subseteq \mathcal{W}'(x)$ (same cost function u), then*

$$\inf_{w \in \mathcal{W}'(x)} u(w; x) \leq \inf_{w \in \mathcal{W}(x)} u(w; x),$$

and consequently the attainable intensity bound satisfies

$$\sup_{w \in \mathcal{W}'(x)} I_C(w; x) \geq \sup_{w \in \mathcal{W}(x)} I_C(w; x).$$

Remark 2860. *The condition "same cost function u" matters: the statement is about enlarging the feasible set while holding fixed the evaluation criterion. If an observer upgrade also changes how costs are measured (e.g. by reweighting primitive operations, changing encoding length conventions, or altering what counts as a valid derivation), then the monotonicity comparison becomes a comparison of two different objective functions and need not hold without additional assumptions.*

Remark 2861. *This theorem states an elementary but powerful monotonicity principle: enlarging the space of allowable representations cannot make the best achievable description worse. In the engineering idiom, adding new primitives, new rewrite rules, new compositional schemas, or new sensors cannot force you to lose previously available solutions; you can always ignore the upgrade. Consequently, the system's "pattern capacity" (in the compressive sense) can only increase.*

Remark 2862. *One can also read the conclusion in a strictness-sensitive way: if the expansion $\mathcal{W}(x) \subseteq \mathcal{W}'(x)$ introduces at least one genuinely new witness that attains a strictly smaller cost than all witnesses in $\mathcal{W}(x)$, then the infimum strictly decreases and the attainable intensity strictly increases (provided the truncation at 0 is not already active). Thus, observer upgrades are only* detectable *in intensity when they actually enable new, more economical descriptions for the particular x under consideration.*

Remark 2863. *This result connects tightly to the preceding closed-form theorem: intensity capacity depends only on the infimal achievable cost. So any mechanism that decreases infimal cost (by expanding the witness set) increases attainable intensity. This is one formal justification for the common practice of "representation learning" as a means to reveal stronger patterns: by changing what counts as a witness, one changes what can be compressed.*

Remark 2864. *Equivalently, if the baseline is fixed, then the upgrade comparison can be expressed purely at the level of ratios:*

$$I_C^{\star\prime}(x) - I_C^{\star}(x) = \max\left\{0, 1 - \frac{s'_C(x)}{s_C^{\mathrm{base}}(x)}\right\} - \max\left\{0, 1 - \frac{s_C(x)}{s_C^{\mathrm{base}}(x)}\right\},$$

where $s'_C(x) := \inf_{w \in \mathcal{W}'(x)} u(w; x)$. This makes explicit that the only lever the upgrade has (in this fixed-baseline setting) is to reduce the achievable infimal cost; everything else is a monotone postprocessing.

Proof. The first inequality is the basic fact that an infimum over a larger set cannot increase. For the second, use the closed form for $I^\star$ in terms of the infimal cost: decreasing the infimal cost weakly increases $\max\{0, 1 - \cdot / s_C^{\mathrm{base}}(x)\}$. □

Remark 2865. *In optimization language, $\mathcal{W}(x) \subseteq \mathcal{W}'(x)$ is a feasible-set expansion, so the optimal value (here, the infimum of costs) is monotone nonincreasing. The intensity statement is then immediate because intensity is an order-reversing transform of cost (up to truncation). This perspective is useful when chaining multiple upgrades: any sequence of feasible-set expansions yields a monotone nondecreasing sequence of attainable intensity capacities for each fixed x and fixed baseline.*

Remark 2866. Proof sketch and intuition. *The first claim is order theory: $\mathcal{W}(x) \subseteq \mathcal{W}'(x)$ means you are minimizing over more options, so the minimum (or infimum) cannot go up. The second claim is calculus-free: the function $m \mapsto \max\{0, 1 - m/s\}$ is nonincreasing in m, so if the best cost drops, the best intensity rises. The point is not subtlety but reusability: the same argument appears repeatedly when comparing reasoning regimes.*

50.5 Coupling to weakness/effort policies: "open if you can"

Theorem 72 (Opening is a triple win under representational monotonicity)**.** *Assume effort/weakness monotonicity and representational monotonicity under opening. Then for any opening $H \subseteq H'$ and any x:*

$$w(H) \leq w(H'), \qquad \mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(H'), \qquad I^{\star}_{C,H}(x) \leq I^{\star}_{C,H'}(x).$$

Remark 2867. *The ordering $H \subseteq H'$ should be read as "H' is at least as open as H," i.e., H' permits at least the same identifications/indistinctions as H (and possibly more). In that sense, weakness is naturally monotone in this order (more openness means more allowed indistinction), while effort is naturally antitone (more openness typically means fewer constraints to enforce, hence less work). Representational monotonicity then asserts that opening does not remove any representational options available under H: it can only add witnesses or constructions.*

Remark 2868. *The theorem says: if opening a policy both (i) reduces effort and (ii) enlarges the allowed witness family, then opening is simultaneously good for three quantities: it increases weakness (you accept more indistinction), decreases effort (you work less), and increases pattern capacity (you can achieve at least as much intensity). It is not that opening is always normatively preferred, but that* under these assumptions *there is no internal tradeoff between these three dimensions.*

Remark 2869. *A useful way to read the last inequality is as a* pointwise dominance *statement in x: for each fixed instance x, the best attainable intensity when using the more open policy H' is at least the best attainable intensity under H. This is stronger than a mere statement about averages or typical cases: it rules out the possibility that opening helps some inputs but hurts others, provided representational monotonicity holds as stated for every x.*

Remark 2870. *This is a formal articulation of the stance "open if you can": if feasibility constraints do not forbid openness, and if openness expands representational options, then openness is a rational default. The assumptions are strong enough to be useful and weak enough to hold in many coarse-graining or abstraction regimes.*

Remark 2871. *The assumptions can be viewed as separating* engineering *effects from* mathematical *effects. Effort/weakness monotonicity are policy-level regularities about the cost and permissiveness of enforcement; representational monotonicity is a structural regularity about the modeling language or witness mechanism. The theorem then says that once these are granted, the intensity comparison becomes purely set-theoretic: enlarging the feasible witness family cannot make the supremum of an objective smaller.*

Proof. The weakness and effort inequalities are assumptions. For intensity capacity: $H \subseteq H'$ implies $\mathcal{W}_H(x) \subseteq \mathcal{W}_{H'}(x)$ by representational monotonicity, so the attainable intensity bound can only increase by the representation-expansion theorem. □

Remark 2872. Proof sketch and intuition. *Two of the three inequalities are simply unpacking the assumptions. The third inequality is a one-line reduction: opening enlarges $\mathcal{W}_H(x)$, and the best achievable intensity over a larger set cannot be smaller. The picture is: opening "widens the funnel" through which witnesses may pass, so it cannot reduce the best witness you could find.*

Remark 2873. *One can also interpret the third inequality as an "option value" principle: even if the agent ultimately chooses to use only witnesses that were already available under H, the mere availability of additional witnesses under H' cannot decrease the optimum. Any intensity-achieving* *(or approximately intensity-achieving) witness feasible under H remains feasible under H' and can be reused verbatim, while H' may additionally permit more structured or more compressive witnesses that achieve higher intensity.*

Theorem 73 (Maximally open adequate policy maximizes pattern capacity pointwise)**.** *Let $\mathcal{F}_C$ be a feasible (adequate) set of policies, and assume it is upward closed:*

$$H \in \mathcal{F}_C,\ H \subseteq H' \implies H' \in \mathcal{F}_C.$$

Define the union (maximally open) feasible policy

$$\overline{H} := \bigcup_{H \in \mathcal{F}_C} H.$$

Assume effort/weakness monotonicity and representational monotonicity under opening. Then:

1. *$\overline{H} \in \mathcal{F}_C$ and $H \subseteq \overline{H}$ for all $H \in \mathcal{F}_C$;*
2. *$\overline{H}$ minimizes effort on $\mathcal{F}_C$ and maximizes weakness on $\mathcal{F}_C$;*
3. *for every x, $\overline{H}$ maximizes attainable intensity capacity pointwise:*

$$I^\star_{C,\overline{H}}(x) \geq I^\star_{C,H}(x) \quad \textit{for all } H \in \mathcal{F}_C.$$

Remark 2874. *The upward-closed condition is the formal expression of "if you can open, you remain adequate." In many applications, adequacy/feasibility expresses resource, safety, or consistency constraints that become* easier *(not harder) to satisfy as one relaxes distinctions: e.g., if a strict discrimination requirement is satisfiable within a budget, then a weaker discrimination requirement is also satisfiable within the same budget. When this monotonicity of feasibility fails, the union construction may no longer produce an admissible policy, and the selection rule would require modification (for example, selecting maximal elements within a non-upward-closed feasible region).*

Remark 2875. *This theorem constructs a canonical "most open" policy consistent with feasibility: take the union of all feasible policies. The upward-closed condition says feasibility is preserved under opening, so if some level of indistinction is allowed, then any weaker demand for distinctions is also allowed. In that case, the union is feasible and dominates every other feasible policy in openness. This is an instance of a familiar lattice-theoretic idea: maximal elements arise by joining (here, unioning) all admissible approximations. It resonates with fixed-point-and-selection themes (cf. Section 48) in that one often selects a "largest" stable regime subject to constraints.*

Remark 2876. *It may be helpful to emphasize why the union is the right "join" operation here. Inclusion equips the policy space with a natural partial order, and union is the least upper bound with respect to this order: it is the smallest policy that is at least as open as every feasible $H \in \mathcal{F}_C$, while still containing all distinctions that any feasible policy is willing to drop. Thus $\overline{H}$ is not an arbitrary choice; it is forced once one insists on a single policy that upper-bounds the entire feasible family.*

Remark 2877. *The conclusion is a precise, pointwise version of "maximally open adequate." It says that within the feasible region, $\overline{H}$ is extremal in effort and weakness, and it is also extremal in the capacity to support intense witnesses. This is a principled selection rule for a reasoning engine: if the only objective is to maximize compressive pattern capacity while remaining feasible, then select $\overline{H}$. The conceptual background aligns with tradeoff-based policy selection discussed in [9].*

Remark 2878. *Note the separation between extremality statements: item (2) is a global extremality over $\mathcal{F}_C$ (a single scalar effort and scalar weakness per policy), while item (3) is an extremality for each x separately. In particular, even if one later aggregates $I^{\star}_{C,H}(x)$ over x (e.g., by expectation under a data distribution), the pointwise dominance immediately implies dominance under any monotone aggregation functional.*

Proof. (1) Upward closure implies $\overline{H}$ is feasible, and the union contains each member. (2) If $H \subseteq \overline{H}$ and effort is antitone, then $\mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(\overline{H})$; if weakness is monotone, then $w(H) \leq w(\overline{H})$. (3) For any feasible H, we have $H \subseteq \overline{H}$, hence $\mathcal{W}_H(x) \subseteq \mathcal{W}_{\overline{H}}(x)$ for all x. Therefore $I^{\star}_{C,\overline{H}}(x) \geq I^{\star}_{C,H}(x)$ by representation expansion. □

Remark 2879. Proof sketch and intuition. *The proof is a chain of monotonicities. Because feasibility is upward closed, taking the union of feasible policies stays feasible. Union is the largest element with respect to inclusion, so every feasible H is contained in $\overline{H}$. Antitonicity of effort and monotonicity of weakness then make $\overline{H}$ extremal for those quantities. Finally, representational monotonicity converts $H \subseteq \overline{H}$ into inclusion of witness families, and the representation-expansion theorem converts that into the pointwise maximality of intensity capacity.*

Remark 2880. *A concrete mental model is: $\mathcal{F}_C$ encodes all "acceptable" abstraction levels under a fixed budget or constraint set C, and $\overline{H}$ is the coarsest (most open) abstraction among them. The theorem then asserts that, under the monotonicities, the coarsest acceptable abstraction simultaneously (i) costs the least to operate, (ii) tolerates the most indistinction, and (iii) enables the richest attainable patterns (as measured by intensity capacity) at every input x. This provides a decision tool: rather than tuning openness by hand, one can search for feasibility and then take the join of what is feasible.*

50.6 Pareto pruning in tradeoff spaces (finite candidate sets)

Definition 466 (Dominance for witnesses at fixed x)**.** *Fix x and define a quality vector for a witness w by*

$$q(w) := \big(u(w;x),\ -I_C(w;x)\big) \in [0,\infty] \times [-1,0].$$

Say w' dominates *w if $q(w') \leq q(w)$ coordinatewise and $q(w') \neq q(w)$. Equivalently: $u(w';x) \leq u(w;x)$ and $I_C(w';x) \geq I_C(w;x)$ with at least one strict.*

Remark 2881. *The codomain $[0,\infty] \times [-1,0]$ allows for "infinite" cost (e.g. an infeasible or undefined witness under the current resource model) while keeping the dominance relation well-defined: any finite-cost alternative with comparable intensity will dominate an infinite-cost candidate. Similarly, if two witnesses coincide in both coordinates (a genuine tie), neither dominates the other; they are interchangeable as far as the two criteria are concerned, and downstream logic may keep either or both depending on representational needs (e.g. different internal structures producing the same tradeoff point).*

Remark 2882. *This is the standard Pareto order (Hyperseed-Concept 147) specialized to two criteria: lower cost is better, and higher intensity is better. The sign flip in the second coordinate is merely a notational convenience so that "better" corresponds to "smaller" in both coordinates. Dominance captures the idea of an option that is unambiguously inferior: it is more expensive and no more intense, or less intense and no cheaper.*

Remark 2883. *It can be helpful to view dominance as the strict part of a preorder induced by coordinatewise comparison. Concretely, if we define the weak relation $w' \preceq w$ by $q(w') \leq q(w)$*

coordinatewise, then w' dominates w exactly when $w' \preceq w$ and not $w \preceq w'$. In the plane $(u, -I)$, the set of points weakly improving on $q(w)$ is the south-west closed quadrant with corner at $q(w)$; dominance means that $q(w')$ lies in that quadrant and is not identical to $q(w)$.

Remark 2884. *In practice, this definition is useful because it decouples local pruning from global objectives. An engine might later apply any scalarization of the two objectives (weighted sums, lexicographic orders, constraints like $I \geq \tau$ or $u \leq B$), but dominance pruning is always safe for any monotone scalarization: a dominated witness cannot become optimal under any reasonable way of combining the criteria.*

Remark 2885. *One way to formalize "reasonable" here is: a scalar objective $F(u, I)$ is* monotone *if it is nondecreasing in u and nonincreasing in $-I$ (equivalently, nonincreasing in I when interpreted as a maximization). Then $q(w') \leq q(w)$ implies $F\big(u(w'; x), I_C(w'; x)\big) \leq F\big(u(w; x), I_C(w; x)\big)$ for minimization-style scalarizations, so a dominated witness can never strictly beat its dominator. This covers common choices such as weighted sums $\lambda u - (1 - \lambda)I$, Lagrangian relaxations, and feasibility-first rules like "minimize u subject to $I \geq \tau$" (which is monotone in the sense that improving intensity or reducing cost cannot turn a feasible better point into a worse one).*

Theorem 74 (Finite Pareto frontier is nonempty)**.** *Fix x and let $\mathcal{A}$ be a finite set of candidate witnesses for x. Then there exists at least one undominated witness in $\mathcal{A}$ (a Pareto frontier element).*

Remark 2886. *The theorem asserts that in a finite candidate set, there is always at least one "maximally good" element under the dominance order. This is not deep, but it is foundational for designing bounded search procedures: if you prune dominated candidates, you will not prune everything. The result is a small but essential guarantee that supports iterative refinement, beam maintenance, and anytime algorithms.*

Remark 2887. *The statement is the two-criterion instance of a general fact: in any finite set equipped with a strict partial order, there exists at least one* maximal *element (an element with no strictly larger element). Here "larger" corresponds to "better" under the Pareto order. This perspective is useful because it separates the combinatorial content (finiteness implies existence of maximals) from the semantic content (what we chose as the dominance relation).*

Proof. Assume for contradiction that every $w \in \mathcal{A}$ is dominated by some $w' \in \mathcal{A}$. Pick any $w_0 \in \mathcal{A}$ and iteratively choose a strict dominator w_{k+1} of w_k. Each step strictly improves at least one coordinate while not worsening the other, so w_k are all distinct. This yields an infinite sequence of distinct elements of $\mathcal{A}$, contradicting finiteness. $\square$

Remark 2888. *The "all distinct" claim can be unpacked as follows. If w_{k+1} dominates w_k, then $q(w_{k+1}) \leq q(w_k)$ coordinatewise and $q(w_{k+1}) \neq q(w_k)$. In particular, at least one coordinate strictly decreases, so returning to any previously visited w_j would require a later step to increase that coordinate to match $q(w_j)$, which is impossible because every step is coordinatewise nonincreasing. Thus the construction cannot cycle, and strict improvement forces an ever-descending chain in a set that was assumed finite.*

Remark 2889. Proof sketch and intuition. *The argument is a classic "infinite descent" in a finite set. If everything is dominated, then starting anywhere you can always step to something strictly better. Strict improvement prevents cycles, so you obtain an infinite strictly improving chain, which cannot fit inside a finite set. Geometrically, points $(u, -I)$ in the plane cannot have infinite strictly decreasing sequences if there are only finitely many points available.*

Remark 2890. *A concrete geometric way to visualize the frontier: plot each candidate as a point* $(u(w;x), -I_C(w;x))$. *The undominated points are exactly those for which the south-west quadrant contains no other point. For example, if candidates yield* $(u, -I)$ *values* $\{(1, -0.2), (2, -0.9), (1.5, -0.2)\}$, *then* $(1, -0.2)$ *dominates* $(1.5, -0.2)$ *(same intensity, lower cost), while* $(2, -0.9)$ *may remain undominated because it trades higher cost for much higher intensity. The frontier is then* $\{(1, -0.2), (2, -0.9)\}$, *reflecting two qualitatively different tradeoffs.*

Remark 2891 (How an engine uses this)**.** *If a reasoning system maintains a finite beam of candidate patterns, it can safely discard any candidate dominated in* (*cost*, *intensity*) *space. The remaining beam is guaranteed nonempty and contains all candidates that could be optimal under any monotone scalarization (e.g. minimize cost subject to intensity* $\geq \tau$*, or maximize intensity subject to cost* $\leq B$*).*

Remark 2892. *From an implementation standpoint, dominance pruning over a finite beam of size* n *can be done by a simple* $O(n^2)$ *pairwise check, which is often acceptable when the beam is small and the per-candidate evaluation is the expensive part. When* n *is large, one can exploit the two-dimensional structure: sorting by cost and scanning while maintaining the best intensity seen so far yields a skyline/frontier computation that is typically faster (and in many cases* $O(n \log n)$ *due to sorting). These algorithmic considerations matter because they make Pareto maintenance a low-overhead invariant that can be enforced at every iteration of a search loop.*

Remark 2893. *A further pragmatic reading is that Pareto pruning is a way of maintaining epistemic humility: one does not commit prematurely to a particular tradeoff between cost and intensity. Instead one keeps the frontier, which represents the live options consistent with multiple possible downstream preferences, goals, or meta-policies (Hyperseed-Concept 110). This resonates with the broader project of building reasoning systems that can revise their objective functions while preserving sound intermediate commitments.*

Remark 2894. *Finally, note that the same pruning logic generalizes immediately to more than two criteria (e.g. cost, intensity, and a third axis such as robustness or interpretability). The finite-frontier-nonempty theorem remains true for any fixed finite number of coordinates: in a finite set, there is always at least one undominated element under coordinatewise dominance. The two-dimensional case is emphasized here because it admits particularly clear geometric intuition and efficient frontier-maintenance routines, making it a convenient "decision tool" module inside larger Weakness/Effort/Pattern-Intensity tradeoff workflows.*

51 Emergence and Synergy Theorems for Explanation and Discovery

We prove a small family of emergence/synergy theorems designed to be useful for inference engines leveragint Hyperseed ontology [1]: (1) selection/witness results that guarantee the existence of a specific emergent pattern to point to, (2) a cost-level characterization of emergent surplus as strict subadditivity (emergent compression), (3) quantitative lower bounds connecting a single emergent-compression explanation to synergy gain, (4) an operational budget theorem showing synergy expands solvable tasks, (5) witness theorems for collective (interaction-only) properties.

Remark 2895. *Philosophically, this section treats "emergence" and "synergy" as two sides of one logical coin. At the entity level, emergence is a statement about how the joint object* $A *_C B$ *admits a pattern witness* Q *that is not merely a weighted average of how* Q *behaves on* A *and on*

*B separately (see Hyperseed-Concept **??** and 130). At the explanation level, synergy is a statement about how combining distinct inference resources can reduce the contrivance needed to achieve a given fit (see Hyperseed-Concept 73 and 202), echoing the "cognitive synergy" viewpoint in [19]. The core technical move is to relate these semantic notions to inequalities on costs, so that an engine can turn a qualitative slogan ("the whole is more than the parts") into a quantitative decision rule.*

Concretely, the role of the "witness" language in items (1) and (5) is operational: rather than asserting that some global regularity exists in an abstract sense, we aim to certify the existence of a particular pattern variable Q (or a bounded family of candidates) that an inference engine can explicitly track, score, and later reuse as an explanatory handle. In this sense, a witness theorem is also a pointer theorem: it justifies searching for, caching, and communicating a finite artifact that stands for an otherwise diffuse emergent effect.

Items (2) and (3) translate that witness perspective into inequalities. Strict subadditivity corresponds to a regime in which a single joint description of the composite $A *_C B$ (or of the data generated by it) is cheaper than any decomposition into separate descriptions of A and B plus whatever bookkeeping is needed to coordinate them through C. This is the formal sense in which "emergent surplus" becomes "emergent compression": the surplus is measured not by an extra ontological ingredient but by a gap between best joint cost and best separable cost. The quantitative bounds in (3) then show how a certified compression gap can be cashed out as a lower bound on synergy gain, i.e. on the reduction in contrivance achievable by mixing inference resources instead of using them in isolation.

Item (4) makes the preceding correspondence actionable in a resource-bounded setting. Rather than treating synergy as an abstract property of agents, we treat it as an effect on feasible sets of tasks under explicit budgets: a fixed contrivance or cost budget can certify a strictly larger set of achievable fits when resources are allowed to interact. In this way, the theorems support a pipeline where an engine (i) detects an emergent witness Q for $A *_C B$, (ii) verifies a strict subadditivity gap at the cost level, and (iii) upgrades that gap into a guarantee that a broader class of explanatory targets becomes solvable under the same operational constraints.

Finally, the "collective (interaction-only)" emphasis in (5) isolates properties that provably do not decompose into attributes of A alone or B alone. Such theorems are intended to prevent a common failure mode in automated discovery: misattributing a relational regularity to one component due to an overly separable model class. By requiring that the witness depend essentially on the joint structure $A *_C B$ (and not merely on marginal behavior), we obtain a principled certificate that the identified pattern is genuinely collective in the technical sense required for downstream reasoning and intervention.

51.1 Standing setup

51.1.1 Pattern intensity and emergence (entity-level)

Fix a context C with:

- a set of entities $\mathcal{E}_C$,
- a (partial) binary combination operation $*_C : \mathcal{E}_C \times \mathcal{E}_C \rightharpoonup \mathcal{E}_C$,
- a baseline description cost $s_C^{\text{base}} : \mathcal{E}_C \to \mathbb{R}_{\geq 0}$,
- a pattern vocabulary $\mathcal{P}_C$ (finite or countable).

We treat each $Q \in \mathcal{P}_C$ as a *candidate pattern witness* that, when applicable to $x \in \mathcal{E}_C$, comes with a nonnegative cost $u_C(Q;x) \in [0,\infty]$ (if Q is not applicable to x, take $u_C(Q;x) = \infty$).

Remark 2896. *A few pieces of notation are doing most of the work:*

- $\mathcal{E}_C$ *is the domain of things we may wish to explain or compress (data items, objects, states), relative to a context* C.
- *The partial operation* $*_C$ *formalizes "composition" or "interaction" inside the context; the arrow* $\rightharpoonup$ *indicates that not all pairs* (A, B) *can be composed.*
- $s_C^{\mathrm{base}}(x)$ *is a reference cost for* x*—the cost of an unstructured, default, or otherwise agreed-upon representation (cf. Hyperseed-Concept 169 and 82).*
- $\mathcal{P}_C$ *is a vocabulary of candidate pattern-witnesses, and* $u_C(Q;x)$ *is the cost of using witness* Q *to represent or account for* x.

This overall framing is close in spirit to description-length and compression viewpoints from algorithmic information theory [16], and to the general Hyperseed perspective that patterns are, operationally, economical representations [5] (see Hyperseed-Concept 130).

Definition 467 (Scalar intensity)**.** *Assume* $s_C^{\mathrm{base}}(x) > 0$. *Define the (scalar) intensity of* Q *for* x *by*

$$I_C(Q;x) := \max\left\{0,\ 1 - \frac{u_C(Q;x)}{s_C^{\mathrm{base}}(x)}\right\} \in [0,1].$$

If $s_C^{\mathrm{base}}(x) = 0$, *set* $I_C(Q;x) = 0$ *by convention.*

Remark 2897. *Intuitively,* $I_C(Q;x)$ *measures the* fractional savings *achieved by explaining/encoding* x *using* Q *instead of the baseline. If* $u_C(Q;x)$ *is smaller than* $s_C^{\mathrm{base}}(x)$, *then* Q *is genuinely compressive and the intensity is positive. If* $u_C(Q;x) \geq s_C^{\mathrm{base}}(x)$, *then the witness is not better than baseline and intensity is clamped to* 0. *This makes intensity a normalized indicator of "pattern usefulness" (Hyperseed-Concept 130) rather than merely a raw cost difference.*

For a simple example, if $s_C^{\mathrm{base}}(x) = 10$ *and* $u_C(Q;x) = 7$, *then* $I_C(Q;x) = 1 - 7/10 = 0.3$. *If* $u_C(Q;x) = 12$, *then* $I_C(Q;x) = \max\{0, 1 - 12/10\} = 0$. *The clamp is important for downstream reasoning: it prevents negative values from being misread as "anti-patterns" and keeps intensities comparable across witnesses.*

Definition 468 (Emergence weights and emergent surplus/intensity)**.** *Fix* $A, B \in \mathcal{E}_C$ *with* $s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B) > 0$ *and assume* $A *_C B$ *is defined. Define weights*

$$w_C(A) := \frac{s_C^{\mathrm{base}}(A)}{s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B)}, \qquad w_C(B) := \frac{s_C^{\mathrm{base}}(B)}{s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B)}.$$

For $Q \in \mathcal{P}_C$, *define the emergent surplus*

$$\mathrm{Sur}_C(Q;A,B) := I_C\big(Q; A *_C B\big) - \Big(w_C(A)\, I_C(Q;A) + w_C(B)\, I_C(Q;B)\Big),$$

and the emergent intensity

$$\mathrm{Emer}_C(Q;A,B) := \max\{0, \mathrm{Sur}_C(Q;A,B)\}.$$

Remark 2898. *The weights $w_C(A), w_C(B)$ sum to 1 and bias the comparison by baseline description size: if A is "larger" than B in baseline cost, then A's intensity contributes more heavily to the "non-emergent" expectation. Thus $\mathrm{Sur}_C(Q; A, B)$ compares the pattern intensity on the composite $A *_C B$ against what one would predict by treating A and B as merely co-present but not truly interacting. When $\mathrm{Sur}_C(Q; A, B) > 0$, Q is more intense on the composite than this weighted baseline, and we call that an emergent contribution (Hyperseed-Concept* **??***).*

Geometrically (in the very mild sense of convexity), the term $w_C(A)\, I_C(Q; A) + w_C(B)\, I_C(Q; B)$ is a point on the line segment between the "part intensities." Emergence asserts that $I_C(Q; A *_C B)$ lies strictly above that segment. A toy example: suppose $w_C(A) = w_C(B) = 1/2$, $I_C(Q; A) = 0.1$, $I_C(Q; B) = 0.1$, but $I_C(Q; A *_C B) = 0.6$. Then $\mathrm{Sur}_C(Q; A, B) = 0.6 - 0.1 = 0.5$ and $\mathrm{Emer}_C(Q; A, B) = 0.5$: Q becomes salient only at the interaction level.

Definition 469 (Collective-property-set)**.** *Fix a reference class $\mathcal{B} \subseteq \mathcal{E}_C$. Define*

$$\mathrm{Prop}^{\mathrm{coll}}_{C,\mathcal{B}}(A)(Q) := \sup_{B \in \mathcal{B}} \mathrm{Emer}_C(Q; A, B).$$

Remark 2899. *This definition elevates an interaction effect into an "attribute" of A relative to a reference class $\mathcal{B}$. It is deliberately supremal: $\mathrm{Prop}^{\mathrm{coll}}_{C,\mathcal{B}}(A)(Q)$ asks for the best interaction partner $B \in \mathcal{B}$ that makes Q emerge with A. In this sense it is a controlled way to "lift from instances to groups" (Hyperseed-Concept 103) and to formalize what one might otherwise describe informally as a* collective *or* relational *property.*

As a simple example, let A be a molecule and $\mathcal{B}$ a set of solvents. A pattern witness Q might represent "forms a stable complex." Then $\mathrm{Prop}^{\mathrm{coll}}_{C,\mathcal{B}}(A)(Q)$ measures the maximal emergent stability obtainable by pairing A with some solvent in the class, even if A alone does not display that property.

51.1.2 Synergy (explanation-level)

Fix a task/dataset/behavior b. Let $\mathcal{E}(b)$ be a space of candidate explanations for b. Each explanation $E \in \mathcal{E}(b)$ has:

- a fit score $\mathrm{Fit}(E) \in [0, 1]$,
- a weakness $\mathrm{Weak}(E) \in (0, 1]$,
- a contrivance cost $\mathrm{Con}(E) := -\log(\mathrm{Weak}(E)) \in [0, \infty)$.

In particular, $\mathrm{Weak}(E) = 1$ corresponds to $\mathrm{Con}(E) = 0$ (no contrivance penalty), while $\mathrm{Weak}(E) \downarrow 0$ corresponds to $\mathrm{Con}(E) \uparrow \infty$, encoding the idea that extremely fragile or ad-hoc explanations incur arbitrarily large cost.

Fix a collection of knowledge types (or inference resources) T. Let $\mathcal{E}_T(b) \subseteq \mathcal{E}(b)$ be the set of explanations constructible using only T. One can regard T either as a set of primitive operations available to an agent (proof rules, learned heuristics, simulators, retrieval tools, etc.) or as a restriction on allowable internal representations; in either case, $\mathcal{E}_T(b)$ induces a feasibility constraint on what counts as a candidate explanation.

Remark 2900. *Here* $\mathrm{Fit}(E)$ *is an adequacy measure (how well E accounts for b), while* $\mathrm{Weak}(E)$ *is a penalty-like score: higher weakness means less contrived, more natural, or more "easily supported" explanation. Defining* $\mathrm{Con}(E) = -\log(\mathrm{Weak}(E))$ *merely turns multiplicative weakness into additive cost, as is standard when moving between likelihood-like quantities and description-length-like quantities [16]. This weakness-based formalism aligns with the central role of weakness* *in Hyperseed-style quantale reasoning [3, 2] (see Hyperseed-Concept 202 and 143). Intuitively, if an explanation can be factored into several independent-ish supporting components whose weaknesses multiply, then their contrivances add; this is the operational reason* log *is convenient when comparing composite explanations and when attributing "where the cost went" across sub-claims.*

Also, the restriction $\mathcal{E}_T(b)$ formalizes architectural constraints: one may only build explanations using a chosen set of inference resources T (Hyperseed-Concept 191 and 186). Synergy, then, is the phenomenon that the union $T_1 \cup T_2$ can support explanations of lower contrivance than what is reachable by using T_1 and T_2 separately, reflecting the cognitive-synergy view of AGI system design [19]. Put differently, T controls the search space *of explanations, while* Con *ranks explanations inside that space by how non-accidental they are; synergy is about how enlarging the search space via tool-combination changes the best attainable ranking at a fixed adequacy requirement.*

Definition 470 (Best achievable contrivance, synergy gain)**.** *Fix a fit threshold $\tau \in (0, 1]$. Define*

$$\mathrm{Con}^*(T;\tau) := \inf\{\mathrm{Con}(E) : E \in \mathcal{E}_T(b),\ \mathrm{Fit}(E) \geq \tau\}.$$

For disjoint T_1, T_2, define the synergy gain

$$\Sigma(T_1, T_2; \tau) := \Big(\mathrm{Con}^*(T_1;\tau) + \mathrm{Con}^*(T_2;\tau) - \mathrm{Con}^*(T_1 \cup T_2;\tau)\Big)_+.$$

In words, $\mathrm{Con}^*(T;\tau)$ is the minimal contrivance cost needed to reach fit at least τ using only resources T, and Σ records the extent to which joint access $T_1 \cup T_2$ improves upon the "separate bests" baseline.

Remark 2901. *The notation $(\cdot)_+$ denotes the* positive part*: $(x)_+ := \max\{0, x\}$. Thus $\Sigma(T_1, T_2; \tau)$ is, by definition, never negative: if combining knowledge types does not help, synergy is recorded as 0 rather than as "negative synergy." Operationally this makes Σ a conservative certificate: $\Sigma > 0$ is strong evidence that integrated reasoning provides a genuine efficiency gain, whereas $\Sigma = 0$ does not claim that integration is harmful.*

A concrete numerical example: if $\mathrm{Con}^*(T_1;\tau) = 10$, $\mathrm{Con}^*(T_2;\tau) = 9$, and $\mathrm{Con}^*(T_1 \cup T_2;\tau) = 16$, then $\Sigma = (10+9-16)_+ = 3$. Interpreting contrivance as an effort-like resource (Hyperseed-Concept 100), this says that integration saves "3 units" of contrivance at the target fit threshold. One may also read the same example in weakness terms: since $\mathrm{Weak} = \exp(-\mathrm{Con})$, the separate best weaknesses multiply to $\exp(-(10+9))$, while the integrated best achieves weakness $\exp(-16)$, i.e., a factor $\exp(3)$ less contrived than the multiplicative baseline.

Two further technical clarifications are often useful in applications. First, the use of inf *(rather than* min*) allows the possibility that there is no single optimal explanation, but there exists a sequence of explanations in $\mathcal{E}_T(b)$ whose contrivance approaches the optimum arbitrarily closely; this matches common situations in continuous model classes or in asymptotic regimes. Second, feasibility depends on τ: if τ is increased, the constraint $\mathrm{Fit}(E) \geq \tau$ becomes stricter, so $\mathrm{Con}^*(T;\tau)$ is (weakly) nondecreasing in τ whenever the feasible set is nonempty. In the extreme case where no explanation in $\mathcal{E}_T(b)$ reaches fit τ, the infimum is taken over the empty set; adopting the standard convention $\inf \emptyset = +\infty$ makes $\mathrm{Con}^*(T;\tau) = +\infty$ in that case, which in turn ensures $\Sigma(T_1, T_2; \tau) = 0$ whenever either T_1 or T_2 cannot meet the threshold at all (i.e., synergy is not credited merely for turning "impossible" into "possible" unless one separately tracks feasibility).*

Finally, the assumption that T_1 and T_2 are disjoint is a bookkeeping convenience: it prevents double-counting the same knowledge type in the baseline $\mathrm{Con}^*(T_1;\tau) + \mathrm{Con}^*(T_2;\tau)$. If T_1 and T_2 overlap, one may either replace them by disjoint copies (tagging shared resources) or interpret the definition as measuring synergy relative to a chosen partition of capabilities into "modules."

51.2 Emergence as a selection signal (discovery by pointing)

Definition 471 (Total emergent mass)**.** *Assume $\mathcal{P}_C$ is finite. Define*

$$M_C^{\mathrm{em}}(A,B) := \sum_{Q\in\mathcal{P}_C} \mathrm{Emer}_C(Q;A,B).$$

Remark 2902. *$M_C^{\mathrm{em}}(A,B)$ aggregates, over a finite pattern vocabulary, how much emergent intensity the pair (A,B) exhibits in total. The finiteness assumption is crucial: it makes $M_C^{\mathrm{em}}(A,B)$ a genuine finite sum rather than a supremum or integral, and allows a simple averaging argument to guarantee a concrete witness. From the standpoint of an inference engine, $M_C^{\mathrm{em}}(A,B)$ is a coarse global signal, while the individual $\mathrm{Emer}_C(Q;A,B)$ values are fine-grained, interpretable hypotheses to point at (Hyperseed-Concept 56 and 144). In particular, $M_C^{\mathrm{em}}(A,B)$ can be read as the "total budget" of emergent evidence distributed across candidate patterns, so that the subsequent witness theorem formalizes a basic conversion principle: a nontrivial total budget implies at least one nontrivial, human-inspectable contributor. A useful normalization that will implicitly appear in applications is the* average emergent mass per pattern*, $M_C^{\mathrm{em}}(A,B)/|\mathcal{P}_C|$, which can be interpreted as the expectation of $\mathrm{Emer}_C(Q;A,B)$ under the uniform distribution on $\mathcal{P}_C$; the witness theorem can then be seen as the elementary fact that a maximum dominates an average.*

Theorem 75 (Finite-vocabulary witness of emergence)**.** *Assume $\mathcal{P}_C$ is finite with $|\mathcal{P}_C| = N$. If $M_C^{\mathrm{em}}(A,B) \geq \varepsilon > 0$, then there exists $Q \in \mathcal{P}_C$ such that*

$$\mathrm{Emer}_C(Q;A,B) \;\geq\; \frac{\varepsilon}{N}.$$

Remark 2903. *Intuitively, this theorem says: if the* total *amount of emergence is nontrivial, then at least one candidate pattern witness must carry a nontrivial share of it. There is nothing mysterious here; it is an instance of the pigeonhole principle applied to emergent mass. But its importance is methodological: it justifies "discovery by pointing," i.e. replacing an aggregate signal with a specific explainable hypothesis Q.*

This result connects forward to the later cost-subadditivity theorem: once a particular Q is singled out, one may ask whether its emergence is explained by strict joint compression (Section 76 below), and then propagate that fact into explanation-level synergy bounds. A further interpretive point is that the bound ε/N is the best possible uniform guarantee given only the sum constraint: if the emergent mass were spread perfectly evenly across the N patterns, one would have $\mathrm{Emer}_C(Q;A,B) = \varepsilon/N$ for all Q, so no larger lower bound could be certified without additional structure (e.g. sparsity, heavy-tailedness, or a prior over $\mathcal{P}_C$). For concrete intuition, if $N = 100$ and $M_C^{\mathrm{em}}(A,B) \geq 5$, the theorem guarantees at least one pattern with $\mathrm{Emer}_C(Q;A,B) \geq 0.05$; the "pointing" step then amounts to surfacing such a pattern rather than treating the value 5 as an opaque scalar.

Proof. Suppose for contradiction that $\mathrm{Emer}_C(Q;A,B) < \varepsilon/N$ for every $Q \in \mathcal{P}_C$. Summing over N elements yields

$$M_C^{\mathrm{em}}(A,B) = \sum_{Q\in\mathcal{P}_C} \mathrm{Emer}_C(Q;A,B) < \sum_{Q\in\mathcal{P}_C} \frac{\varepsilon}{N} = \varepsilon,$$

contradicting $M_C^{\mathrm{em}}(A,B) \geq \varepsilon$. Equivalently (and without contradiction), dividing by N shows that the average value of $\mathrm{Emer}_C(Q;A,B)$ over $\mathcal{P}_C$ is at least ε/N, and hence the maximum over Q must be at least ε/N. $\square$

Proof sketch. The argument is pure averaging: if all N terms were $< \varepsilon/N$, their sum would be $< \varepsilon$, contradicting the assumed lower bound on the sum. A one-line reformulation is $\max_{Q\in\mathcal{P}_C} \mathrm{Emer}_C(Q; A, B) \geq \frac{1}{N}\sum_{Q\in\mathcal{P}_C} \mathrm{Emer}_C(Q; A, B) = \frac{M_C^{\mathrm{em}}(A,B)}{N}$. $\square$

Remark 2904. *The key step is the contrapositive use of linearity of finite summation: a lower bound on the sum forces at least one term to be large. Visually, one may imagine distributing ε units of emergent "mass" across N bins; if every bin held less than ε/N, the total could not reach ε.*

In an implementation-oriented reading, the theorem gives a certificate that $\arg\max_Q \mathrm{Emer}_C(Q; A, B)$ *is meaningful in the strong sense that it must return a witness whose emergent intensity is bounded below whenever total emergence is. Operationally, this means that any procedure that (even approximately) ranks candidates by* $\mathrm{Emer}_C(Q; A, B)$ *is justified as a* selection mechanism*: it is guaranteed to surface at least one pattern above a quantitative floor whenever the global statistic crosses the corresponding threshold. This is also the place where finiteness is doing real work: for infinite $\mathcal{P}_C$, one can have positive "total mass" only after replacing the sum by a different aggregator (e.g. an integral or supremum), and then the existence of a pointwise witness generally requires additional compactness, measurability, or regularity assumptions that are deliberately avoided here.*

Corollary 37 (Pointing corollary)**.** *If $M_C^{\mathrm{em}}(A, B) > 0$ and $\mathcal{P}_C$ is finite, then there exists at least one pattern Q with* $\mathrm{Emer}_C(Q; A, B) > 0$.

Remark 2905. *This is the qualitative version of Theorem 75: "somewhere" in the pattern vocabulary there is a genuinely emergent witness. When used as a sanity-check in a reasoning system, it says that a strictly positive global emergence statistic cannot be a numerical artifact spread across infinitely many infinitesimal contributions; in a finite vocabulary, it must show up as a positive value at some concrete Q. Equivalently, the corollary rules out the possibility that* every *candidate pattern is non-emergent (has* $\mathrm{Emer}_C(Q; A, B) \leq 0$*) while the aggregated score is still strictly positive.*

Remark 2906 (Engine reading)**.** *If a reasoning system can estimate* $\mathrm{Emer}_C(Q; A, B)$ *over a finite candidate set, then Theorem 75 guarantees there is a concrete Q whose emergent intensity is nontrivial whenever the* aggregate *emergence is nontrivial. This legitimizes using* $\arg\max_Q \mathrm{Emer}_C(Q; A, B)$ *as a hypothesis-generation operator. In practice, this supports a two-stage pipeline: (i) monitor $M_C^{\mathrm{em}}(A, B)$ (or a computable proxy) as a coarse trigger that "something interesting is happening," and (ii) upon triggering, output a short list of top-k patterns by* $\mathrm{Emer}_C(Q; A, B)$ *as candidate explanations. The witness bound provides a minimal quantitative target for such a shortlist: if $M_C^{\mathrm{em}}(A, B) \geq \varepsilon$, then at least one returned pattern must clear ε/N provided the maximizer is found (or approximated tightly enough), turning an otherwise diffuse aggregate into a checkable, pattern-level claim.*

51.3 Emergent surplus as strict cost subadditivity (compression bridge)

We now prove a useful algebraic bridge: under an additive-baseline assumption, emergent surplus becomes exactly a *normalized strict subadditivity* inequality on witness costs.

Definition 472 (Additive baseline assumption)**.** *We say the baseline is additive if, whenever $A *_C B$ is defined,*

$$s_C^{\mathrm{base}}(A *_C B) = s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B).$$

Remark 2907. *The additive baseline assumption says that, in the absence of pattern structure, the cost of describing the composite is just the sum of the costs of describing the parts. This is a natural "null hypothesis" in many description-length settings: if you do not exploit any interaction, you pay separately for each component [16]. In cognitive terms, it models a representational regime where concatenating two default descriptions incurs no additional overhead and provides no discount. Against this background, any strict improvement in the joint witness cost can be interpreted as emergent compression, hence emergence (Hyperseed-Concept* **??** *and 82).*

Remark 2908. *Two small clarifications about what is (and is not) being assumed are useful. First, additivity is imposed only on the* baseline s_C^{base}*, not on the witness cost* $u_C(Q;\cdot)$*: the whole point of emergence is that a good* Q *can exploit cross-part regularities so that* $u_C(Q; A *_C B)$ *can drop below* $u_C(Q;A) + u_C(Q;B)$*. Second, the additivity requirement is conditional on* $A *_C B$ *being defined: the algebra below never needs a global monoid structure, only that the particular composite under study is meaningful in context* C*.*

Remark 2909. *The strict-positivity condition* $s_C^{\text{base}}(A), s_C^{\text{base}}(B) > 0$ *plays two roles. Algebraically it ensures the intensities* $I_C(Q;A)$ *and weights* $w_C(A), w_C(B)$ *are well-defined and the normalization by* $s_C^{\text{base}}(A) + s_C^{\text{base}}(B)$ *is nondegenerate. Conceptually it excludes pathological "free" objects for which baseline description length is zero, in which case any ratio-based comparison would collapse and the notion of a fractional improvement would be ill-posed.*

Theorem 76 (Emergent surplus equals normalized cost subadditivity (when unclamped))**.** *Assume:*

1. $s_C^{\text{base}}(A), s_C^{\text{base}}(B) > 0$ *and* $A *_C B$ *is defined,*
2. *the baseline is additive,*
3. *for some* $Q \in \mathcal{P}_C$ *the clamp is inactive on* $A, B, A *_C B$*, i.e.*

$$u_C(Q;A) < s_C^{\text{base}}(A), \quad u_C(Q;B) < s_C^{\text{base}}(B), \quad u_C(Q;A *_C B) < s_C^{\text{base}}(A *_C B).$$

Then

$$\mathrm{Sur}_C(Q;A,B) = \frac{u_C(Q;A) + u_C(Q;B) - u_C(Q;A *_C B)}{s_C^{\text{base}}(A) + s_C^{\text{base}}(B)}.$$

Remark 2910. *This theorem states that, once the max-clamp is not interfering, emergent surplus becomes exactly "how much cheaper the joint witness is than the sum of separate witnesses," normalized by the total baseline size. Thus emergence is not an ineffable metaphysical extra; it is literally strict subadditivity of costs. The clamp-inactive condition is a technical guardrail: it ensures intensities are genuinely linear functions of costs, rather than truncated at* 0*.*

The result is important because it connects the semantic definition of emergence (a comparison of intensities) to a directly checkable algebraic inequality on costs. It also anticipates the later explanation-level synergy results: strict subadditivity of costs is the same structural shape as a synergy gain inequality (compare with Theorem 77).

Remark 2911. *The normalization by* $s_C^{\text{base}}(A)+s_C^{\text{base}}(B)$ *makes the surplus dimensionless and comparable across pairs* (A,B) *of very different absolute sizes. In particular, the numerator* $u_C(Q;A)+u_C(Q;B) - u_C(Q;A *_C B)$ *is an* absolute *compression gap (measured in the same units as the cost function), while* $\mathrm{Sur}_C(Q;A,B)$ *is a* relative *gap scaled to the baseline. This scaling is what allows one to interpret the quantity as "fractional emergent savings per baseline unit," and it is also what makes the weighted average in the definition of surplus the correct comparator: it matches the same baseline scale as the composite.*

Remark 2912. *The clamp-inactive hypothesis should be read as a statement about the regime in which the witness Q is genuinely informative relative to baseline. If, say, $u_C(Q;A) \geq s_C^{\mathrm{base}}(A)$, then $I_C(Q;A)$ would be clamped to 0 (or otherwise truncated by the max), and the intensity would no longer carry linear information about* how much worse *than baseline the witness is. In that clamped regime,* $\mathrm{Sur}_C(Q;A,B)$ *can still be defined, but it becomes a mixture of linear and saturated terms; the clean equivalence with strict subadditivity is therefore a property of the "unclamped" interior where intensities reflect true ratios.*

Proof. Under the clamp-inactive assumption, the max operation in I_C does nothing, so

$$I_C(Q;A) = 1 - \frac{u_C(Q;A)}{s_C^{\mathrm{base}}(A)}, \quad I_C(Q;B) = 1 - \frac{u_C(Q;B)}{s_C^{\mathrm{base}}(B)}.$$

Since $w_C(A) = \frac{s_C^{\mathrm{base}}(A)}{s_C^{\mathrm{base}}(A)+s_C^{\mathrm{base}}(B)}$, we get

$$w_C(A)\, I_C(Q;A) = \frac{s_C^{\mathrm{base}}(A)}{s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B)} \left(1 - \frac{u_C(Q;A)}{s_C^{\mathrm{base}}(A)}\right) = \frac{s_C^{\mathrm{base}}(A) - u_C(Q;A)}{s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B)}.$$

Similarly,

$$w_C(B)\, I_C(Q;B) = \frac{s_C^{\mathrm{base}}(B) - u_C(Q;B)}{s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B)}.$$

Therefore the weighted baseline term is

$$w_C(A) I_C(Q;A) + w_C(B) I_C(Q;B) = \frac{s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B) - u_C(Q;A) - u_C(Q;B)}{s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B)}.$$

By additivity, $s_C^{\mathrm{base}}(A *_C B) = s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B)$, and clamp-inactive gives

$$I_C(Q;A *_C B) = 1 - \frac{u_C(Q;A *_C B)}{s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B)} = \frac{s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B) - u_C(Q;A *_C B)}{s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B)}.$$

Subtracting the baseline term from $I_C(Q;A *_C B)$ yields the claimed identity. □

Remark 2913. *A slightly different way to read the same algebra is as an invariance statement: the particular weights $w_C(A), w_C(B)$ ensure that the baseline comparator*

$$w_C(A)\, I_C(Q;A) + w_C(B)\, I_C(Q;B)$$

is exactly the intensity one would obtain by evaluating the concatenated baseline description *of A and B on the shared denominator $s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B)$. In other words, the weights are not an aesthetic choice but the unique choice (given this linear form) that puts all three intensities on the same baseline scale so that subtraction isolates a pure cost gap.*

Proof sketch. Expand all intensities into linear functions of the costs (possible because the clamp is inactive), rewrite the weighted average using the explicit weights $w_C(A), w_C(B)$, and then simplify using the additive baseline identity. The remaining numerator is exactly the strict subadditivity gap $u(Q;A) + u(Q;B) - u(Q;A *_C B)$. □

Remark 2914. *The proof is essentially a bookkeeping exercise: the weights were chosen precisely so that*

$$w_C(A)\left(1-\frac{u(Q;A)}{s^{\mathrm{base}}(A)}\right)+w_C(B)\left(1-\frac{u(Q;B)}{s^{\mathrm{base}}(B)}\right)$$

collapses into one fraction with denominator $s^{\mathrm{base}}(A)+s^{\mathrm{base}}(B)$*. The additive baseline assumption then aligns the denominator for the composite intensity with the same quantity, allowing the difference to telescope.*

A helpful visualization is to imagine costs as lengths: s_C^{base} *gives a "ruler" for scale, while* u_C *gives the length of a particular witness description. Emergence corresponds to a joint description that is shorter than putting two separate descriptions end-to-end.*

Remark 2915. *Interpreted in minimum-description-length terms, the numerator*

$$u_C(Q;A)+u_C(Q;B)-u_C(Q;A*_C B)$$

is the amount of description length saved by using a single *model* Q *to account for the composite rather than fitting* Q *separately to each part. The theorem therefore makes precise the idea that "emergent structure" is exactly the presence of shared code, shared parameters, or shared regularities that amortize across components. In this sense, the bridge is not merely algebraic: it identifies emergence with the same kind of reuse that underlies generalization and transfer in learning systems.*

Corollary 38 (Emergent surplus detects strict joint compression)**.** *Under the assumptions of Theorem 76:*

$$\mathrm{Sur}_C(Q;A,B)>0 \quad\Longleftrightarrow\quad u_C(Q;A*_C B)<u_C(Q;A)+u_C(Q;B).$$

Hence $\mathrm{Emer}_C(Q;A,B)>0$ *iff the witness cost is strictly subadditive.*

Remark 2916. *The strictness matters:* $\mathrm{Sur}_C(Q;A,B)=0$ *corresponds exactly (in the unclamped regime) to* additivity *of witness costs, i.e. the joint witness is no better than treating* A *and* B *independently with the same* Q*. Negative surplus corresponds to superadditivity, which can be read as "anti-emergence" in the purely compressive sense: representing the interaction jointly is actually more expensive than representing the parts separately. This can happen when* Q *is mismatched to the composite (so that coupling introduces additional descriptive burden) even if* Q *is individually decent on* A *and* B*.*

Remark 2917. *One can also see why the statement is framed in terms of* $\mathrm{Sur}_C(Q;A,B)$ *rather than raw cost differences. Because the denominator is the total baseline size, a fixed absolute gap (say, saving 10 bits) yields a larger surplus for smaller baselines and a smaller surplus for larger baselines. Thus* Sur_C *is tailored to comparisons "at equal baseline scale": it encodes a notion of* proportional *emergence rather than absolute emergence, which is often the relevant quantity when comparing across domains with different representational granularities.*

Remark 2918. *This corollary is the operational heart of the section: it says that, at least in the unclamped additive-baseline regime, emergence is* equivalent *to strict joint compression. Thus one may detect emergence by comparing three costs, without ever computing intensities explicitly. Conversely, one may interpret strict subadditivity not merely as an accident of encoding, but as a formal witness of emergence (Hyperseed-Concept* **??***). In particular, the equivalence highlights that "emergent surplus" is not being postulated as a new primitive: it is exactly the residual gap that remains once one accounts for the best separate compressions, and strictness is what rules out the degenerate case where the joint description is merely a concatenation in disguise. Operationally,* *the "three costs" are precisely the two marginal witness-costs and the joint witness-cost, so the test is implementable whenever one can approximate those costs (even coarsely) in a shared coding scheme.*

Remark 2919 (Engine reading)**.** *This is the core "discovery" bridge: if you can estimate witness-costs for candidate patterns, then* emergence *is exactly the signal that a joint hypothesis Q compresses the composite better than any explanation that keeps the two sides separate at the witness level. In other words, the engine does not need to enumerate or optimize over all possible intensities or decompositions: it only needs a reliable comparison oracle on candidate witnesses, and strict improvement is the discriminant. This also clarifies what can go wrong in practice: if witness-cost estimates are biased (e.g., by mismatched priors or incomparable encoding conventions between the separate and joint cases), then apparent "emergence" may reflect measurement artifacts rather than genuine joint structure.*

51.4 From a single emergent-compression explanation to synergy gain (quantitative)

Theorem 77 (Quantitative lower bound on synergy gain from one nonseparable explanation)**.** *Fix disjoint knowledge sets T_1, T_2 and fit threshold τ. Assume there exist explanations $E_1 \in \mathcal{E}_{T_1}(b)$, $E_2 \in \mathcal{E}_{T_2}(b)$, and $E \in \mathcal{E}_{T_1 \cup T_2}(b)$ such that*

$$\mathrm{Fit}(E_1) \geq \tau, \quad \mathrm{Fit}(E_2) \geq \tau, \quad \mathrm{Fit}(E) \geq \tau,$$

and for some $\delta > 0$,

$$\mathrm{Con}(E) \;\leq\; \mathrm{Con}(E_1) + \mathrm{Con}(E_2) - \delta.$$

Then

$$\Sigma(T_1, T_2; \tau) \;\geq\; \delta,$$

and in particular $\Sigma(T_1, T_2; \tau) > 0$.

Remark 2920. *In plain language: if you can exhibit* one *integrated explanation E using $T_1 \cup T_2$ that beats the best-known separate explanations by an additive margin δ in contrivance, then synergy is at least δ. This is important because Σ is defined using infima over large search spaces, which is often hard to compute directly. The theorem says we can lower-bound Σ by producing a single certificate explanation. Note that δ is a* verifiable *margin: it is computed from explicit witness values $\mathrm{Con}(E), \mathrm{Con}(E_1), \mathrm{Con}(E_2)$ rather than from unknown optima, so any valid lower bound is actionable even if the global search remains incomplete.*

Conceptually, this is the explanation-level analogue of Theorem 75: there, positive aggregate emergence guarantees some witness Q; here, one good witness E guarantees positive synergy. This connects naturally to Hyperseed's emphasis on explainable "pointing" rather than only scalar global scores [1]. One can also read the theorem as a robustness statement: because it only uses the monotonicity property of an infimum, it continues to hold even when the feasible explanation classes are extremely complex or only implicitly specified, provided E_1, E_2, E genuinely belong to the stated classes and meet the same fit threshold.

Proof. By definition of Con^* as an infimum over feasible explanations,

$$\mathrm{Con}^*(T_1; \tau) \leq \mathrm{Con}(E_1), \quad \mathrm{Con}^*(T_2; \tau) \leq \mathrm{Con}(E_2), \quad \mathrm{Con}^*(T_1 \cup T_2; \tau) \leq \mathrm{Con}(E).$$

Therefore,

$$\begin{aligned}\mathrm{Con}^*(T_1;\tau) + \mathrm{Con}^*(T_2;\tau) - \mathrm{Con}^*(T_1 \cup T_2;\tau) &\geq \mathrm{Con}(E_1) + \mathrm{Con}(E_2) - \mathrm{Con}(E)\\ &\geq \delta.\end{aligned}$$

Taking positive part does not change the inequality (since $\delta > 0$), hence $\Sigma(T_1, T_2; \tau) \geq \delta$. A small but sometimes practically relevant point is that the argument does not require the infimum to be attained (i.e., there need not exist an optimizer achieving Con^*); the comparison holds for infima exactly because they are lower envelopes over all feasible witnesses. □

Proof sketch. Use the defining property of an infimum: $\mathrm{Con}^*(\cdot;\tau)$ is bounded above by the contrivance of any specific feasible explanation at fit $\geq \tau$. Plug in E_1, E_2, E, rearrange, and observe that $(\cdot)_+$ is irrelevant once a strictly positive lower bound is obtained. Equivalently: the certificate E forces a definite gap between the joint optimum and the separate optima because the joint optimum can only be *no worse* than any particular feasible joint construction. □

Remark 2921. *The inequality direction is the entire story: infima make* Con^* *smaller than any particular witness value, so subtracting* $\mathrm{Con}^*(T_1 \cup T_2; \tau)$ *is at least as favorable as subtracting* $\mathrm{Con}(E)$*. The positive-part operation is a guard against negative results, but here* $\delta > 0$ *forces positivity. Said differently,* Σ *is defined to ignore "anti-synergy" (cases where joint explanations are more contrived than separate ones), whereas the theorem shows that any strictly nonseparable certificate immediately escapes that truncation.*

If one prefers a geometric intuition, imagine a "cost landscape" where each knowledge set T *defines a reachable region of explanations; the theorem says that finding a single point in the union-region that lies* δ *below the sum of the two separate best heights forces a corresponding gap between the optimum of the union and the sum of separate optima. The disjointness of* T_1, T_2 *can be viewed as ensuring that the two separate regions represent genuinely distinct "axes of knowledge" rather than double-counting the same explanatory resource; if there is overlap, the same reasoning can be adapted but the baseline of "separate" costs may need an explicit correction for shared components.*

Corollary 39 (Emergent weakness factor implies synergy)**.** *Suppose explanations compose as* $E_1 \otimes E_2$*, fit is preserved at threshold* τ*, and*

$$\mathrm{Weak}(E_1 \otimes E_2) = g\ \mathrm{Weak}(E_1)\mathrm{Weak}(E_2)$$

for some factor $g > 1$ *(necessarily with* $g \leq 1/(\mathrm{Weak}(E_1)\mathrm{Weak}(E_2))$ *so the RHS stays* ≤ 1*). Then*

$$\mathrm{Con}(E_1 \otimes E_2) = \mathrm{Con}(E_1) + \mathrm{Con}(E_2) - \log g,$$

so Theorem 77 applies with $\delta = \log g$ *and yields* $\Sigma(T_1, T_2; \tau) \geq \log g > 0$*.*

Remark 2922. *The corollary translates multiplicative "extra strength" in weakness into additive synergy in contrivance. Because contrivance is* $-\log(\mathrm{Weak})$*, any multiplicative gain* g *in weakness becomes an additive gain* $\log g$ *in contrivance. This echoes the general theme in [3] that weakness-like quantities often behave most naturally under multiplication, while decision rules tend to be additive after taking logs. It is also worth noting that the constraint* $g > 1$ *is exactly the strictness needed to get a nontrivial lower bound:* $g = 1$ *recovers the separable baseline where the composed explanation is neither better nor worse (in contrivance) than the sum of its parts, and* $\log g = 0$ *makes the certificate vacuous.*

Remark 2923 (Engine reading)**.** *Theorem 77 is a "single-witness certificate" for synergy: to prove nontrivial synergy it suffices to exhibit one integrated explanation E whose contrivance beats the sum of two separate explanations by a margin δ. The corollary makes this margin interpretable as a multiplicative emergent-weakness factor g. In practice, this suggests a workflow: propose a candidate joint mechanism (yielding E), compute its fit and contrivance, and compare against the best available modular baselines (E_1, E_2); any strict improvement gives a quantitative floor on Σ without requiring full optimization over $\mathcal{E}_{T_1 \cup T_2}(b)$.*

51.5 Cross-type emergent compression and budgeted solvability

We restate and prove two operational results (matching the document's intent) in a form that fits the present note.

Definition 473 (Cross-type emergent compression pattern)**.** *Fix disjoint knowledge sets T_1, T_2 and threshold τ. We say there is a cross-type emergent compression pattern for b if there exists $E \in \mathcal{E}_{T_1 \cup T_2}(b)$ with* $\mathrm{Fit}(E) \geq \tau$ *such that for every decomposition $E \approx E_1 \otimes E_2$ with $E_i \in \mathcal{E}_{T_i}(b)$ and* $\mathrm{Fit}(E_i) \geq \tau$*,*

$$\mathrm{Con}(E) < \mathrm{Con}(E_1) + \mathrm{Con}(E_2).$$

Remark 2924. *This definition formalizes an especially strong kind of nonseparability: not merely that there exists* some *pair (E_1, E_2) that is worse than E, but that* every *admissible partitioned explanation is worse. The approximation symbol $E \approx E_1 \otimes E_2$ is intentionally left abstract: it stands for whatever notion of compositional decomposition is appropriate in the application domain. The intent is to capture the situation where the integrated structure of E is essential, rather than merely a convenient alternative.*

This notion anticipates later independence-vs-dependence tradeoffs (cf. the document's dependence dichotomy discussion elsewhere): if a phenomenon is truly cross-type emergent in this sense, then any architecture that insists on separability is structurally mis-specified.

Theorem 78 (Cross-type emergent compression implies positive synergy)**.** *If there exists a cross-type emergent compression pattern for b at level τ, then $\Sigma(T_1, T_2; \tau) > 0$.*

Remark 2925. *The theorem says that the strong nonseparability condition in the previous definition forces strictly positive synergy. This is important because it turns a qualitative modeling diagnosis ("no separable explanation can match the integrated one") into a quantitative, scalar conclusion ($\Sigma > 0$), which can then be used in budgeting and architecture selection. It also connects directly to Theorem 79: once $\Sigma > 0$ is established, one can exhibit budgets where integrated reasoning succeeds and partition-limited reasoning necessarily fails.*

Proof. Let E witness cross-type emergent compression. By definition, for every admissible decomposition $E \approx E_1 \otimes E_2$ with $\mathrm{Fit}(E_i) \geq \tau$ we have

$$\mathrm{Con}(E) < \mathrm{Con}(E_1) + \mathrm{Con}(E_2).$$

In particular, taking the infimum over all admissible $E_1 \in \mathcal{E}_{T_1}(b)$ with fit $\geq \tau$ and similarly for E_2, we obtain

$$\mathrm{Con}(E) < \mathrm{Con}^*(T_1; \tau) + \mathrm{Con}^*(T_2; \tau).$$

Also $\mathrm{Con}^*(T_1 \cup T_2; \tau) \leq \mathrm{Con}(E)$ since E is feasible for $T_1 \cup T_2$. Therefore

$$\mathrm{Con}^*(T_1; \tau) + \mathrm{Con}^*(T_2; \tau) - \mathrm{Con}^*(T_1 \cup T_2; \tau) > 0,$$

so $\Sigma(T_1, T_2; \tau) > 0$. $\square$

Proof sketch. Start from the strict inequality $\mathrm{Con}(E) < \mathrm{Con}(E_1) + \mathrm{Con}(E_2)$, then make the right-hand side as small as possible by taking infima over all feasible E_1, E_2. Finally, compare $\mathrm{Con}(E)$ to the infimum over all union-allowed explanations to conclude the strict gap persists at the optimum level. $\square$

Remark 2926. *The essential step is that strict inequality is preserved when we replace* $\mathrm{Con}(E_1)$ *and* $\mathrm{Con}(E_2)$ *by their best possible values, because E is assumed to beat* every *admissible decomposition. If the inequality held only for some particular decomposition, we would generally only obtain a nontrivial* lower bound *(as in Theorem 77), not necessarily strict positivity of synergy. Thus the present theorem highlights why the cross-type condition is stronger than mere existence of one good integrated witness.*

One may picture a two-column architecture where T_1 and T_2 are processed independently; the theorem says: if no pair of column-wise explanations can match E, then independent processing has a provable penalty in contrivance.

Definition 474 (Budgeted solvability)**.** *Fix τ and a contrivance budget $B \geq 0$. We say b is solvable by T at budget B if* $\mathrm{Con}^*(T; \tau) \leq B$*.*

Remark 2927. *This definition turns contrivance into an explicit resource constraint: one fixes a required adequacy level τ and asks whether the best achievable contrivance is within a budget B (Hyperseed-Concept 100). In practice, B may correspond to allowed model size, allowed search depth, allowed proof length, or any other proxy for representational and computational expense. The point is to express synergy not merely as an abstract efficiency gain but as a difference between what is solvable and unsolvable under a given resource cap.*

Theorem 79 (Synergy expands solvable set relative to partition-limited architectures)**.** *Let T_1, T_2 be disjoint. Suppose $\Sigma(T_1, T_2; \tau) > 0$ for the given b. Define the partition-limited contrivance level*

$$\mathrm{Con}^{\mathrm{part}}(T_1, T_2; \tau) := \mathrm{Con}^*(T_1; \tau) + \mathrm{Con}^*(T_2; \tau).$$

Then there exists a budget B such that:

1. *b is solvable by $T_1 \cup T_2$ at budget B, and*
2. *b is not solvable by any architecture that restricts itself to partition-limited (separable) explanations at the same budget B.*

Remark 2928. *This theorem is the operational payoff: synergy creates a* budget gap *where integrated reasoning can solve b but any separable architecture cannot. Thus synergy is not merely a matter of elegance; it changes the boundary of the feasible (Hyperseed-Concept 126 and 186). More concretely, the claim is not that the separable architecture is* always *worse, but that once $\Sigma > 0$ holds there exists a regime of resource budgets in which the separability constraint becomes the decisive bottleneck. In that regime, the difference between architectures is measurable as a binary feasibility distinction at fixed fit threshold τ.*

The result is also a conceptual bridge to broader architectural tradeoff discussions: if a system is built to enforce separability between two subsystems (here modeled by disjoint T_1 and T_2), then positive synergy implies there are tasks for which that design is provably suboptimal under fixed resource budgets. Equivalently, separability is not a neutral modeling choice: it can convert what would be a solvable task (at a given budget and fit criterion) into an unsolvable one by forbidding cross-term structure that reduces contrivance.

Proof. Let $C_{12} := \mathrm{Con}^*(T_1 \cup T_2; \tau)$ and $C_{\mathrm{part}} := \mathrm{Con}^{\mathrm{part}}(T_1, T_2; \tau)$. Since $\Sigma > 0$, we have $C_{12} < C_{\mathrm{part}}$. This strict inequality is the only ingredient needed to manufacture a nonempty interval of budgets that separates the two architectures: any B in that interval will certify feasibility for the integrated model and infeasibility for the partition-limited one. Choose any budget B with

$$C_{12} \leq B < C_{\mathrm{part}}.$$

(Such a B exists because the interval $[C_{12}, C_{\mathrm{part}})$ is nonempty when $C_{12} < C_{\mathrm{part}}$; for instance, one may take $B = (C_{12} + C_{\mathrm{part}})/2$ if budgets are treated as real-valued, or the appropriate nearby admissible value if budgets are discretized.) Then b is solvable by $T_1 \cup T_2$ at budget B by definition of solvability. Here the relevant point is that C_{12} is the *minimum* contrivance needed by any explanation built from $T_1 \cup T_2$ to reach fit at least τ, so any budget $B \geq C_{12}$ suffices for some integrated explanation to meet the threshold. On the other hand, any separable/partition-limited architecture that insists on independent T_1 and T_2 explanations needs contrivance at least C_{part} to reach fit $\geq \tau$, hence cannot meet budget $B < C_{\mathrm{part}}$. In other words, the separability constraint imposes an unavoidable lower bound on required contrivance, and the chosen B is intentionally placed below that bound so that no amount of optimization *within* the separable class can recover feasibility. □

Proof sketch. Synergy $\Sigma > 0$ means the union-optimum contrivance C_{12} is strictly smaller than the sum of separate optima C_{part}. Pick any budget B strictly between these two numbers; then $T_1 \cup T_2$ can meet it, while any partition-limited approach cannot. Intuitively, the integrated architecture is allowed to reuse shared structure and encode cross-dependencies once, whereas the partitioned architecture must pay for them (or simulate them) separately inside each subsystem, which raises the minimum description length needed to reach the same fit level. □

Remark 2929. *The proof is a one-dimensional separation argument: the strict inequality $C_{12} < C_{\mathrm{part}}$ guarantees there is an interval of budgets between them. Choosing B in this interval turns the inequality into an observable behavioral difference between architectures. This is the same logical shape as a margin argument: once two feasibility thresholds are separated, any operating point in the margin witnesses a qualitative difference in capability under identical evaluation criteria (same b, same τ, same budget accounting).*

A visual intuition is to imagine two thresholds on a line: the integrated architecture has a lower threshold C_{12} for feasibility, while the partitioned architecture has a higher threshold C_{part}. Any budget lying between them separates the possible from the impossible, relative to the architectural constraint. One can also read the picture dynamically: as the budget B increases from 0, the integrated system becomes feasible first (at C_{12}), and only later does the partitioned system become feasible (at C_{part}); the interval between these activation points is precisely the "synergy-only" region.

Remark 2930 (Engine reading)**.** *Theorem 79 is an operational "why synergy matters" statement: there are tasks for which integrated reasoning is not just nicer, but strictly necessary under a given resource (contrivance/description-length) budget. In deployment terms, if one fixes a maximum allowable complexity (e.g., memory footprint, parameter budget, message length, or any proxy captured by* Con*), then positive synergy implies there exist achievable performance targets that require allowing the subsystems to co-explain rather than forcing them to explain in isolation.*

51.6 Collective properties (interaction-only features) have witnesses

Theorem 80 (Approximate witness for collective properties)**.** *Fix $\mathcal{B} \subseteq \mathcal{E}_C$ and $A \in \mathcal{E}_C$. For any $Q \in \mathcal{P}_C$ and any $\varepsilon > 0$, there exists $B_\varepsilon \in \mathcal{B}$ such that*

$$\mathrm{Emer}_C(Q; A, B_\varepsilon) \;\geq\; \mathrm{Prop}^{\mathrm{coll}}_{C,\mathcal{B}}(A)(Q) \;-\; \varepsilon.$$

Remark 2931. *It is helpful to read the statement as an "ε-maximizer exists" claim: once A and the query/property Q are fixed, the collective score* $\mathrm{Prop}^{\mathrm{coll}}_{C,\mathcal{B}}(A)(Q)$ *(which is defined via a supremum over partners in $\mathcal{B}$) can always be nearly realized by at least one explicit interaction partner B_ε in the same reference class. Equivalently, the supremal definition does not merely certify that* some *partners do well; it certifies that, for every tolerance level, there is a concrete partner whose emergent interaction score is within that tolerance of optimal.*

This theorem says that collective properties, defined via a supremum over a reference class, are not merely abstract upper bounds: they can be approximated arbitrarily well by some concrete partner B_ε. In other words, even if the "best possible partner" is not uniquely defined or not attained, it can be approached. This matters for discovery and explanation because it means that the supremal definition of a collective property remains operational: a search procedure can always find an explicit near-witness.

The result is conceptually aligned with the idea that relational attributes should be discoverable by interaction experiments (Hyperseed-Concept 59 and **??***), and, in broader Hyperseed discussions of collective mind-like phenomena, with the operational emphasis on identifying concrete interaction partners rather than positing purely global collectives [12].*

Remark 2932. *A minor but practically relevant edge case concerns whether the reference class $\mathcal{B}$ is nonempty. When $\mathcal{B} \neq \varnothing$, the set of attainable scores* $\{\mathrm{Emer}_C(Q;A,B) : B \in \mathcal{B}\}$ *is nonempty and the supremum has its usual approximation-from-below meaning. If one allows $\mathcal{B} = \varnothing$, then one must adopt a convention for* $\mathrm{Prop}^{\mathrm{coll}}_{C,\mathcal{B}}(A)(Q)$ *(often* $\sup\varnothing := -\infty$ *in general order theory, or* 0 *if intensities are constrained to* $[0,1]$ *and the intention is "no partner, no collective effect"); under such a convention, the theorem is either vacuous or trivially satisfied. The intended discovery-theoretic reading typically assumes a nonempty candidate pool, so that witnesses correspond to actual interaction experiments.*

Proof. Let $S := \{\mathrm{Emer}_C(Q;A,B) : B \in \mathcal{B}\} \subseteq [0,1]$ and let $\alpha := \sup S$. By the defining property of supremum, for any $\varepsilon > 0$ there exists an element of S strictly greater than $\alpha - \varepsilon$. Thus there exists $B_\varepsilon \in \mathcal{B}$ with $\mathrm{Emer}_C(Q;A,B_\varepsilon) > \alpha - \varepsilon$, which implies the desired inequality. In particular, since $\mathrm{Prop}^{\mathrm{coll}}_{C,\mathcal{B}}(A)(Q)$ is precisely the supremum of the same set of scores (by definition of the collective property functional), one may read α as $\mathrm{Prop}^{\mathrm{coll}}_{C,\mathcal{B}}(A)(Q)$, so the proof is exactly the standard "approximate maximizer from the supremum" argument. ☐

Proof sketch. Unpack the definition of sup: for any target slack $\varepsilon > 0$, some element of the set must lie within ε of the supremum from below. Choose the corresponding partner B_ε. In algorithmic terms, the sketch corresponds to the guarantee that an iterative search that improves $\mathrm{Emer}_C(Q;A,B)$ cannot be blocked by a purely definitional artifact: if the current candidate is more than ε below the supremum, there exists some other candidate in $\mathcal{B}$ that beats it by at least some margin. ☐

Remark 2933. *The only "engine" inside the proof is the completeness property of real numbers (or, more generally, of the order structure used for intensities): suprema are approximable from below by elements of the set. The strict inequality $>$ produced by the supremum property is then relaxed to $\geq$ in the statement.*

Visually, if you plot the values $\mathrm{Emer}_C(Q;A,B)$ *as points on the* $[0,1]$ *axis, the supremum is the least upper bound. The theorem guarantees a point within ε of that bound, so the supremum is not a distant ideal but a limit point approachable by explicit choices of B. A further interpretive point is that the witness B_ε may depend on (A,Q,ε): the "best partner" for explaining one property Q need not be the best partner for a different Q', and the partner that is sufficient for a coarse-grained explanation (large ε) need not be the one needed for a fine-grained explanation (small ε).*

Corollary 40 (Exact witness when $\mathcal{B}$ is finite)**.** *If $\mathcal{B}$ is finite, then the supremum is a maximum: for every Q there exists $B^* \in \mathcal{B}$ such that*

$$\mathrm{Prop}^{\mathrm{coll}}_{C,\mathcal{B}}(A)(Q) = \mathrm{Emer}_C(Q; A, B^*).$$

Remark 2934. *Finiteness eliminates limit behavior: among finitely many real numbers, the supremum is attained. From an implementation viewpoint, this says that if $\mathcal{B}$ is a finite candidate set (e.g. a finite cohort of interaction partners), then one can always point to an exact maximizing witness B^* rather than merely an approximation. In addition, the finite case supports a simple explanation protocol: compute* $\mathrm{Emer}_C(Q; A, B)$ *for each $B \in \mathcal{B}$ and select an argmax. The distinction between the theorem and this corollary mirrors the practical distinction between (i) searching in a large, possibly unstructured hypothesis space and (ii) selecting among a finite menu of experimental conditions or partner prototypes.*

Remark 2935. *More generally, exact witnesses can also arise in infinite families $\mathcal{B}$ when additional structure ensures attainment of the supremum (for example, compactness of the partner space together with appropriate continuity or upper semicontinuity of $B \mapsto \mathrm{Emer}_C(Q; A, B)$). This highlights that the approximate-witness theorem is the minimal guarantee (needing only the order-completeness of $[0, 1]$), while exact attainment is an extra regularity phenomenon rather than a definitional necessity.*

Remark 2936 (Engine reading)**.** *This legitimizes an "interaction partner search" routine: to explain why A has a collective property Q, search for B that maximizes* $\mathrm{Emer}_C(Q; A, B)$ *(or approximately maximizes it). One can also read the theorem as justifying stopping criteria: if an empirical procedure produces a B with* $\mathrm{Emer}_C(Q; A, B)$ *within a pre-specified tolerance of the best attainable value over $\mathcal{B}$, then the procedure has already produced a valid explanatory witness at that tolerance level.*

52 Exploring Emergence, Weakness, and McBride-Pattern Sensitivities

This section states and proves several additional theorems suggested by the quantale pattern theory and McBride-derivative material in *Weakness is All You Need*, as related to Hyperseed. The goal is to produce results that are (i) structurally "meaty" and (ii) directly usable as decision tools for reasoning systems: tests for emergence, invariances, sensitivity and interaction diagnostics, greedy-selection guarantees in important quantales, and a clean link between delay-logistic dynamics and bursty/chaotic pattern intensities.

Remark 2937. *The underlying point of view is that many quantities used in reasoning systems—"how much evidence supports a predicate," "how strongly a pattern is present," "how emergent a joint description is"—can be represented in a single algebraic language: a commutative quantale with residuation. This is the quantale-weakness stance developed in [3], and it is one of the mathematical backbones of the Hyperseed ontology program [1]. The present section focuses on the operational payoffs: when the semantics is quantalic, one can derive robust invariances, testable emergence criteria, and sensitivity/interaction diagnostics that are lightweight enough to be embedded in automated decision-making.*

52.1 Preliminaries (definitions and standing notation)

Definition 475 (Commutative quantale with residuation)**.** *A* commutative quantale *is a complete lattice* $(V, \leq)$ *equipped with a commutative, associative binary operation* $\otimes$ *with unit* e*, such that* $\otimes$ *distributes over arbitrary joins. The* residuated implication $\multimap$ *is defined by the adjunction:*

$$a \otimes b \leq c \quad \Longleftrightarrow \quad b \leq a \multimap c.$$

Remark 2938 (Intuition, notation, and examples)**.** *A commutative quantale is a way to do "graded logic" where degrees of truth/evidence live in a lattice* V*, and where* $\otimes$ *plays the role of combining evidence (or composing resources), while* $\oplus$ *(i.e. join) plays the role of taking the least upper bound of alternatives. Completeness of the lattice means that arbitrary joins* $\bigvee S$ *exist (here* $\bigvee$ *is the lattice join* $\bigvee$ *written with the macro* `\bigjoin`*), so one can aggregate evidence across arbitrarily large families. Distributivity of* $\otimes$ *over joins is the algebraic expression of a familiar computational idea: combining with a fixed resource should commute with taking suprema over choices.*

The residuation law $a \otimes b \leq c \iff b \leq a \multimap c$ *defines* $\multimap$ *as the "largest* b*" that, when combined with* a*, stays below* c*. If* $\otimes$ *is thought of as multiplying plausibilities, then* $\multimap$ *behaves like a division/normalization; if* $\otimes$ *is like conjunction, then* $\multimap$ *behaves like an implication. Concrete examples include: (i)* $V = \{0, 1\}$ *with* $\otimes = \wedge$ *and* $\multimap$ *the usual material implication; (ii)* $V = [0, 1]$ *with* $\otimes = \times$*, join* $= \max$*, and* $\multimap$ *the truncated ratio* $\min(1, b/a)$*; and (iii)* $V = \mathbb{R}_{\geq 0}$ *with* $\otimes = \times$ *and* $\multimap$ *literal division* b/a *when* $a > 0$*. Quantales of this sort are the ambient setting for quantale weakness (Hyperseed-Concept 143) and for formalized notions of* Weakness *(Hyperseed-Concept 202) and* Pattern *(Hyperseed-Concept 130).*

Definition 476 (Weakness, intensity, synergy)**.** *Fix a universe* X*, a valuation* $\phi : X \to V$*, and predicates* $m, y, z : X \to V$*. Define the weakness*

$$\mathrm{Weak}(p) \;:=\; \bigvee_{x \in X} \phi(x) \otimes p(x).$$

Define the composite weakness $h(y, z) := \mathrm{Weak}(y) \otimes \mathrm{Weak}(z)$ *and the (joint) pattern intensity*

$$I_{y,z}(m) \;:=\; (\mathrm{Weak}(y) \otimes \mathrm{Weak}(z)) \multimap \mathrm{Weak}(m).$$

Define individual intensities $I_y(m) := \mathrm{Weak}(y) \multimap \mathrm{Weak}(m)$ *and* $I_z(m) := \mathrm{Weak}(z) \multimap \mathrm{Weak}(m)$*. Define emergent synergy*

$$\sigma_{y,z}(m) \;:=\; (I_y(m) \otimes I_z(m)) \multimap I_{y,z}(m).$$

We say (y, z) *is a* pattern *in* m *when* $I_{y,z}(m) \geq e$*; and* emergent *in* m *when* $\sigma_{y,z}(m) \geq e$*.*

Remark 2939 (What the symbols mean, and why these definitions are natural)**.** *Here* X *is the universe of "items" being aggregated (examples: events, links, data-points, micro-features),* $\phi(x) \in V$ *is a weight/valuation assigning importance or availability to each* x*, and a predicate* $p : X \to V$ *is a* V*-valued membership function (so* $p(x)$ *is the degree to which* x *supports or belongs to* p*). The weakness* $\mathrm{Weak}(p)$ *is then the join-aggregation over* x *of the combined contribution* $\phi(x) \otimes p(x)$*. When* $V = [0, 1]$ *with join* $= \max$ *and* $\otimes = \times$*, this is literally "the strongest weighted supporting element":* $\mathrm{Weak}(p) = \max_x \phi(x)p(x)$*. When* $V = \mathbb{R}_{\geq 0}$ *with join as* $\sup$ *and* $\otimes = \times$*, it becomes a supremum-weighted score.*

The intensities are residuated normalizations of weakness: $I_y(m) = \mathrm{Weak}(y) \multimap \mathrm{Weak}(m)$ *answers the question "relative to how strong* y *is, how strong is* m*?" The joint intensity* $I_{y,z}(m)$ *asks* *the analogous question but with the combined baseline* Weak$(y) \otimes$ Weak(z)*. Finally, the synergy* $\sigma_{y,z}(m)$ *compares the joint intensity to what would be expected from the individual intensities combined via* $\otimes$*; thus* $\sigma_{y,z}(m) \geq e$ *formalizes "the whole exceeds the multiplicative baseline." This is an algebraic capture of* Emergence *(Hyperseed-Concept* **??***) in the sense emphasized in pattern-based accounts [5].*

Remark 2940 (Simple examples (Boolean and max-product))**.** *If* $V = \{0, 1\}$ *with* $\otimes = \wedge$ *and join* $= \vee$*, then* Weak$(p) = 1$ *iff there exists some* x *with* $\phi(x) = 1$ *and* $p(x) = 1$*. In this case* $I_y(m) = 1$ *expresses that whenever* y *is witnessed (in the weighted sense), so is* m*; the joint version similarly matches a conjunctive entailment. At the other extreme, if* $V = [0, 1]$ *with* $\otimes = \times$ *and join* $= \max$*, then* Weak(p) *picks the best single* x *supporting* p *under* ϕ*, and intensities become truncated ratios. These are precisely the kinds of semantics that make the subsequent greedy/submodular results computationally useful.*

Remark 2941 (McBride derivative conventions used here)**.** *We will use a McBride-style "partial derivative w.r.t. the inclusion of* $x \in X$*" denoted* $\partial_x(\cdot)$*, consistent with the derivative identities for* Weak*,* I_y*,* $I_{y,z}$*, and* $\sigma_{y,z}$ *given in Weakness Theory 10. Separately, we will also use ordinary multivariate calculus derivatives* $\frac{\partial}{\partial \theta_i}$ *for the* parameterized soft model *setting (the curvature/Hessian results).*

Remark 2942. *The notational coexistence is deliberate. The McBride-style* ∂_x *is a derivative with respect to a* discrete structural perturbation *(whether a particular* x *is present/active), whereas* $\frac{\partial}{\partial \theta_i}$ *is the ordinary analytic derivative with respect to a real parameter in a soft relaxation. The former is natural when one is doing symbolic or combinatorial sensitivity analysis (as in [22]), and the latter is natural when one is optimizing a differentiable surrogate. Theorems later in this section explain when first-order (one-hole) information is reliable, and when higher-order interaction terms must be accounted for.*

52.2 Shape-2-style: Conditional-intensity factorization and an emergence test

Lemma 156 (Currying for residuation)**.** *In any commutative quantale,*

$$(a \otimes b) \multimap c \;=\; b \multimap (a \multimap c).$$

Remark 2943 (Intuition and why this matters)**.** *This lemma says that residuation "curries" exactly as implication curries in ordinary logic: an implication out of a tensor-product* $a \otimes b$ *can be re-read as an implication out of* b *into an implication out of* a*. In computational terms, it is the algebraic justification for rewriting a joint-normalization into a nested normalization, which is the key step behind conditional intensities. Once this is available, many emergence conditions become one-line comparisons rather than opaque ratios.*

Proof. Let $t \in V$. Using the residuation adjunction twice and associativity/commutativity:

$$\begin{aligned} t \leq (a \otimes b) \multimap c &\iff (a \otimes b) \otimes t \leq c \\ &\iff b \otimes (a \otimes t) \leq c \\ &\iff a \otimes t \leq b \multimap c \\ &\iff t \leq a \multimap (b \multimap c). \end{aligned}$$

By commutativity of $\otimes$, $a \multimap (b \multimap c) = b \multimap (a \multimap c)$, hence the claim. $\square$

Proof sketch. The strategy is purely order-theoretic: characterize each side as the set of all t such that a certain inequality holds, then use the defining adjunction of $\multimap$ to rewrite the inequality step-by-step until it matches the other side. The only "content" is associativity/commutativity of $\otimes$, which lets us re-bracket and swap a and b. $\square$

Remark 2944 (Geometric/order intuition). *In a residuated structure, each map $b \mapsto a \otimes b$ has a right adjoint $c \mapsto a \multimap c$. The lemma is then the statement that the right adjoint of the composite $b \mapsto (a \otimes b) \otimes (\cdot)$ can be computed in two stages, corresponding to two successive adjunctions. This is the lattice-theoretic analogue of "integrating out" one variable at a time.*

Definition 477 (Conditional intensity and conditional amplification). *Define the conditional intensity of z "given y" in context m as*

$$I(z \mid y; m) \;:=\; \mathrm{Weak}(z) \multimap I_y(m).$$

Define the conditional amplification (a "lift" measure) of z induced by y as

$$A(y \to z; m) \;:=\; I_y(m) \multimap I_{y,z}(m).$$

Remark 2945 (Intuition and simple reading). *The quantity $I(z \mid y; m)$ is a nested normalization: first measure how intense m is relative to y (via $I_y(m)$), then measure how that quantity compares to the baseline strength of z (via $\mathrm{Weak}(z) \multimap$). In probabilistic language one might think of it as a conditional score; in resource language it is the "residual slack" for z after accounting for y.*

The amplification $A(y \to z; m)$ measures how much stronger the joint *story (y, z) makes m look, compared to the y-only baseline. When $V = \mathbb{R}_{>0}$ with $\otimes = \times$ and $\multimap$ division, $A(y \to z; m) = I_{y,z}(m)/I_y(m)$ is literally a multiplicative lift factor.*

Remark 2946 (Why these are useful (decision-tool perspective)). *In a reasoning system, one often wants to ask: "Does adding z to an existing explanatory component y actually buy me anything?" The quantity $A(y \to z; m)$ is designed to answer exactly this, and the next theorem shows that synergy can be decided by comparing $A(y \to z; m)$ to the baseline intensity $I_z(m)$. This turns emergence detection (Hyperseed-Concept* **??***) into a single inequality check.*

Theorem 81 (Conditional-intensity factorization and an emergence test). *For any $m, y, z : X \to V$:*

1. *(Conditional factorization)*

$$I_{y,z}(m) \;=\; \mathrm{Weak}(z) \multimap I_y(m) \;=\; \mathrm{Weak}(y) \multimap I_z(m).$$

   Equivalently, $I_{y,z}$ is a conditional intensity in either direction.

2. *(Synergy as "amplification beyond baseline")*

$$\sigma_{y,z}(m) \;=\; I_z(m) \multimap A(y \to z; m) \;=\; I_y(m) \multimap A(z \to y; m).$$

3. *(Emergence test) The following are equivalent:*

$$\sigma_{y,z}(m) \geq e \quad \iff \quad A(y \to z; m) \geq I_z(m) \quad \iff \quad A(z \to y; m) \geq I_y(m).$$

Remark 2947 (Plain-language meaning and connections)**.** *Part (1) says: the intensity of the joint pattern (y, z) in m can be read as a* conditional *intensity, either "z given y" or "y given z." Part (2) then expresses synergy as the gap between the conditional amplification and the baseline. Part (3) is the operational punchline: emergence holds exactly when the amplification provided by y is at least as large as the baseline intensity of z (and symmetrically).*

This theorem connects directly to the definition of synergy in [3], but it packages the algebra in a form suited to fast diagnostics. It is also conceptually consonant with pattern/emergence discussions in [5]: "emergence" is not merely that a joint description exists, but that the joint description improves the explanatory leverage beyond what the parts already warrant.

Proof. (1) By Lemma 156 with $a = \mathrm{Weak}(y)$, $b = \mathrm{Weak}(z)$, $c = \mathrm{Weak}(m)$:

$$(\mathrm{Weak}(y) \otimes \mathrm{Weak}(z)) \multimap \mathrm{Weak}(m) \;=\; \mathrm{Weak}(z) \multimap (\mathrm{Weak}(y) \multimap \mathrm{Weak}(m)) \;=\; \mathrm{Weak}(z) \multimap I_y(m).$$

The symmetric identity follows by commutativity.

(2) Apply Lemma 156 to $a = I_y(m)$, $b = I_z(m)$, $c = I_{y,z}(m)$:

$$(I_y(m) \otimes I_z(m)) \multimap I_{y,z}(m) \;=\; I_z(m) \multimap (I_y(m) \multimap I_{y,z}(m)).$$

But $I_y(m) \multimap I_{y,z}(m) = A(y \to z; m)$ by definition. (3) Using the adjunction with $a = I_z(m)$, $b = e$, $c = A(y \to z; m)$:

$$\sigma_{y,z}(m) \geq e \iff e \leq I_z(m) \multimap A(y \to z; m) \iff I_z(m) \otimes e \leq A(y \to z; m) \iff I_z(m) \leq A(y \to z; m).$$

Here the first equivalence is simply an order-rewriting into the internal $\leq$ relation (so that the adjunction can be applied uniformly), the middle equivalence is the residuation law $b \leq a \multimap c \iff a \otimes b \leq c$, and the last equivalence uses that e is the tensor unit (hence $I_z(m) \otimes e = I_z(m)$). In particular, this chain exhibits the emergence test as a pure comparison between two "local" quantities associated to m: the baseline $I_z(m)$ and the conditional gain $A(y \to z; m)$. The symmetric direction is identical with roles swapped. Concretely, interchanging y and z replaces $I_z(m)$ by $I_y(m)$ and $A(y \to z; m)$ by $A(z \to y; m)$, and the same adjunction steps go through verbatim because they only depend on the monoidal closed structure, not on any asymmetry of the symbols. ☐

Proof sketch. Everything is driven by currying (Lemma 156). First, rewrite the joint residuation $(\mathrm{Weak}(y) \otimes \mathrm{Weak}(z)) \multimap \mathrm{Weak}(m)$ as a nested residuation to obtain the conditional-factorization. Next, apply the same currying trick to the definition of $\sigma_{y,z}$ to expose $I_y(m) \multimap I_{y,z}(m)$, which is precisely the amplification $A(y \to z; m)$. Finally, translate $\sigma_{y,z}(m) \geq e$ into an inequality by unrolling the adjunction with e as the "do-nothing" tensor unit. At a slightly more granular level, the first step uses that in a monoidal closed setting one has

$$(\alpha \otimes \beta) \multimap \gamma \;=\; \beta \multimap (\alpha \multimap \gamma),$$

so one can read a joint-to-target comparison as an "incremental" comparison: first account for α, then ask how much β is needed to reach γ thereafter. In the present notation, this incremental reading is exactly what makes the subsequent appearance of a conditional term like $I_y(m) \multimap I_{y,z}(m)$ unsurprising: it is the residuated counterpart of "holding y fixed and asking what changes when z is added." Likewise, the last step is not merely a change of symbols: expressing $\sigma_{y,z}(m) \geq e$ as $e \leq I_z(m) \multimap A(y \to z; m)$ forces the quantity $A(y \to z; m)$ into the right-hand position of an implication, where residuation converts it into a tensor-inequality and then into a plain comparison against $I_z(m)$ after using $\otimes e$-neutrality. ☐

Remark 2948 (Key step intuition). *The repeated use of the adjunction is not mere algebraic cleverness; it is the mechanism by which a global comparison is reduced to a local budget check. If one thinks of* $\multimap$ *as "how much more do I need," then* $A(y \to z; m) = I_y(m) \multimap I_{y,z}(m)$ *asks "how much extra does* z *contribute once* y *is already in place." The emergence test then says: emergence occurs precisely when this "extra" meets or exceeds the baseline* $I_z(m)$ *that* z *would have had without the help of* y*. Equivalently,* $I_z(m) \leq A(y \to z; m)$ *can be read as a dominance condition: the conditional gain attributable to adding* z *after* y *is at least as large as the standalone "credit" of* z*. The adjunction makes this dominance test compositional: it compares* $I_z(m)$ *and* $A(y \to z; m)$ *without requiring one to explicitly expand* $\sigma_{y,z}$ *into a multi-term expression and then simplify. This also clarifies why* e *is the right threshold: since* e *is the neutral element for* $\otimes$*, the inequality* $\sigma_{y,z}(m) \geq e$ *is exactly the point at which the synergy score becomes non-deficient relative to the monoidal baseline, so that converting it via residuation yields a statement with no remaining reference to any extraneous scale factor.*

Remark 2949 (Why this is a useful reasoning-system tool). *Theorem 81(3) says you can test emergence by comparing a conditional-amplification quantity ("how much does* y *boost* z *jointly?") against the baseline intensity of* z*, without directly computing the full ratio-style synergy expression. This is often numerically and conceptually simpler, and it suggests causal/diagnostic interpretations: emergence means* y *makes* z *"more pattern-like than it otherwise is." In practice, this separation is helpful because* $I_z(m)$ *and* $A(y \to z; m)$ *typically come from different kinds of estimates:* $I_z(m)$ *is a marginal intensity (a single-input assessment), whereas* $A(y \to z; m)$ *is a conditional change (a two-stage assessment). The theorem therefore supports modular diagnostics: one can keep track of baseline intensities for many* m *and then, only when needed, evaluate which pairs* (y, z) *yield conditional gains large enough to surpass those baselines. Moreover, because the criterion is an order comparison rather than an equality, it is robust under approximation: if one can bound* $A(y \to z; m)$ *from below (or* $I_z(m)$ *from above), one can certify emergence without needing exact values. This is especially useful when the underlying computations occur in a qualitative or partially ordered setting where the emphasis is on entailment/feasibility rather than on precise numeric magnitudes.*

52.3 Shape-3-style: Gauge invariance and robustness under rescaling

Definition 478 (Tensor-cancellative scale elements). *An element* $k \in V$ *is* tensor-cancellative *if for all* $u, v \in V$,

$$k \otimes u \leq k \otimes v \iff u \leq v.$$

Remark 2950 (Intuition and examples). *Tensor-cancellativity is the quantalic analogue of multiplying both sides of an inequality by a positive scalar: in* $\mathbb{R}_{\geq 0}$ *with* $\otimes = \times$*, it holds exactly when* $k > 0$*. Conceptually,* k *is then a "pure change of units" rather than a genuine distortion. This condition is what allows us to treat intensities and synergies as* dimensionless *quantities: they depend on ratios/implications, not on the absolute scale of weights.*

Lemma 157 (Uniform rescaling of valuation rescales weakness). *Let* $\phi_k(x) := k \otimes \phi(x)$*. Then for any predicate* p,

$$w_{\phi_k}(p) \;=\; k \otimes w_\phi(p).$$

Remark 2951 (Intuition and why it is the right lemma). *Weakness is defined by aggregating* $\phi(x) \otimes p(x)$ *across* x*. If every* $\phi(x)$ *is uniformly scaled by the same factor* k*, then the entire aggregation should scale by* k *as well; this is a minimal sanity requirement for any notion of "weighted support."*

The lemma formalizes that sanity check using exactly the quantale axiom that $\otimes$ distributes over joins.

Proof. Using distributivity of $\otimes$ over joins,

$$w_{\phi_k}(p) = \bigvee_x (k \otimes \phi(x)) \otimes p(x) = \bigvee_x k \otimes (\phi(x) \otimes p(x)) = k \otimes \bigvee_x \phi(x) \otimes p(x) = k \otimes w_\phi(p).$$

□

Proof sketch. Pull the constant k outside the join: distributivity lets one rewrite the join of $k \otimes (\cdot)$ as $k\otimes$ (join of $\cdot$). The rest is associativity of $\otimes$. □

Remark 2952 (Operational intuition)**.** *If ϕ encodes "attention weights" or "resource availability" and we re-normalize those weights, the weakness score changes predictably. The deeper question, addressed next, is whether* intensities *(which are comparative) stay fixed.*

Lemma 158 (Cancellation passes through residuation)**.** *If k is tensor-cancellative, then for all $a, b \in V$,*

$$(k \otimes a) \multimap (k \otimes b) \ = \ a \multimap b.$$

Remark 2953 (Why this is the heart of gauge invariance)**.** *Residuation $\multimap$ is the operation that turns "absolute" quantities into "relative" ones. This lemma states that if k is a pure rescaling (cancellative), then relative comparisons are unaffected: scaling both the antecedent and consequent by the same k does not change the implication value. This is precisely the condition one expects if intensities are to behave like ratios rather than raw magnitudes.*

Proof. For any $t \in V$,

$$\begin{aligned} t \le (k \otimes a) \multimap (k \otimes b) &\iff (k \otimes a) \otimes t \le k \otimes b \\ &\iff k \otimes (a \otimes t) \le k \otimes b \\ &\iff a \otimes t \le b \qquad \text{(by tensor-cancellativity)} \\ &\iff t \le a \multimap b. \end{aligned}$$

Thus the two elements have the same lower set, hence are equal. □

Proof sketch. Use the adjunction definition of $\multimap$ on both sides: both are characterized by which t satisfy a certain inequality. Tensor-cancellativity lets one cancel the leading k from that inequality, reducing it to the unscaled condition. □

Remark 2954 (Order-theoretic picture)**.** *A right adjoint is determined by the preimage of principal down-sets. The proof shows that scaling by a cancellative k preserves these down-sets exactly, so the right adjoint (residuation) is unchanged. This is the lattice version of the familiar fact that dividing kb by ka yields b/a.*

Theorem 82 (Gauge invariance of intensities and synergy under uniform valuation scaling)**.** *Assume $k \in V$ is tensor-cancellative and define $\phi_k(x) := k \otimes \phi(x)$. Then for any m, y, z,*

$$I_y^{(\phi_k)}(m) = I_y^{(\phi)}(m), \qquad I_{y,z}^{(\phi_k)}(m) = I_{y,z}^{(\phi)}(m), \qquad \sigma_{y,z}^{(\phi_k)}(m) = \sigma_{y,z}^{(\phi)}(m).$$

Remark 2955 (Intuitive statement and significance)**.** *The theorem says that if we uniformly rescale the valuation ϕ (e.g. by changing units, renormalizing weights, or globally adjusting confidence), then intensities and synergies do not change. This is important because it means that these quantities are not artifacts of calibration: they are invariant features of the relational structure between y, z, and m. In the language of Hyperseed, it supports treating these values as stable indicators of* Pattern *and* Emergence *(Hyperseed-Concepts 130,* **??***) rather than as numerology dependent on a particular scaling convention.*

Proof. By Lemma 157, $\mathrm{Weak}_{\phi_k}(p) = k \otimes \mathrm{Weak}_\phi(p)$ for any p. Thus

$$I_y^{(\phi_k)}(m) = \mathrm{Weak}_{\phi_k}(y) \multimap \mathrm{Weak}_{\phi_k}(m) = (k \otimes \mathrm{Weak}_\phi(y)) \multimap (k \otimes \mathrm{Weak}_\phi(m)) = \mathrm{Weak}_\phi(y) \multimap \mathrm{Weak}_\phi(m)$$

by Lemma 158. The joint-intensity case is identical. Synergy depends only on these intensities via the same residuation operation, so it is also invariant. □

Proof sketch. First show weakness scales linearly with k (Lemma 157). Then observe that each intensity is an implication between two weaknesses, so scaling both inputs by k cancels out inside $\multimap$ (Lemma 158). Since synergy is built from intensities using the same operations, it inherits the invariance. □

Remark 2956 (Geometric/measurement intuition)**.** *One may regard ϕ as choosing a "measuring instrument" for the universe X. Uniformly changing the instrument's gain changes all raw readings, but it should not change dimensionless ratios. The theorem formalizes exactly that expectation: intensity and synergy are ratio-like, hence gauge invariant.*

Remark 2957 (Interpretation)**.** *Under mild cancellativity, intensities and synergies are* dimensionless*: they do not change if you uniformly rescale the valuation weights. This is a robustness theorem that supports cross-domain reuse: a reasoning system can compare intensities across settings whose raw scales differ (units, normalization conventions, etc.).*

52.4 Emergence via interactions: curvature, multi-hole effects, and reliability of first-order McBride sensitivities

Definition 479 (Soft-link weakness (parameterized model))**.** *Let $\theta \in \mathbb{R}^d$ parameterize a family of soft inclusion probabilities $p_\theta(e) \in [0,1]$ over a finite link set E. Given link weights $\phi(e) \geq 0$, define*

$$w(\theta) := \sum_{e \in E} \phi(e)\, p_\theta(e).$$

Assume w is twice continuously differentiable.

Remark 2958 (Intuition and relationship to "holes")**.** *This is a smooth relaxation of the discrete setting in which one either includes or excludes links $e \in E$. The parameter vector θ encodes how willing the model is to include each link, and $p_\theta(e)$ is the induced soft inclusion probability. The resulting weakness $w(\theta)$ is the expected weighted mass of included links. In McBride-derivative language [22], removing a link corresponds to creating a "hole"; here, the edit $\theta \mapsto \theta - \varepsilon e_i$ is a small differentiable analogue of carving such a hole.*

Remark 2959 (Notation clarification)**.** *e_i denotes the ith standard basis vector of $\mathbb{R}^d$. Later, for a set of indices $S \subseteq \{1, \ldots, d\}$, $\mathbf{1}_S \in \mathbb{R}^d$ denotes the indicator vector with $(\mathbf{1}_S)_i = 1$ if $i \in S$ and 0 otherwise.*

Definition 480 (Interaction gap between two "holes")**.** *For coordinate directions i, j and step size $\varepsilon > 0$, define*

$$\Delta_{ij}(\varepsilon) := w(\theta - \varepsilon e_i - \varepsilon e_j) - w(\theta - \varepsilon e_i) - w(\theta - \varepsilon e_j) + w(\theta).$$

Remark 2960 (Intuition and a sanity check)**.** *$\Delta_{ij}(\varepsilon)$ measures whether the effect of two simultaneous edits is additive. If the two edits were independent in their impact on w, then the inclusion–exclusion combination above would be 0. Thus Δ_{ij} is a quantitative probe for interaction effects, i.e. a second-order signature of emergence among edits. This is the smooth analogue of "multi-hole" effects discussed in the quantale/McBride setting [3, 22].*

Theorem 83 (Mixed curvature is the leading-order interaction term)**.** *Let $H(\theta)$ be the Hessian of w at θ, with entries $H_{ij}(\theta)$. Then*

$$\Delta_{ij}(\varepsilon) \;=\; \varepsilon^2 \, H_{ij}(\theta) \;+\; o(\varepsilon^2) \qquad \text{as } \varepsilon \to 0.$$

In particular, the mixed second derivative H_{ij} is a precise second-order measure of non-additive interaction between the ith and jth one-hole edits.

Remark 2961 (What the theorem is saying, in plain terms)**.** *As ε becomes small, the interaction gap is dominated by the mixed Hessian entry $H_{ij}(\theta)$ times ε^2. So the Hessian is not just a generic curvature object; it is exactly the infinitesimal measurement of "how non-additive" two edits are. If one wants to detect emergent effects that only appear when two components are altered together, H_{ij} is the first place to look.*

Proof. Apply the second-order Taylor expansion of w at θ in the three directions $-\varepsilon e_i - \varepsilon e_j$, $-\varepsilon e_i$, and $-\varepsilon e_j$. Write $g = \nabla w(\theta)$. Then

$$\begin{aligned} w(\theta - \varepsilon e_i - \varepsilon e_j) &= w(\theta) - \varepsilon(g_i + g_j) + \frac{\varepsilon^2}{2}(H_{ii} + 2H_{ij} + H_{jj}) + o(\varepsilon^2), \\ w(\theta - \varepsilon e_i) &= w(\theta) - \varepsilon g_i + \frac{\varepsilon^2}{2} H_{ii} + o(\varepsilon^2), \\ w(\theta - \varepsilon e_j) &= w(\theta) - \varepsilon g_j + \frac{\varepsilon^2}{2} H_{jj} + o(\varepsilon^2). \end{aligned}$$

Subtracting according to the definition of $\Delta_{ij}(\varepsilon)$ cancels the linear and diagonal quadratic terms, leaving

$$\Delta_{ij}(\varepsilon) = \varepsilon^2 H_{ij} + o(\varepsilon^2).$$

□

Proof sketch. Compute Taylor expansions for the three perturbed points and combine them via the inclusion–exclusion pattern defining $\Delta_{ij}(\varepsilon)$. The linear terms cancel automatically, and the pure second-order terms H_{ii}, H_{jj} also cancel, leaving only the cross term $2H_{ij}$, hence the leading $\varepsilon^2 H_{ij}$ contribution. □

Remark 2962 (Visual intuition)**.** *One can picture w as a landscape over parameter space. The term H_{ij} measures how the slope in direction i changes as one moves in direction j. If the landscape is locally "separable" in those coordinates, the mixed curvature is near zero; if it is twisted, the mixed curvature is large, indicating genuine interaction.*

Remark 2963 (Decision-tool reading: emergence of edits)**.** *If $H_{ij}(\theta)$ is large in magnitude, then the combined effect of simultaneously changing parameters i and j differs substantially from the sum of their individual effects. This is exactly the "non-additive interaction between holes" intuition emphasized in the one-hole-context curvature discussion.*

Theorem 84 (Curvature-controlled near-optimality of top-k McBride pruning)**.** *Assume that on a convex region $\mathcal{R}$ containing θ and all points $\theta - \varepsilon \mathbf{1}_S$ with $|S| = k$, the Hessian operator norm is bounded: $\|H(\xi)\|_2 \le M$ for all $\xi \in \mathcal{R}$. Define the first-order sensitivities $s_i := \frac{\partial w}{\partial \theta_i}(\theta)$. For any size-$k$ set S, define the (soft) decrease*

$$D(S) := w(\theta) - w(\theta - \varepsilon \mathbf{1}_S).$$

Let S^{FO} be the set of k indices with largest s_i (the "top-k McBride rule"), and let $S^\star$ maximize $D(S)$ among all $|S| = k$. Then

$$D(S^{\mathrm{FO}}) \;\ge\; D(S^\star) \;-\; M\,\varepsilon^2\,k.$$

Remark 2964 (Intuitive statement and why it is important)**.** *The theorem formalizes a common engineering heuristic: "pick the k parameters with largest first-order effect." It says this greedy-by-gradient choice is near-optimal, up to an explicit error term controlled by curvature M, step size ε, and budget k. Thus, first-order McBride sensitivities are reliable precisely when the model is locally close to linear along the relevant multi-edit directions—and unreliable exactly when strong second-order interactions are present (cf. Theorem 83). This provides a principled trigger for when to upgrade from one-hole diagnostics to multi-hole interaction mining [22]. In particular, the bound distinguishes two separate failure modes of the heuristic: (i) large edit magnitudes ε (which amplify quadratic terms even when curvature is moderate) and (ii) genuinely large local curvature M (where even small edits can interact nontrivially). From an experimental-design viewpoint, it also clarifies what the greedy rule is implicitly optimizing: it is exactly optimal for the linearized surrogate objective, and the theorem quantifies how far the true nonlinear objective can deviate from that surrogate along the k-sparse edit directions that matter operationally.*

Proof. Fix any S with $|S| = k$ and consider the Taylor expansion along $-\varepsilon \mathbf{1}_S$:

$$w(\theta - \varepsilon \mathbf{1}_S) = w(\theta) - \varepsilon \sum_{i \in S} s_i + \frac{\varepsilon^2}{2}\, \mathbf{1}_S^\top H(\xi_S) \mathbf{1}_S$$

for some ξ_S on the segment between θ and $\theta - \varepsilon \mathbf{1}_S$. (Here the remainder is written in the standard second-order mean-value form, i.e., the Hessian is evaluated at an intermediate point ξ_S on the line segment; this is the multivariate analogue of the one-dimensional Taylor theorem with Lagrange remainder.) Thus

$$D(S) = \varepsilon \sum_{i \in S} s_i - \frac{\varepsilon^2}{2}\, \mathbf{1}_S^\top H(\xi_S) \mathbf{1}_S.$$

The first term $\varepsilon \sum_{i \in S} s_i$ is the linear (additive) prediction obtained by summing the individual first-order effects over the chosen indices, while the second term captures all within-set interactions contributed by curvature along the joint direction $\mathbf{1}_S$. By the operator norm bound,

$$\left| \mathbf{1}_S^\top H(\xi_S) \mathbf{1}_S \right| \le \|H(\xi_S)\|_2 \, \|\mathbf{1}_S\|_2^2 \le M \cdot k.$$

The inequality $\left| x^\top A x \right| \le \|A\|_2 \|x\|_2^2$ is a direct consequence of the spectral characterization of the operator norm, and it is precisely the step that collapses potentially complicated cross-terms in the quadratic form into a single worst-case curvature constant M. Hence for all S,

$$\varepsilon \sum_{i \in S} s_i - \frac{\varepsilon^2}{2} M k \le D(S) \le \varepsilon \sum_{i \in S} s_i + \frac{\varepsilon^2}{2} M k.$$

This pair of inequalities can be read as a uniform sandwiching of the true multi-edit gain $D(S)$ between its linear surrogate and an additive tolerance of size $\frac{\varepsilon^2}{2}Mk$, independent of the particular combinatorial choice of S. Since S^{FO} maximizes $\sum_{i\in S} s_i$ among $|S| = k$,

$$\sum_{i\in S^{\mathrm{FO}}} s_i \geq \sum_{i\in S^\star} s_i.$$

Combine the lower bound on $D(S^{\mathrm{FO}})$ with the upper bound on $D(S^\star)$:

$$D(S^{\mathrm{FO}}) \geq \varepsilon \sum_{i\in S^{\mathrm{FO}}} s_i - \frac{\varepsilon^2}{2}Mk \geq \varepsilon \sum_{i\in S^\star} s_i - \frac{\varepsilon^2}{2}Mk \geq D(S^\star) - M\varepsilon^2 k.$$

The final constant $M\varepsilon^2 k$ arises because one pays a quadratic remainder once for the chosen set and once for the comparator set, yielding two halves that add to a full $M\varepsilon^2 k$ gap. □

Proof sketch. Approximate $w(\theta - \varepsilon \mathbf{1}_S)$ by its linear term $w(\theta) - \varepsilon \sum_{i\in S} s_i$ and bound the Taylor remainder using the Hessian norm. The top-k rule is optimal for the linear surrogate because it maximizes the sum of chosen sensitivities. The only loss comes from the bounded quadratic remainder, giving the explicit $M\varepsilon^2 k$ gap. Equivalently, if the gradient is M-Lipschitz in the relevant neighborhood, then the discrepancy between the true objective and its linearization along any k-sparse step of size ε is uniformly controlled, so the combinatorial selection is stable under this controlled nonlinearity. □

Remark 2965 (Why the bound scales as k)**.** *The factor $\|\mathbf{1}_S\|_2^2 = k$ is the geometric reason the penalty grows with the number of simultaneous edits: moving along a k-sparse direction has Euclidean length $\sqrt{k}$, and second-order errors scale like (length)^2. Thus even small curvature can accumulate if one performs many edits at once; this is the smooth analogue of many-hole interference. Another way to view this is that the quadratic form $\mathbf{1}_S^\top H(\xi_S)\mathbf{1}_S$ contains k diagonal contributions and $k(k-1)$ off-diagonal contributions; the operator-norm bound suppresses the detailed combinatorics, but the net effect still grows with the size of the joint move through the $\|\mathbf{1}_S\|_2^2$ factor.*

Remark 2966 (When to trust first-order vs. mine higher-order interactions)**.** *Theorem 84 makes the qualitative curvature guidance quantitative: when curvature is small (small M) and/or step sizes are small, first-order McBride sensitivities give near-optimal multi-edit choices. When M is large, Theorem 83 suggests mining higher-order (two-hole, three-hole) interactions to capture emergence among edits. Operationally, the bound recommends a simple diagnostic: if the estimated interaction scale $M\varepsilon^2 k$ is negligible relative to the achieved improvement $D(S^{\mathrm{FO}})$ (or relative to typical differences among candidate sets), then the top-k selection is robust; if not, then one should expect ranking instabilities where sets with smaller first-order scores can win due to synergistic (or antagonistic) curvature effects, motivating explicit multi-hole searches.*

52.5 A concrete greedy guarantee in an important quantale (max-product)

Definition 481 (Max-product quantale and crisp contexts)**.** *Let $V = [0,1]$ with $\oplus = \max$, $\otimes = \times$, and unit $e = 1$. For a crisp subset $M \subseteq X$, represent its predicate by $m_M(x) = 1$ if $x \in M$ and 0 otherwise. Assume $\phi(x) \in [0,1]$, so*

$$\mathrm{Weak}(m_M) = \max_{x\in M} \phi(x).$$

Fix y, z with constants $A := \mathrm{Weak}(y)$ and $B := \mathrm{Weak}(z)$, and define

$$f(M) := I_{y,z}(m_M) = (AB) \multimap \mathrm{Weak}(m_M).$$

In this quantale, $(a \multimap b) = \min(1, b/a)$ for $a > 0$ (and $0 \multimap b := 1$).

Remark 2967 (Interpreting the residuum in the max-product setting)**.** *Because $\otimes = \times$ on $[0,1]$, the residuum $a \multimap b$ is the largest $c \in [0,1]$ such that $a \times c \leq b$. When $a > 0$, solving $ac \leq b$ gives $c \leq b/a$, hence $a \multimap b = \min(1, b/a)$. Thus $f(M) = (AB) \multimap \mathrm{Weak}(m_M)$ can be read as a* normalized sufficiency score*: it measures how large a multiplicative factor one can apply to the baseline AB while still not exceeding the evidence level $\mathrm{Weak}(m_M)$, capped at 1. In particular, $f(M) = 1$ exactly when $\mathrm{Weak}(m_M) \geq AB$; otherwise $f(M) = \mathrm{Weak}(m_M)/(AB)$.*

Remark 2968 (Degenerate baseline and saturation edge cases)**.** *If $AB = 0$, then by the convention $0 \multimap b = 1$ we have $f(M) = 1$ for all M, i.e. the objective is trivial and every set is optimal. In the nondegenerate regime $AB > 0$ used below, $f(M)$ is a scaled version of $\mathrm{Weak}(m_M)$ that saturates at 1 once the threshold AB is met. This saturation is important conceptually: once some element of M is "good enough," adding more elements cannot further increase the intensity beyond 1.*

Remark 2969 (Why this quantale is "important" and what is being optimized)**.** *The max-product quantale is a natural model for reasoning in which one strong exemplar dominates the evidence: the weakness $\mathrm{Weak}(m_M)$ is the best (largest) weighted support among elements of M. The induced intensity $f(M)$ then asks whether the set M contains an element strong enough to meet the joint baseline AB, up to truncation at 1. This is precisely the sort of objective one encounters when a system can attend to only k items and wants to maximize a pattern intensity score quickly.*

In particular, if AB is viewed as a required joint-strength threshold, then maximizing $f(M)$ is essentially maximizing the best available $\phi(x)$ inside M (but expressed in the intensity language consistent with quantale weakness [3]).

Remark 2970 (A useful explicit form for later inequalities)**.** *When $AB > 0$, combining the definition of $\mathrm{Weak}(m_M)$ with the residuum formula yields the concrete closed form*

$$f(M) = \min\left(1, \frac{\max_{x \in M} \phi(x)}{AB}\right).$$

This makes it clear that the objective depends on M only through the single statistic $\max_{x \in M} \phi(x)$. Equivalently, any two sets with the same maximum ϕ-value have the same intensity score.

Lemma 159 (Submodularity of max-weight)**.** *Let $g(M) = \max_{x \in M} \phi(x)$ (with $g(\emptyset) = 0$). Then g is monotone and submodular: for $S \subseteq T$ and $x \notin T$,*

$$g(S \cup \{x\}) - g(S) \ \geq\ g(T \cup \{x\}) - g(T).$$

Remark 2971 (Equivalent "lattice" form of submodularity in this special case)**.** *For completeness, note that submodularity is also equivalent to $g(S) + g(T) \geq g(S \cup T) + g(S \cap T)$ for all S, T. For the max function this inequality is consistent with the idea that $g(S \cup T) = \max(g(S), g(T))$ while $g(S \cap T) \leq \min(g(S), g(T))$, so the left-hand side dominates the right-hand side. The marginal-gain formulation in Lemma 159 is the one needed for the greedy analysis in Theorem 85.*

Remark 2972 (Intuition and why submodularity appears here)**.** *Submodularity is a formal version of diminishing returns. For a max function it is almost tautological: if you already have a large set T whose maximum $g(T)$ is high, then adding a new element x is less likely to increase the max than if you start from a smaller set S whose max is lower. The lemma packages this intuition into the standard submodularity inequality, which will unlock a canonical greedy approximation theorem.*

Proof. Let $a = g(S)$ and $b = g(T)$ so $a \le b$. Let $c = \phi(x)$. If $c \le b$, then $g(T \cup \{x\}) = b$ so the RHS is 0, while the LHS is nonnegative. If $c > b$, then $g(S \cup \{x\}) = g(T \cup \{x\}) = c$, so the inequality becomes $c - a \ge c - b$, which holds since $a \le b$. □

Proof sketch. Reduce to two cases depending on whether the new element x beats the current maximum of T. If it does not, the marginal gain for T is 0 and the inequality is automatic. If it does, both sets' maxima jump to the same value c, and the inequality reduces to $a \le b$. □

Remark 2973 (Visual intuition)**.** *Imagine $g(M)$ as the height of the tallest pillar among those indexed by M. Adding a new pillar can only increase the height if the pillar is taller than the current tallest. The more pillars you already have, the taller your current tallest tends to be, hence the less marginal benefit you typically get from a new pillar.*

Lemma 160 (Submodularity of the induced joint intensity)**.** *The set function $f(M) = \min(1, g(M)/(AB))$ is monotone and submodular.*

Remark 2974 (Why truncation does not break submodularity here)**.** *The function $t \mapsto \min(1, t/(AB))$ is monotone and saturates at 1. Because g itself only changes by either 0 or a jump to the new value c when an element is added, the truncation cannot invert the diminishing-returns comparison: it can only compress gains further. Thus the same case split from Lemma 159 still works.*

Remark 2975 (A slightly more structural view: "piecewise linear" composition)**.** *On the range $t \in [0, AB]$, the map $t \mapsto t/(AB)$ is linear, hence it preserves the ordering of marginal gains exactly. On the range $t \ge AB$, the map is constant ($= 1$), hence all further marginal gains become 0. Since g is itself a max operator (hence its marginals are already of the form "0 or a single jump"), composing with a function that is linear-then-constant can only maintain or reduce marginal gains, never create a new violation of diminishing returns.*

Proof. Monotonicity is immediate from monotonicity of g and of $t \mapsto \min(1, t/(AB))$. For submodularity, use the same case split as in Lemma 159, observing that $g(S \cup \{x\})$ and $g(T \cup \{x\})$ are either unchanged (marginal 0) or both become c, and the outer truncation $\min(1, \cdot)$ is monotone, so it preserves the inequality of marginal gains. □

Proof sketch. Compose a submodular monotone function g with a monotone saturating transform that does not introduce new kinds of marginal-gain behavior (only 0 vs. jump-to-c). Check the submodularity inequality by the same two cases as for g. □

Remark 2976 (What greedy looks like in this particular objective)**.** *Because $f(M)$ depends only on $\max_{x \in M} \phi(x)$, any set containing an element that attains the global maximum of ϕ achieves the best possible f-value under* any *size constraint $k \ge 1$. Consequently, in this max-product instantiation, the greedy algorithm will select (one of) the highest-ϕ elements at its first step (since that maximizes the marginal gain from $\emptyset$), and after that either (i) the score is already saturated at 1 so all remaining marginals are 0, or (ii) the score is unsaturated but no additional element can beat the current maximum, so again marginals are 0. Thus, while Theorem 85 states the standard $(1 - 1/e)$ guarantee, the realized approximation factor here can in fact be 1 whenever ties and the $k \ge 1$ constraint allow inclusion of an argmax of ϕ.*

Theorem 85 (Greedy maximization of intensity has a $(1 - 1/e)$ guarantee)**.** *Let f be as above. Among all subsets $M \subseteq X$ of size at most k, let $M^\star$ maximize $f(M)$. Let M^{gr} be the result of the greedy algorithm that starts from $\emptyset$ and repeatedly adds the element with the largest marginal increase in f until k elements are chosen. Then*

$$f(M^{\mathrm{gr}}) \;\ge\; \left(1 - \frac{1}{e}\right) f(M^\star).$$

Remark 2977 (How the standard theorem applies (and what hypotheses were proved above))**.** *The classical greedy approximation theorem requires exactly the properties established in Lemma 160: f must be normalized ($f(\emptyset) = 0$), monotone, and submodular, and the feasible sets are those of cardinality at most k. Here normalization holds because $g(\emptyset) = 0$, hence $f(\emptyset) = \min(1, 0/(AB)) = 0$ when $AB > 0$ (and in the $AB = 0$ degenerate case the objective is constant, so the inequality is trivially satisfied). Therefore the hypotheses line up directly with the standard analysis (e.g. the Nemhauser–Wolsey–Fisher guarantee for greedy under a cardinality constraint).*

Remark 2978 (Plain-English meaning and where it fits)**.** *This is the classic guarantee for greedy maximization of a monotone submodular set function under a cardinality constraint. In our setting, it says: if you have a budget of k elements to select in order to maximize a quantale-derived pattern intensity, then greedy selection achieves at least a $(1 - 1/e)$ fraction of the optimum. Within this document's broader arc, this is an explicit bridge from quantale pattern-intensity semantics to an algorithmic decision rule with a worst-case performance certificate.*

Proof. By Lemma 160, f is monotone submodular and $f(\emptyset) = 0$. In particular, for $A \subseteq B$ and $x \notin B$ we have the diminishing-returns property

$$f(A \cup \{x\}) - f(A) \;\geq\; f(B \cup \{x\}) - f(B),$$

and monotonicity gives $f(A) \leq f(B)$ whenever $A \subseteq B$. These two facts are the only structural inputs used below.

Let S_t be the greedy set after t steps ($|S_t| = t$). Equivalently, $S_{t+1} = S_t \cup \{g_t\}$ where g_t is chosen to maximize the marginal gain $f(S_t \cup \{x\}) - f(S_t)$ among all available elements $x \notin S_t$.

Let OPT be an optimal size-k set. By submodularity and monotonicity,

$$f(OPT) - f(S_t) \leq \sum_{x \in OPT \setminus S_t} \big(f(S_t \cup \{x\}) - f(S_t)\big).$$

To see why this inequality holds, list the elements of $OPT \setminus S_t$ as $x_1, \ldots, x_m$ (with $m \leq k$) and write a telescoping expansion

$$f(S_t \cup (OPT \setminus S_t)) - f(S_t) = \sum_{i=1}^{m} \Big(f\big(S_t \cup \{x_1, \ldots, x_i\}\big) - f\big(S_t \cup \{x_1, \ldots, x_{i-1}\}\big)\Big).$$

Submodularity (diminishing returns) upper-bounds each term in this telescoping sum by the corresponding singleton marginal $f(S_t \cup \{x_i\}) - f(S_t)$, yielding

$$f(S_t \cup (OPT \setminus S_t)) - f(S_t) \;\leq\; \sum_{x \in OPT \setminus S_t} \big(f(S_t \cup \{x\}) - f(S_t)\big).$$

Finally, monotonicity implies $f(OPT) \leq f(S_t \cup OPT) = f(S_t \cup (OPT \setminus S_t))$, which gives the displayed inequality above.

There are at most k terms on the RHS, so at least one x has marginal gain at least $\frac{1}{k}(f(OPT) - f(S_t))$. (If there are fewer than k terms, the same conclusion still holds because dividing by k only weakens the lower bound.) Greedy picks an element with marginal at least this large, hence

$$f(S_{t+1}) - f(S_t) \;\geq\; \frac{1}{k}\big(f(OPT) - f(S_t)\big).$$

It is sometimes helpful to rearrange this inequality into a "gap-shrinking" form:

$$f(OPT) - f(S_{t+1}) \;\leq\; \Big(1 - \frac{1}{k}\Big)\big(f(OPT) - f(S_t)\big).$$

Let $R_t := f(OPT) - f(S_t)$. Then $R_{t+1} \le (1 - \frac{1}{k})R_t$, so iterating gives

$$R_t \le \left(1 - \frac{1}{k}\right)^t R_0.$$

Since $S_0 = \emptyset$, we have $R_0 = f(OPT) - f(\emptyset) = f(OPT)$, and therefore $R_k \le (1 - \frac{1}{k})^k f(OPT) \le e^{-1} f(OPT)$. The final inequality uses the standard estimate $(1 - \frac{1}{k})^k \le e^{-1}$, which follows for example from $\ln(1-u) \le -u$ (with $u = 1/k$), or from $(1 + 1/(k-1))^{k-1} \ge e$.

Thus $f(S_k) = f(OPT) - R_k \ge (1 - e^{-1}) f(OPT)$. In other words, after k greedy steps the achieved value is within a $(1 - 1/e)$ fraction of optimal for this monotone submodular objective. □

Proof sketch. Submodularity implies that the total remaining gap to optimum can be distributed across at most k elements of an optimal set, so one of them must close at least a $1/k$ fraction of the gap. Greedy picks an element that does at least as well, leading to a multiplicative decay of the gap and hence the $(1 - 1/e)$ bound after k steps. Equivalently, the "regret" $R_t = f(OPT) - f(S_t)$ contracts by a factor of at most $(1 - 1/k)$ at each step; after k steps one has $R_k \le (1 - 1/k)^k R_0 \le e^{-1} f(OPT)$, so the achieved value is at least $(1 - e^{-1}) f(OPT)$. □

Remark 2979 (Why this guarantee is philosophically comforting)**.** *Greedy selection is a local method: it trusts immediate marginal gains. The theorem shows that for the max-product quantale intensity objective, such local trust is not blind faith but is justified by the global convexity-like property encoded by submodularity. In that sense, the lattice order provides a disciplined middle ground between brute-force search and mere heuristic. One can also read the proof as saying that "local evidence" (marginals at S_t) cannot systematically mislead, because diminishing returns prevents the optimum from hiding all of its value in complicated multiway synergies that are invisible to single-step gains. The guarantee is therefore a structural statement about the objective: it rules out pathological landscapes in which every locally best move is globally disastrous.*

Remark 2980 (Why this matters)**.** *This gives a formal justification for a greedy pattern-mining heuristic (under a natural quantale): a reasoning system that must allocate a limited budget of "attended elements" to maximize a target pattern intensity can do so with a principled approximation guarantee. In particular, even when exact optimization is computationally expensive, the greedy strategy comes with a worst-case bound that is independent of the ambient ground-set size, depending only on the budget k through the universal constant $1 - 1/e$. This separates the method from purely ad hoc heuristics: the approximation factor is a theorem-level consequence of monotonicity and submodularity of the intensity objective in the max-product setting.*

52.6 Dynamics: delay-logistic and "bursty" emergence

Theorem 86 (Delay-logistic inheritance for pattern intensity)**.** *Work in $V = \mathbb{R}_{\ge 0}$ with $\otimes = \times$ and assume* $\mathrm{Weak}(m(t)) = W(t)$ *satisfies the classical delay-logistic equation*

$$\dot{W}(t) = r\, W(t) \left(1 - \frac{W(t-\tau)}{K}\right), \qquad r > 0,\ K > 0.$$

Fix any predicate y with constant $c := \mathrm{Weak}(y) > 0$, and define $I_y(t) := I_y(m(t)) = c \multimap W(t) = W(t)/c$. Then $I_y(t)$ satisfies a delay-logistic equation of the same form:

$$\dot{I}_y(t) = r\, I_y(t) \left(1 - \frac{I_y(t-\tau)}{K/c}\right).$$

Remark 2981 (Further technical context: initial histories and well-posedness)**.** *A delay differential equation is specified not only by parameters (r, τ, K) but also by an initial* history *function (e.g. $W_0 \colon [-\tau, 0] \to \mathbb{R}_{\geq 0}$) so that $W(t) = W_0(t)$ for $t \in [-\tau, 0]$. Under the change of variables $W = c\, I_y$, the corresponding initial history is simply $I_{y0} = W_0/c$. Thus the "inheritance" statement should be read as: for any admissible history W_0, the induced history I_{y0} generates a unique trajectory $I_y(t)$ whose dynamics is the rescaled delay-logistic system. This clarifies that the result is not merely pointwise in t, but holds at the level of solution operators determined by the underlying delay system.*

Remark 2982 (Intuitive meaning and why it belongs in this section)**.** *If weakness* $\mathrm{Weak}(m(t))$ *evolves according to a known dynamical law, then intensities derived from weakness inherit a related law. Here the transformation is a simple scaling $W(t) = c\, I_y(t)$ (because $\multimap$ is division in this quantale), so the entire delay-logistic structure is preserved, with only the carrying capacity rescaled. This is a dynamical analogue of the earlier gauge-invariance theme: relative quantities evolve by the same shape of equation.*

Remark 2983 (On the role of $c > 0$ and the quantale residual)**.** *The assumption $c = \mathrm{Weak}(y) > 0$ ensures that $c \multimap W = W/c$ is well-defined as a finite real quantity and that the map $W \mapsto I_y$ is invertible on $\mathbb{R}_{\geq 0}$ (with inverse $I_y \mapsto c\, I_y$). In $V = \mathbb{R}_{\geq 0}$ with $\otimes = \times$, the residual $a \multimap b$ is the largest x such that $ax \leq b$; for $a > 0$ this indeed coincides with b/a. This makes explicit that the theorem is really about* residual-based normalization *of weakness by a fixed reference predicate, which is precisely the kind of "pattern-sensitive" renormalization that arises in McBride-style comparisons.*

Proof. Since $W(t) = c\, I_y(t)$, we have $\dot{W}(t) = c\, \dot{I}_y(t)$ and $W(t - \tau) = c\, I_y(t - \tau)$. Substitute into the equation for $\dot{W}(t)$:

$$c\, \dot{I}_y(t) = r\, (c\, I_y(t)) \left(1 - \frac{c\, I_y(t - \tau)}{K}\right).$$

Divide by $c > 0$ to obtain

$$\dot{I}_y(t) = r\, I_y(t) \left(1 - \frac{I_y(t - \tau)}{K/c}\right).$$

In particular, the delay enters only through evaluation at $t - \tau$, and the scaling commutes with this evaluation, so no additional terms appear. $\square$

Proof sketch. The proof is a change of variables: define $I_y(t) = W(t)/c$, substitute $W = cI_y$ into the differential equation, and simplify. Because the delay term is linear in $W(t - \tau)$, the same substitution works there as well. $\square$

Remark 2984 (Dynamical-systems intuition)**.** *A delay-logistic equation can be viewed as a feedback loop with memory τ. Multiplying the state variable by a constant does not alter the qualitative feedback structure; it only rescales the level at which saturation occurs. Thus the same mechanism that yields oscillations or chaos in W can do so in I_y as well.*

Remark 2985 (Phase-space viewpoint for delay equations)**.** *Although written as a scalar equation, a delay system is naturally a dynamical system on a function space, where the "state" at time t is the history segment $W_t(\theta) := W(t + \theta)$ for $\theta \in [-\tau, 0]$. The scaling map $W_t \mapsto I_{yt} := W_t/c$ is then a homeomorphism of the history space (on the appropriate subset where the solutions live), so the inheritance claim can be interpreted as an equivalence of semiflows on these history spaces. This is the precise sense in which the qualitative behaviors (e.g. recurrent dynamics) are transported between W and I_y.*

Corollary 41 (Chaotic regimes transfer through intensity transforms)**.** *If $W(t)$ exhibits chaotic dynamics for some (r, τ, K), then $I_y(t) = W(t)/c$ exhibits chaotic dynamics for the same (r, τ) and carrying capacity K/c. Moreover, any invertible monotone transform of $W(t)$ (e.g. $\sigma(t) = 1/W(t)$ on $(0, \infty)$) inherits chaos via topological conjugacy.*

Remark 2986 (Domain restrictions for monotone transforms)**.** *The example $\sigma(t) = 1/W(t)$ implicitly requires $W(t) > 0$ along the trajectory (or at least on the time interval of interest), since inversion is not continuous at 0 on $\mathbb{R}_{\geq 0}$. More generally, for a monotone transform to yield a conjugacy, it must be a homeomorphism on an invariant subset of the state space (or of the history space in the delay setting). Operationally, this means that "score transforms" are safest when they preserve the relevant invariant region and do not introduce singularities that could masquerade as additional burstiness.*

Remark 2987 (Why the corollary is not merely formal)**.** *The corollary warns against a naive expectation that "scores" derived from weakness should be smoother than weakness itself. If the underlying weakness dynamics is bursty or chaotic, then intensities (and other monotone transforms) can be equally bursty. Thus, a reasoning system that monitors pattern intensity (Hyperseed-Concept 130) should treat volatility as a possible* structural *phenomenon rather than as mere measurement noise.*

Remark 2988 (Concrete dynamical implication for "bursts")**.** *In practice, delay-logistic systems are known to admit sustained oscillations and more complicated behavior for certain ranges of $r\tau$ (with the onset of oscillatory instability occurring when the feedback delay is large relative to the intrinsic growth rate). The corollary therefore supports a mechanistic picture in which long-lag feedback in global weakness can generate intermittent surges in I_y even when the reference predicate y (hence c) is time-independent. This connects the qualitative language of "bursty emergence" to a specific and testable dynamical mechanism: delayed negative feedback combined with amplification.*

Proof. Scaling $W \mapsto W/c$ is an invertible continuous map with continuous inverse. Thus the flow on W is conjugate to the flow on I_y. The same holds for any invertible monotone transform on the relevant state domain (e.g. inversion on $(0, \infty)$), which preserves qualitative dynamical complexity such as chaos. In the delay setting, the same argument applies to the induced map on history segments (sending W_t to I_{y_t}), giving conjugacy of the associated semiflows on the history space, which is the standard framework in which "chaos" for delay equations is stated. □

Proof sketch. Use the dynamical-systems principle that invertible continuous reparameterizations of state space yield conjugate flows. Conjugacy preserves qualitative behaviors like chaos. Scaling and monotone inversion (on the appropriate domain) are examples of such reparameterizations. □

Remark 2989 (Operational reading)**.** *This supports a concrete "bursty emergence" picture: if the global weakness evolves by a known chaotic delay-feedback mechanism, then intensities (and any monotone score derived from them) can inherit chaotic fluctuations, providing a mathematical basis for unpredictable surges in detected patterns.*

Remark 2990 (Connection to McBride-pattern sensitivities)**.** *Because $I_y = \mathrm{Weak}(y) \multimap \mathrm{Weak}(m)$ is a relative quantity, it can be viewed as a "pattern-sensitive" normalization of weakness: different choices of predicate y change only the scale, not the qualitative dynamics. Thus, when comparing intensities across predicates (a typical McBride-style sensitivity analysis), differences in observed burstiness should not automatically be attributed to different underlying mechanisms; they may simply reflect different normalizing constants or transforms applied to the same underlying weak* *dynamics. This is especially relevant when one predicate yields values near a transform singularity (e.g. inversion near* 0*), in which case apparent bursts can be amplified artifacts of the chosen representation rather than changes in the underlying system.*

52.7 Log-linearization: emergence as an information-like inequality

Theorem 87 (Log-synergy and an additive "mutual-emergence" quantity)**.** *Assume $V = \mathbb{R}_{>0}$ with $\otimes = \times$ and $\multimap$ given by division: $a \multimap b = b/a$. Assume $I_y(m), I_z(m), I_{y,z}(m) > 0$. Then*

$$\sigma_{y,z}(m) = \frac{I_{y,z}(m)}{I_y(m)\, I_z(m)}.$$

Define the log-synergy (mutual-emergence) quantity

$$\mathrm{ME}(y, z; m) := \log \sigma_{y,z}(m).$$

Then

$$\mathrm{ME}(y, z; m) = \log I_{y,z}(m) - \log I_y(m) - \log I_z(m),$$

and the emergence criterion $\sigma_{y,z}(m) \geq 1$ is equivalent to $\mathrm{ME}(y, z; m) \geq 0$, i.e.

$$\log I_{y,z}(m) \geq \log I_y(m) + \log I_z(m).$$

Moreover, since $\sigma_{y,z}(m) \geq 1$ is equivalent to $I_{y,z}(m) \geq I_y(m)I_z(m)$, one can view $\mathrm{ME}(y, z; m)$ as a signed "gap" (in log-units) measuring the extent to which the joint intensity exceeds (or falls below) what would be predicted by a simple multiplicative baseline. In particular, $\mathrm{ME}(y, z; m) = 0$ corresponds exactly to the multiplicative factorization $I_{y,z}(m) = I_y(m)I_z(m)$, while $\mathrm{ME}(y, z; m) > 0$ and $\mathrm{ME}(y, z; m) < 0$ represent (respectively) super-multiplicative and sub-multiplicative joint behavior relative to that baseline.

Remark 2991 (Intuition and conceptual connection)**.** *When $\otimes$ is multiplication and $\multimap$ is division, synergy becomes a familiar multiplicative interaction ratio: joint intensity divided by the product of individual intensities. Taking logs converts products into sums, yielding an additive inequality. This resembles the way information theory turns multiplicative likelihood ratios into additive log-likelihoods, and it resonates with the general use of log-costs (description length, contrivance) elsewhere in the framework [3]. In particular, the expression*

$$\log I_{y,z}(m) - \log I_y(m) - \log I_z(m)$$

is formally analogous to pointwise mutual information (PMI) when I-terms are interpreted as probability-like or likelihood-like quantities; the sign of $\mathrm{ME}(y, z; m)$ then indicates whether the (y, z) joint is more or less "surprising" than would be expected under multiplicative independence. This analogy is purely structural here (no probabilistic assumptions are required beyond positivity), but it motivates treating ME as an "information-like" score in downstream selection and comparison tasks.

Proof. With $a \multimap b = b/a$, the definition of $\sigma_{y,z}$ gives the displayed ratio directly. Taking logs yields the additive identity. Since log is monotone increasing, $\sigma_{y,z}(m) \geq 1 \iff \log \sigma_{y,z}(m) \geq 0$. The assumption $I_y(m), I_z(m), I_{y,z}(m) > 0$ is exactly what ensures $\sigma_{y,z}(m) > 0$ and makes $\log \sigma_{y,z}(m)$ well-defined without additional case distinctions. ☐

Proof sketch. Unroll the definitions using the concrete form of $\multimap$ as division, then apply log to linearize multiplication into addition. Monotonicity of log preserves the direction of the emergence inequality. The positivity assumptions guarantee that both the division and the logarithm are valid operations in $V = \mathbb{R}_{>0}$, so the derivation requires no further algebraic side conditions. $\square$

Remark 2992 (Log base, units, and scale invariances)**.** *The base of the logarithm in* $\mathrm{ME}(y, z; m)$ *can be chosen arbitrarily (e.g. natural log or base-2); changing the base only rescales* ME *by a positive constant factor and therefore does not affect the sign test* $\mathrm{ME}(y, z; m) \geq 0$*. Because* $\sigma_{y,z}(m)$ *is a ratio, it is dimensionless even when the intensities* $I_y, I_z, I_{y,z}$ *carry units; correspondingly,* $\mathrm{ME}(y, z; m)$ *is naturally interpreted as a "log-unit" gap. In addition, if each intensity is rescaled multiplicatively by fixed positive constants (e.g. due to a change of overall normalization), the ratio* $\sigma_{y,z}(m)$*, and hence* $\mathrm{ME}(y, z; m)$*, remains unchanged whenever the same scaling convention is applied consistently to* $I_y, I_z, I_{y,z}$ *so that the joint-to-marginal comparison is preserved.*

Remark 2993 (Why logs help in practice)**.** *Many reasoning systems already operate in log-space to avoid numerical underflow and to make additive budgets natural (e.g. one can add costs rather than multiply probabilities). The quantity* $\mathrm{ME}(y, z; m)$ *is then directly comparable to other additive scores: one can threshold emergence by a single scalar and combine it with other terms in a multi-objective selection rule without leaving log-space. An additional practical benefit is interpretability: differences in* ME *correspond to multiplicative factors in* $\sigma_{y,z}$*. For example,* $\mathrm{ME}(y, z; m)$ *increasing by* $\log 2$ *means the synergy ratio doubled, regardless of the absolute scale of the underlying intensities.*

Remark 2994 (A small numerical illustration)**.** *If (for a fixed* m*) one has* $I_y(m) = 2$*,* $I_z(m) = 3$*, and* $I_{y,z}(m) = 12$*, then* $\sigma_{y,z}(m) = 12/(2 \cdot 3) = 2$*, hence* $\mathrm{ME}(y, z; m) = \log 2 > 0$*, indicating emergence under the* $\sigma_{y,z}(m) \geq 1$ *criterion. Conversely, if* $I_{y,z}(m) = 5$ *with the same* $I_y(m), I_z(m)$*, then* $\sigma_{y,z}(m) = 5/6 < 1$ *and* $\mathrm{ME}(y, z; m) = \log(5/6) < 0$*, indicating a shortfall of the joint intensity relative to the multiplicative baseline. Such examples emphasize that the sign of* ME *captures the direction of deviation, while its magnitude quantifies the deviation on a logarithmic (multiplicative) scale.*

Remark 2995 (Why this is practically helpful)**.** *In domains where a reasoning system already uses log-scores (description lengths, contrivance, clarity), Theorem 87 turns a multiplicative emergence condition into an additive inequality. This often simplifies thresholding, budgeting, and multi-objective tradeoffs. It also makes sensitivity analyses more straightforward: a small additive perturbation to* $\log I_{y,z}(m)$*,* $\log I_y(m)$*, or* $\log I_z(m)$ *produces an equally small additive perturbation to* $\mathrm{ME}(y, z; m)$*, which is often easier to track than the corresponding multiplicative perturbations in the original ratio* $\sigma_{y,z}(m)$*.*

53 Independence as the Pivot: Connecting Hyperseed Pattern-Intensity Tradeoffs to the Dependence Dichotomy and the Tradeoff Theorem

We formalize several cross-links between (i) Hyperseed-style tradeoffs among effort, weakness, and pattern intensity, and (ii) the Dependence Dichotomy / tradeoff theorem framework in which any attempt to increase evidential quality must choose between enforcing independence (Route A) and explicitly modeling dependence (Route B) [9, 8]. More concretely, the Hyperseed viewpoint treats "pattern intensity" as a measure of how strongly a regularity asserts itself across observations and internal representations, while "effort" captures the resource expenditure required to find, test, and maintain that regularity, and "weakness" captures the degree to which the pattern is fragile, approximate, or contingent on hidden context. The dependence framework, in turn, treats evidential quality as a function not only of the amount of data but of whether distinct pieces of evidence behave as genuinely independent samples (so that aggregation yields near-additive information) or whether they are entangled by common causes, feedback, or shared construction (so that naive aggregation overstates confidence). The bridge between the two is that high pattern intensity can arise either from many weakly-related confirmations (an independence-friendly regime) or from a smaller number of tightly coupled mechanisms that reinforce each other (a dependence-dominated regime), and these two sources have very different costs and failure modes.

The results emphasize independence as a unifying latent variable, yielding practical decision rules: when synergy is observed, Route B is forced; when residual dependence is small, conditional independence approximations are sound; when double-counting exists, redundant couplings can be pruned; and on the Pareto frontier, marginal gains per unit effective cost must equalize across all active "independence vs coupling" knobs. Here "synergy" is meant in the operational sense that the combined evidential impact of two sources exceeds what would be predicted by treating them as conditionally independent given the current model; this indicates that there is unmodeled shared structure (a coupling) that is carrying information and must be represented if one wishes to claim calibrated confidence. "Residual dependence is small" refers to the regime in which, after conditioning on the model's latent variables and known confounders, the remaining correlations among evidential channels are weak enough that the error introduced by a factorized approximation falls below the decision-relevant threshold. "Double-counting" arises when correlated evidence is fed into an inference pipeline as if independent, producing artificially high effective sample size; pruning redundant couplings means either removing duplicate channels, collapsing them into a single sufficient statistic, or introducing an explicit dependence term so that the combined update reflects the true degrees of freedom. Finally, the Pareto-frontier statement can be read as a Lagrange-multiplier condition: once one trades off evidential quality against computational and modeling cost, optimal allocation requires equalizing the marginal return of spending effort on independence-enforcing transformations (e.g., whitening, deconfounding, decorrelation, or experimental design) versus spending effort on richer coupling structure (e.g., additional latent variables, interaction terms, or explicit graph edges). This makes the "independence vs coupling" dial analogous to the Hyperseed allocation between pursuing stronger patterns and paying the price in complexity and maintenance.

Remark 2996. *Philosophically, the theme is that "independence" is not merely a modeling convenience; it is a kind of hidden coordinate for the whole enterprise. If the world (or the agent's representation of it) is close to independent, then explanation can be modular and cheap; if it is not, then any claim to high-quality evidence must purchase its legitimacy by paying for coupling. This is the same tension that appears, in different vocabulary, in quantale weakness theory [3, 2] and in the Hyperseed treatment of patterns and emergent structure [5, 1]. In this sense, independence functions like a "gauge choice" for reasoning: one may either (a) transform the representation so that interactions are pushed into the background and the remaining components behave nearly separably, or (b) keep the representation closer to the raw generative process and account explicitly for the interaction terms that remain. The former yields reusable modules and clearer accounting of evidence, but risks systematic bias if the transformations only partially remove coupling; the latter yields higher fidelity but can suffer from combinatorial explosion and overfitting if the dependence structure is expanded without adequate constraints. The unifying claim is not that independence is always attainable, but that reasoning systems must track how far they are from it, because this distance controls both the effective strength of patterns (how much signal truly accumulates) and the* *effective cost of using them (how much structure must be represented to avoid illusory confidence).*

53.1 Preliminaries (minimal)

53.1.1 Hyperseed-style compositional patterns and intensity

Fix a context C. A compositional pattern witness for x is a triple $P = (y, z, t)$ with $x = y *_C z$ and glue/interaction overhead $t \geq 0$. Define composite cost

$$h_C(P) := s_C(y) + s_C(z) + t.$$

With baseline cost $s_C^{base}(x) > 0$, define scalar pattern intensity

$$I_C(P; x) := \max\left\{0, \frac{s_C^{base}(x) - h_C(P)}{s_C^{base}(x)}\right\} \in [0, 1].$$

Remark 2997 (Notation and intuition). *Here $*_C$ is a (possibly partial) composition operator internal to the context C (so $y *_C z$ may or may not be defined). The quantity $s_C(\cdot)$ is a description or construction cost (one may read it as "how many resources it takes to specify/build the entity"), and $s_C^{base}(x)$ is the baseline cost used to normalize intensity. The overhead t is the "price of interaction": everything that cannot be attributed cleanly to describing y and z separately. This overhead is the informal locus of dependence: if y and z were perfectly independent, one expects little or no glue.*

The intensity $I_C(P; x)$ simply measures relative compression: if the composite description $h_C(P)$ is close to the baseline $s_C^{base}(x)$, then the witness does not help much and intensity is near 0; if $h_C(P)$ is much smaller, intensity approaches 1. This matches the Hyperseed view of Pattern *and* Emergence *as forms of compressive explanatory power (Hyperseed-Concept 130, Hyperseed-Concept* **??***) [5].*

Remark 2998 (Examples). *A simple example is string composition: let x be a long string, let y and z be substrings, and let $*_C$ be concatenation with a small delimiter. Then t corresponds to delimiter/format overhead. If x is literally y followed by z, then t can be tiny and intensity can be high. If instead x is an intricate interleaving of bits of y and z, then any decomposition forces large t, and intensity collapses.*

Another example is a model composed of two submodels: y predicts one subset of variables, z predicts another, and t represents the extra parameters needed to coordinate them (shared latent variables, attention links, synchronization constraints). In this reading, t is a quantitative avatar of Dependency *(Hyperseed-Concept 93) and of the* Effort *needed to manage it (Hyperseed-Concept 100).*

53.1.2 Quantale pattern intensity and synergy (emergence witness)

Let $(V, \otimes, \oplus, e)$ be a commutative quantale with residuation $\multimap$ satisfying $a \otimes b \leq c \iff b \leq a \multimap c$. For a valuation $\varphi : X \to V$ and predicates $y, z, m : X \to V$, define

$$w_\varphi(p) := \bigoplus_{x \in X} \varphi(x) \otimes p(x), \qquad h(y, z) := w_\varphi(y) \otimes w_\varphi(z).$$

Define intensities

$$I_y(m) := w_\varphi(y) \multimap w_\varphi(m), \quad I_z(m) := w_\varphi(z) \multimap w_\varphi(m), \quad I_{y,z}(m) := h(y, z) \multimap w_\varphi(m).$$

Define synergy

$$\sigma_{y,z}(m) := (I_y(m) \otimes I_z(m)) \multimap I_{y,z}(m).$$

Call (y, z) emergent in m if $\sigma_{y,z}(m) \geq e$.

Remark 2999 (Notation and conventions)**.** *The symbol* $\oplus$ *denotes join (supremum) in the quantale, while* $\otimes$ *is the commutative monoidal product. The unit* e *is the multiplicative identity for* $\otimes$*. The residuation* $\multimap$ *is the (right) adjoint to left-multiplication:* $a \otimes b \leq c$ *iff* $b \leq a \multimap c$*. Intuitively,* $a \multimap c$ *measures "how much* b *you can afford" given budget* a *to stay under* c*.*

The map $w_\varphi(p)$ *is the quantale-theoretic analogue of "aggregated support" or "weakness" for predicate* p *under weighting* φ*, as in quantale weakness theory (Hyperseed-Concept 143, Hyperseed-Concept 202) [3, 2]. In the Boolean quantale,* w_φ *reduces to existence-of-a-witness; in probabilistic quantales, it resembles a weighted expectation; in cost/log semirings, it resembles soft-min or log-sum-exp aggregation.*

Remark 3000 (Intuition: why residuated intensities encode "pattern" and "emergence")**.** *The intensity* $I_y(m) = w_\varphi(y) \multimap w_\varphi(m)$ *reads: "relative to the baseline support of* y*, how strongly does* m *hold?". The joint intensity* $I_{y,z}(m)$ *compares* m *to the joint baseline* $h(y,z) = w_\varphi(y) \otimes w_\varphi(z)$*, i.e. the independent product baseline. Synergy* $\sigma_{y,z}(m)$ *then measures whether the joint intensity exceeds what one would expect from simply multiplying the individual intensities: if* $\sigma_{y,z}(m) > e$*, then* m *looks "more true" given the pair than one can justify from the individuals alone. This is the quantale version of an emergence witness: the whole is stronger than the parts under the chosen aggregation semantics (Hyperseed-Concept* **??***) [3, 5].*

53.1.3 Tradeoff-theorem viewpoint: Route A vs Route B

Abstractly, we have:

- a cost lattice/quantale Q_{comp} (effort/resources),
- an evidence lattice/quantale Q_{evid} (accuracy / evidential adequacy),
- a product order on $Q := Q_{comp}^{op} \times Q_{evid}$,
- circuits/architectures f with cost $\kappa(f) \in Q_{comp}$ and evidence $\iota(f) \in Q_{evid}$,
- Route A = independence-enforcing transforms (decorrelation/comonad action),
- Route B = explicit multi-ary couplings (arity ≥ 2 generators).

A penalty-bridge (quantale morphism) $\phi : Q_{comp}^{op} \to Q_{evid}$ yields

$$W(f) := \iota(f) \otimes \phi(\kappa(f)) \in Q_{evid},$$

interpreted as a weakness-regularized evidence score.

Remark 3001 (What the objects mean, operationally)**.** *The product order* $Q := Q_{comp}^{op} \times Q_{evid}$ *is the formal way to encode the usual engineering preference:* lower *computational cost and* higher *evidence. Taking* Q_{comp}^{op} *flips the order on costs so that "better" means "smaller cost". The map* $\kappa(f)$ *is whatever cost model one uses (time, memory, samples, energy), relating to Hyperseed-Concept 100. The map* $\iota(f)$ *is an evidential adequacy measure (accuracy, likelihood, calibration, constraint satisfaction), relating to Hyperseed-Concept* **??** *and Hyperseed-Concept 139. In particular, writing the target as a* product *order makes explicit that we are not assuming a single scalar utility a priori: we are tracking a two-axis (or more generally multi-axis) preference and thereby working with a Pareto-style comparison where improvements in one coordinate do not automatically compensate for deterioration in the other. The choice of* Q_{comp} *and* Q_{evid} *as posets (rather than* $\mathbb{R}$*) also allows one to encode coarse-grained or partially comparable resource budgets (e.g. different kinds* *of memory, heterogeneous hardware, or hard-vs-soft constraints) and similarly structured notions of evidence (e.g. accuracy vs. calibration, likelihood vs. coverage), while still retaining a disciplined notion of "no worse than" via the order. Operationally, an arrow f (model, procedure, component, or sub-system) is thus judged by the pair $(\kappa(f), \iota(f))$, and the product order asserts that a design is preferred when it is cheaper* and *at least as evidentially adequate, with the op ensuring that "cheaper" is aligned with "greater" in the combined preference. One typically also expects κ and ι to be monotone with respect to the relevant refinement/implementation order on artifacts f (when such an order is present), so that a refinement that genuinely increases evidence or decreases cost is reflected as an improvement in Q.*

Route A is "make things independent enough that simple composition is legitimate"; Route B is "admit dependence and represent it explicitly". Both are manifestations of Hyperseed-Concept 93 and Hyperseed-Concept 88 at the architectural level. The general Route A/Route B dichotomy is treated as a central organizing device in [9, 8]. The operational distinction is that Route A spends design effort on interventions (modularization, isolation, randomization, buffering, architectural separation, careful interface contracts) that reduce unwanted couplings so that composed performance is close to the performance predicted by simpler factorizations. Route B, by contrast, treats the couplings as first-class: the system carries extra representational and computational machinery (joint models, graphical structure, dependence-aware estimators, coordination protocols, explicit shared-state) so that composition remains sound even when independence is false. In terms of the order Q, Route A often lowers κ for downstream inference/composition by enforcing simpler semantics at interfaces, whereas Route B often increases κ (and sometimes ι) by paying for the additional structure needed to track dependencies explicitly; the point of the framework is to make that cost–evidence exchange legible rather than implicit.

Remark 3002 (Why the penalty bridge ϕ is the right abstraction)**.** *The weakness-regularized score $W(f) = \iota(f) \otimes \phi(\kappa(f))$ expresses the idea that evidential adequacy is meaningful only when paid for honestly. One may think of ϕ as converting cost into an evidential penalty (or "contrivance tax"), matching the spirit of weakness-as-regularization in [3, 2]. In the simplest numeric setting, ϕ could be $k \mapsto e^{-\lambda k}$ so that multiplying by $\phi(\kappa)$ discounts evidence by an exponential in cost. The advantage of the quantale formulation is that it remains valid when evidence and cost are not scalars but structured quantities (multi-objective, partially ordered, or compositional). More concretely, the bridge $\phi : Q_{comp} \to Q_{evid}$ (or into the evidential side of the ambient quantale, depending on the chosen encoding) is the abstraction that enforces a disciplined* exchange rate *between resources spent and evidential credit received: higher cost should not be able to masquerade as "free" evidence, and conversely a cost reduction should not be treated as a loss of evidence unless the application explicitly chooses such a trade. The tensor $\otimes$ is deliberately left abstract because the appropriate combination law depends on what "evidence" means: in a multiplicative setting it behaves like weighting/discounting, while in a log-domain or additive quantale it can correspond to adding a penalty term (e.g. $-\lambda k$) to a score. The quantale perspective guarantees that W composes coherently with whatever notion of combination is already built into the evidential semantics (for instance, conjunction of constraints, fusion of independent likelihood factors, or aggregation of multiple validation criteria), while still respecting monotonicity of the order. Operationally, ϕ is also where one can encode hard budgets and infeasibility: a design whose $\kappa(f)$ exceeds an allowable budget can be sent by ϕ to a bottom/absorbing penalty (so that $W(f)$ becomes decisively poor), whereas modest costs can be penalized gently to reflect a "pay as you go" engineering regime. In this way, ϕ isolates the normative choice (how strongly to punish complexity or resource use) from the descriptive choice of ι (how to measure evidential adequacy), which is precisely why it is the right abstraction for comparing routes and architectures that may differ widely in where they spend* *computation to buy robustness, calibration, or other forms of evidence.*

53.2 New theorems connecting tradeoffs to the tradeoff theorem

53.2.1 Glue overhead as an independence bottleneck

Lemma 161 (Intensity ceiling induced by glue overhead)**.** *Fix C and x with $s_C^{base}(x) > 0$. For any compositional witness $P = (y, z, t)$ of x,*

$$I_C(P; x) \le \max\left\{0,\, 1 - \frac{t}{s_C^{base}(x)}\right\}.$$

Equivalently, if $I_C(P; x) \ge \alpha$ for some $\alpha \in [0, 1]$, then

$$t \le (1 - \alpha)\, s_C^{base}(x).$$

Remark 3003 (What the lemma is saying, in plain language)**.** *This lemma isolates the simplest possible obstruction to strong compositional explanation: even if y and z were "free" to describe, the glue t alone already caps the intensity. So intensity cannot be high unless glue is small. One may read t as a numerical proxy for dependence: high dependence forces high glue, and high glue suppresses intensity.*

This is important because it turns the somewhat qualitative slogan "independence helps compositionality" into a quantitative inequality. In the Route A vs Route B framing [9], it says that Route A (decorrelation, factorization, abstraction) is not optional ornamentation: it is precisely the attempt to reduce the effective t so that high intensity becomes possible.

Proof. By definition, $I_C(P; x) = \max\{0, (s_C^{base}(x) - [s_C(y) + s_C(z) + t])/s_C^{base}(x)\}$. Dropping the nonnegative terms $s_C(y) + s_C(z) \ge 0$ can only increase the bracketed expression, so

$$\frac{s_C^{base}(x) - [s_C(y) + s_C(z) + t]}{s_C^{base}(x)} \le \frac{s_C^{base}(x) - t}{s_C^{base}(x)} = 1 - \frac{t}{s_C^{base}(x)}.$$

Clamping with $\max\{0, \cdot\}$ preserves the inequality, giving the first claim. The second claim is immediate by rearranging $I_C(P; x) \ge \alpha$ in the unclamped regime.

It is also worth noting that the positivity assumption $s_C^{base}(x) > 0$ is exactly what makes the normalization meaningful: the statement is a bound on a *fractional* (relative) gain compared to a nontrivial baseline. When the baseline were 0, the normalization would be undefined and one would instead work with the unnormalized slack $s_C^{base}(x) - [s_C(y) + s_C(z) + t]$. □

Proof sketch. The proof uses a single monotonicity idea: removing nonnegative costs (here $s_C(y)$ and $s_C(z)$) can only make the witness look better, hence can only increase the un-clamped intensity expression. Therefore the largest intensity compatible with glue t occurs in the fictitious best case $s_C(y) = s_C(z) = 0$, yielding $1 - t/s_C^{base}(x)$. Geometrically, one may picture the baseline cost as a fixed "budget" and t as a mandatory tax; the remaining budget fraction is an absolute upper bound on relative compression. □

Remark 3004. *Lemma 161 formalizes a key intuition: high pattern intensity forces small "interaction overhead" t, i.e., the composite must be close to independent/low-glue. This is where Route A typically enters: it is a mechanism whose purpose is to* reduce *effective glue by enforcing independence.*

Remark 3005 (A few immediate boundary cases)**.** *The inequality has two useful edge-case readings that are easy to miss:*

1. *If $t \geq s_C^{base}(x)$, then the right-hand side is ≤ 0, hence $I_C(P;x) = 0$. In words: if the glue alone costs at least as much as the entire baseline description of x, then* no *compositional explanation of this form can have positive intensity.*

2. *If $t = 0$, then the lemma only yields the trivial ceiling $I_C(P;x) \leq 1$. This is as it should be: eliminating glue removes the* dependence-induced *obstruction, but the remaining terms $s_C(y) + s_C(z)$ may still prevent high intensity.*

3. *Solving $I_C(P;x) \geq \alpha$ for t emphasizes a linear "price of intensity": each additional $\Delta\alpha$ of guaranteed intensity requires shrinking allowable glue by $\Delta\alpha \cdot s_C^{base}(x)$. Thus, when $s_C^{base}(x)$ is large, even modest target intensities can impose large absolute reductions in admissible glue.*

These are merely restatements of Lemma 161, but they often serve as quick sanity checks when applying the bound.

53.2.2 Synergy forces explicit coupling (independence is not free)

Definition 482 (Strong monoidality on the independence fragment)**.** *Let $\mathcal{A}$ denote the "independence fragment" (Route A-only) of circuits: those built without any multi-ary generator of arity ≥ 2. Assume the evidence evaluator is* strong monoidal *on $\mathcal{A}$: for all $f, g \in \mathcal{A}$,*

$$\iota(f \otimes g) = \iota(f) \otimes \iota(g).$$

Remark 3006 (Intuition and why this assumption is natural)**.** *Strong monoidality says: if you build a system by placing two independent subcircuits side-by-side (via $\otimes$), then the evidence of the whole is exactly the monoidal product of the evidences of the parts. In more everyday terms, there is no hidden bonus (and no hidden penalty) from mere juxtaposition. Any departure from this multiplicativity must come from explicit coupling.*

This is precisely the formalization needed to make "synergy" a witness of dependence. Without it, one could not rule out the possibility that the evaluator itself secretly bakes in cross-channel terms. Conceptually, this assumption is the mathematical counterpart of the idea that independence is a modeling constraint with bite, not a vague aspiration (Hyperseed-Concept 93, Hyperseed-Concept 202) [9, 3].

Remark 3007 (On the role of residuation in the definition of synergy)**.** *The expression $I_{ind} \multimap \iota(f)$ uses the residuated implication $\multimap$ of the underlying quantale (or, more generally, a residuated monoidal poset). Operationally, $\Sigma(f) = I_{ind} \multimap \iota(f)$ is intended to be the* largest *element σ such that*

$$I_{ind} \otimes \sigma \;\leq\; \iota(f),$$

when such a largest σ exists. This makes $\Sigma(f)$ a canonical "multiplicative gap" between the independence baseline and the actual evidence: it is exactly the missing factor one must supply to the baseline in order to reach (or upper-bound) the observed evidence. In particular, $\Sigma(f) = e$ means "no multiplicative surplus beyond baseline," whereas $\Sigma(f) > e$ means there is a strictly positive surplus that cannot be attributed to mere juxtaposition under strong monoidality.

Theorem 88 (Synergy is a dependence witness: emergent synergy forces Route B)**.** *Assume strong monoidality on the independence fragment $\mathcal{A}$. Let a system decompose into two subchannels, and* *let f be the overall circuit. Define the "independence baseline" evidence as $I_{ind} := \iota(f_A) \otimes \iota(f_B)$, where f_A, f_B are the induced subcircuits if f factorizes (i.e., $f = f_A \otimes f_B$). Define a synergy factor $\Sigma(f)$ (when the residual exists) by*

$$\Sigma(f) := I_{ind} \multimap \iota(f).$$

Then:

1. *If $f \in \mathcal{A}$ (no multi-ary couplings), then $\Sigma(f) = e$.*

2. *If $\Sigma(f) > e$, then $f \notin \mathcal{A}$, hence any generator decomposition of f must contain at least one multi-ary (arity ≥ 2) coupling (Route B activation).*

Proof. For (1), if $f \in \mathcal{A}$ and the system is presented as two independent subchannels, then f must be representable (within the fragment) as a monoidal juxtaposition $f = f_A \otimes f_B$ with $f_A, f_B \in \mathcal{A}$. By strong monoidality on $\mathcal{A}$,

$$\iota(f) = \iota(f_A \otimes f_B) = \iota(f_A) \otimes \iota(f_B) = I_{ind}.$$

Therefore $\Sigma(f) = I_{ind} \multimap \iota(f) = I_{ind} \multimap I_{ind} = e$, using the standard residuation identity $a \multimap a = e$.

For (2), we argue by contrapositive. Suppose $f \in \mathcal{A}$. Then by (1) we have $\Sigma(f) = e$, which implies it is *not* the case that $\Sigma(f) > e$. Hence if $\Sigma(f) > e$, it must be that $f \notin \mathcal{A}$. By definition of $\mathcal{A}$, leaving $\mathcal{A}$ means that any construction of f from generators must invoke at least one multi-ary (arity ≥ 2) generator, i.e., some explicit coupling, corresponding to Route B. □

Remark 3008 (Plain-English reading and why it matters)**.** *The theorem says: under a clean independence semantics, any "extra" evidence beyond the factorized baseline is a certificate of dependence. If you compute a synergy residual $\Sigma(f)$ and it is strictly above the neutral element e, then the circuit cannot live in the independence-only fragment; some explicit coupling is logically necessary.*

This result is important because it is a one-bit decision procedure*: synergy observed $\Rightarrow$ Route B is forced. It connects the quantale-emergence notion (synergy as residuated surplus) to the architecture-level Route A/Route B dichotomy [9]. In the language of Hyperseed-Concept* **??***, it tells us that emergence is not a decorative label: it has a sharp computational implication about which class of explanatory mechanisms must be invoked.*

Remark 3009 (Caveats and interpretive notes)**.** *Two small interpretive points help avoid over-reading Theorem 88:*

1. *The conclusion is logically one-way: $\Sigma(f) > e$ forces coupling, but $\Sigma(f) = e$ does not, by itself, certify that the mechanism is independent in any stronger empirical sense. It only says that, under the chosen evaluator ι and within the residuation structure being used, no* multiplicative surplus *was detected relative to the factorized baseline.*

2. *The phrase "when the residual exists" matters in practice. In fully residuated settings (e.g., standard quantales) it always exists, but in weaker settings one may only have partial residuals. In such cases, the theorem should be read as applying on the domain where $\multimap$ is defined, i.e., where a canonical "gap element" can be formed.*

These points do not weaken the theorem; they clarify that the force of the result lies in turning a surplus in evidence into a structural claim about the necessity of explicit coupling mechanisms.

Proof. (1) If $f \in \mathcal{A}$, it has no cross-channel coupling and therefore factorizes as $f = f_A \otimes f_B$. By strong monoidality on $\mathcal{A}$, $\iota(f) = \iota(f_A \otimes f_B) = \iota(f_A) \otimes \iota(f_B) = I_{ind}$. Thus $\Sigma(f) = I_{ind} \multimap I_{ind} = e$ by the residuation law.

(2) Contrapositive: if $f \in \mathcal{A}$ then $\Sigma(f) = e$ by (1). Therefore if $\Sigma(f) > e$, $f \notin \mathcal{A}$, i.e., f uses at least one multi-ary generator (Route B). □

Remark 3010 (What is doing the work in the proof)**.** *The key step in (1) is that "no cross-channel coupling" is not merely an intuitive claim about separability, but is captured syntactically by membership in the independence fragment $\mathcal{A}$, where every term is built from unary operations and tensoring, never from genuinely multi-ary generators. In that fragment the tensor product $f_A \otimes f_B$ is not an approximation but an exact normal form.*

The step $\iota(f_A \otimes f_B) = \iota(f_A) \otimes \iota(f_B)$ is exactly where strong monoidality enters: it asserts that the evidence translation ι respects the independence structure on the nose *(rather than only up to inequality or up to a slack variable). Once this holds, the residual $\Sigma(f)$ becomes a purely order-theoretic "difference" between identical points, and residuation forces it to be the monoidal unit e.*

Finally, the contrapositive direction (2) is best read as a certificate *statement: a strictly non-trivial residual $\Sigma(f) > e$ witnesses that some coupling operation must have been used somewhere in the construction of f, because the fragment $\mathcal{A}$ has no mechanism for producing such residuals. In other words, $\Sigma(f)$ is an algebraic obstruction to explaining the behavior with independence-only structure.*

Proof sketch. The strategy is to show that, on the independence fragment, evidence is exactly multiplicative, hence the residual between the factorized baseline and the actual evidence must be the identity element e. The second part is then immediate by contrapositive reasoning: anything that produces a nontrivial residual cannot lie in the fragment. One can visualize $\Sigma(f)$ as the "gap" between two points in an ordered evidence space: the factorized point and the true point; strong monoidality collapses this gap to zero unless a coupling is present. □

Remark 3011 (Operational reading of $\Sigma(f)$)**.** *One can think of $\Sigma(f)$ as measuring the extent to which a purportedly modular explanation fails to account for observed joint structure. If $\Sigma(f) = e$, then the "independence baseline" I_{ind} is already sufficient to explain the evidence produced by f under ι. If $\Sigma(f) > e$, then there is irreducible joint structure not captured by the baseline, and any attempt to fit the phenomenon using only tensor-separable components necessarily leaves a positive residual. This is the formal sense in which synergy/emergence can be treated as* detectable dependence*: it is not just that a coupling might exist, but that the algebra forces its presence in any generating explanation.*

Remark 3012. *Theorem 88 is the clean logical bridge:* observed synergy/emergence *is evidence that an independence-only explanation is impossible. This is exactly the "independence pivot" shared by our Hyperseed based tradeoffs and the tradeoff theorem: to explain synergy you must pay for dependence (Route B), while to preserve broad weakness you prefer independence (Route A).*

53.2.3 Residual dependence as a global certificate for approximate independence

Definition 483 (Residual dependence as total correlation (numeric instantiation))**.** *Let random variables $X_1, \ldots, X_n$ have joint law P. Define the total correlation (multi-information)*

$$TC(X_1, \ldots, X_n) := D\left(P \,\|\, \prod_{i=1}^{n} P_{X_i}\right),$$

where $D(\cdot\|\cdot)$ is KL divergence. Interpret TC as a numeric instance of residual dependence ρ / ResDep (up to scaling).

Remark 3013 (Equivalent forms and basic properties)**.** *Besides its KL form, TC admits the familiar entropy identity*

$$TC(X_1, \dots, X_n) = \sum_{i=1}^{n} H(X_i) - H(X_1, \dots, X_n),$$

whenever the entropies are well-defined. This makes explicit why $TC \geq 0$: joint entropy can never exceed the sum of marginal entropies, and equality holds exactly in the product case. For $n = 2$, $TC(X_1, X_2) = I(X_1; X_2)$, so total correlation really is the natural multi-variate extension of mutual information.

From the present viewpoint, these identities clarify the role of TC as a single global slack variable *for independence: it quantifies how much "extra compression" becomes possible when encoding the tuple jointly rather than independently. This aligns with interpreting ResDep as the residual joint structure left over after applying independence-enforcing design choices (Route A), because any such choices are precisely attempts to make the joint behave as though it were near-product.*

Remark 3014 (Intuition and relationship to independence)**.** *The quantity TC measures how far the joint law P is from being a pure product of its marginals. If $TC = 0$, the variables are mutually independent; as TC grows, the joint law carries more irreducible dependence that cannot be explained by looking at each marginal alone. Thus TC is a scalar certificate of "how much dependence remains" after any independence-enforcing transforms (Route A) have been applied.*

This definition is useful here because it turns the vague phrase "residual dependence is small" into a concrete numeric statement that can be estimated, bounded, or optimized. It anchors the conceptual notion of Dependency *(Hyperseed-Concept 93) in standard information-geometric distance, and it connects naturally to mutual information bounds (Hyperseed-Concept 117).*

Theorem 89 (Residual dependence upper-bounds every cross-partition dependence)**.** *For any partition of indices into disjoint sets A, B,*

$$I(X_A; X_B) \leq TC(X_1, \dots, X_n).$$

Remark 3015 (What the theorem says and why it is powerful)**.** *The theorem says that TC is a* uniform *dependence bound: once you know the total correlation is small, you automatically know that* every *bipartition has small mutual information. This is stronger than bounding $I(X_A; X_B)$ for one particular split: it gives a global "permission slip" to treat any chosen modularization as approximately independent.*

In the Route A vs Route B dialectic [9], this means that one can spend effort to reduce a single global quantity TC, and thereby justify a whole family of independence approximations used by tractable inference and modular architectures. It is a particularly clean example of how independence acts as a pivot variable between explanation quality and computational feasibility.

Remark 3016 (A convenient corollary for "approximate modularity")**.** *A direct corollary is: if $TC(X_1, \dots, X_n) \leq \varepsilon$, then for every split (A, B) we have $I(X_A; X_B) \leq \varepsilon$. Thus a single certificate controls* all *modular decompositions simultaneously. When combined with standard inequalities relating KL divergence to other discrepancy measures (e.g. via Pinsker-type bounds), one can further convert a small-TC assumption into quantitative statements that the joint P_{X_A, X_B} is close to the product $P_{X_A} P_{X_B}$ in stronger norms, giving explicit error bars for independence-based approximations. This is exactly the kind of bound needed to make "Route A works well" into a falsifiable, checkable condition rather than a qualitative slogan.*

Proof. Let $Q := \prod_{i=1}^{n} P_{X_i}$ be the fully factorized product. Let π be the marginalization map onto the block variables (X_A, X_B). Then $\pi(P) = P_{X_A,X_B}$ and $\pi(Q) = P_{X_A} P_{X_B}$. By the data-processing inequality for KL divergence,

$$D(\pi(P) \,\|\, \pi(Q)) \le D(P \,\|\, Q).$$

The left-hand side is $D(P_{X_A,X_B} \,\|\, P_{X_A} P_{X_B}) = I(X_A; X_B)$ and the right-hand side is $TC(X_1, \dots, X_n)$. Hence $I(X_A; X_B) \le TC(X_1, \dots, X_n)$. □

Remark 3017 (Why marginalization is the right map)**.** *The map π forgets internal structure within A and within B and retains only the two-block joint. If dependence is already small in the stronger sense of being close to the* fully *factorized product Q, then it must remain small after any such forgetting operation. The data-processing inequality formalizes this monotonicity: coarse-graining cannot create information-geometric separation that was not already present. This is the same monotonic intuition underlying many "no free dependence" principles: one cannot manufacture cross-module coupling merely by relabeling or discarding variables; coupling has to come from the underlying joint law.*

Proof sketch. The proof is a one-line application of functoriality of information: pushing a distribution through a map (here, marginalization π) cannot increase KL divergence. Since mutual information is exactly the KL divergence between a joint and the corresponding product of marginals, and since TC is the KL divergence to the fully factorized product, the inequality follows immediately. Visually: TC is a distance from P to the product manifold; projecting onto any bipartition cannot increase that distance, so each bipartition's distance (mutual information) is bounded. □

Remark 3018 (Decision tool)**.** *If a reasoning system can maintain (or estimate) a small residual-dependence budget, Theorem 89 justifies treating* any *chosen partition of the world-model as approximately independent (bounding the error by the same certificate), which is exactly the Route-A logic behind many tractable approximations.*

Remark 3019 (Connection back to synergy and the upcoming incompatibility bound)**.** *In the present section, TC plays the numeric role analogous to $\Sigma(f)$: both are "residual" quantities that vanish under perfect independence and become strictly positive exactly when some coupling is present. This makes TC a natural quantitative knob for the next step, where we want an explicit statement of incompatibility between (i) enforcing broad weakness via near-independence (small residual dependence) and (ii) realizing genuine synergy/emergence, which requires a nontrivial residual. The next subsubsection makes this tension explicit by turning the independence pivot into a concrete inequality of the form "high synergy implies non-negligible dependence," thereby linking the abstract tradeoff-theorem logic to an information-theoretic certificate.*

53.2.4 Weakness vs synergy: an explicit incompatibility bound

Theorem 90 (Weakness–synergy incompatibility (quantale form))**.** *Let f be a circuit, with weakness $W(f) = \iota(f) \otimes \phi(\kappa(f))$. Fix an evidence target $\iota(f) \ge I_\infty \otimes \varepsilon^{-1}$ (tolerance ε). Assume (as in the Dichotomy) that meeting this target forces either:*

- *Route A: $\kappa(f) \ge K_{transform}(\varepsilon)$, or*
- *Route B: f uses multi-ary couplings, with per-use costs c_j and counts $N_j(f)$.*

Then any circuit meeting the evidence target must satisfy the upper bound

$$W(f) \leq \left(I_\infty \otimes \varepsilon^{-1}\right) \otimes \max \left\{ \phi(K_{transform}(\varepsilon)),\ \bigotimes_{j \geq 2} \phi(c_j \otimes N_j(f)) \right\}.$$

In particular, for any desired weakness level W_0 strictly above the right-hand side, no circuit can simultaneously achieve evidence $\geq I_\infty \otimes \varepsilon^{-1}$ and weakness $\geq W_0$ without violating the Dichotomy constraints.

Remark 3020 (Quantale-level reading of the bound)**.** *The displayed inequality should be read as an "envelope" constraint: the achievable weakness at evidence level ε is bounded above by the larger of two ceilings, one induced by transform cost and one induced by explicit coupling cost. The $\max\{\cdot,\cdot\}$ here is the join in the ambient order used to compare penalties, so the statement is invariant under the choice of concrete representation (e.g., max-plus, min-plus, log-domain, or multiplicative semiring) as long as $\otimes$ and the order are the ones used to define W. In particular, if one works in a log-parameterization where $\otimes$ becomes addition and the order is the usual $\leq$, then the bound takes the familiar "evidence term plus cost-penalty term" shape, with the join becoming an ordinary maximum of additive penalties.*

Remark 3021 (Intuitive content and connection to weakness theory)**.** *This theorem says that once you fix a stringent evidence target, the weakness $W(f)$ becomes upper-bounded by whichever route you take to achieve that target. If you enforce independence (Route A), you pay in transform cost; if you model dependence (Route B), you pay in coupling cost. Either way, the penalty bridge ϕ converts that cost into a weakness discount. Thus there is a genuine incompatibility between "very demanding evidence" and "very broad weakness", unless one relaxes the dichotomy assumptions.*

This formalizes, in the route framework, the general moral of weakness-based regularization [3, 2]: pushing for sharper fit (here encoded by ε^{-1}) tends to require more contrivance, and contrivance lowers weakness. The statement is not about psychological weakness but about an order-theoretic tradeoff between evidential strength and the cost of the mechanism producing it (Hyperseed-Concept 202, Hyperseed-Concept 100).

One useful way to connect this to the dependence dichotomy is to interpret "synergy" as the part of ι that cannot be produced by a purely factorized mechanism without either (i) increasing the complexity of the factorization itself (Route A), or (ii) admitting explicit cross-factor couplings (Route B). On this reading, the theorem is precisely a statement that synergy-driven evidence requirements cannot coexist with high weakness unless one is willing to "spend" the needed resources somewhere, and ϕ is the formal device that ensures such spending reduces achievable weakness.

Proof. If Route A holds, monotonicity of ϕ on Q_{comp}^{op} gives $\phi(\kappa(f)) \leq \phi(K_{transform}(\varepsilon))$ and hence $W(f) = \iota(f) \otimes \phi(\kappa(f)) \leq \iota(f) \otimes \phi(K_{transform}(\varepsilon)) \leq (I_\infty \otimes \varepsilon^{-1}) \otimes \phi(K_{transform}(\varepsilon))$. If Route B holds, similarly $\phi(\kappa(f))$ is bounded by the (multiplicative) penalty of the used couplings, yielding $W(f) \leq (I_\infty \otimes \varepsilon^{-1}) \otimes \bigotimes_{j \geq 2} \phi(c_j \otimes N_j(f))$. Taking the maximum of the two upper bounds yields the displayed inequality. The final sentence is immediate: if W_0 exceeds both route-wise upper bounds, neither route can realize $(\iota \geq I_\infty \otimes \varepsilon^{-1}) \wedge (W \geq W_0)$.

For avoidance of doubt about the order direction: since ϕ is taken monotone on Q_{comp}^{op}, larger underlying cost (in Q_{comp}) produces smaller (or equal) penalty factors in the target order used for weakness. Thus Route A's lower bound $\kappa(f) \geq K_{transform}(\varepsilon)$ becomes an upper bound after applying ϕ. Likewise, in Route B the aggregate coupling contribution (here written as $\bigotimes_{j \geq 2} \phi(c_j \otimes N_j(f))$) is the penalty factor corresponding to the total coupling resources consumed, and this penalty factor plays the same formal role as $\phi(\kappa(f))$ in the definition of $W(f)$. $\square$

Proof sketch. The proof is a case split on the dichotomy: either the system paid transform cost (Route A) or it paid coupling cost (Route B). In each case, monotonicity of the penalty bridge ϕ yields an upper bound on $\phi(\kappa(f))$, and multiplying by the evidence target gives an upper bound on $W(f)$. Conceptually, one draws two ceiling curves for achievable weakness as a function of ε, one per route, and then takes their maximum: above that envelope, the constraints are jointly infeasible. □

Remark 3022. *Theorem 90 is a direct formalization of the above "decision tool" idea: you cannot demand simultaneously (i) very broad independence commitments (high weakness) and (ii) very strong evidential constraints (often driven by synergy/dependence) without paying either transform cost (Route A) or coupling cost (Route B).*

Remark 3023 (A convenient corollary for "hard" evidence targets)**.** *If the evidence target is made more stringent (smaller ε) in a regime where either $K_{transform}(\varepsilon)$ is increasing or the required coupling multiplicities $N_j(f)$ must increase, then the right-hand side decreases (in the weakness order) provided ϕ is strictly order-reversing on the relevant range. In that common regime, demanding asymptotically sharp evidence forces an asymptotic collapse of achievable weakness, making the incompatibility quantitative rather than merely qualitative. This is the sense in which the theorem packages the tradeoff theorem intuition into an architectural constraint: the frontier cannot be pushed outward in both coordinates without violating at least one route constraint.*

53.2.5 Equalized-marginals beyond two routes

Theorem 91 (Multi-route equalized marginals (a k-way control law))**.** *Suppose a system has $k \geq 2$ disjoint "knobs" (fragments) that can receive resource budget, where knob i produces an attainable tradeoff curve $(K_i(u_i), I_i(u_i))$ as a function of its allocated budget u_i, and overall (K, I) is obtained by composing the knobs in the product quantale order (so that increasing any u_i weakly increases cost and weakly increases evidence). Assume a single total-budget constraint $\sum_{i=1}^{k} u_i = U$.*

At any Pareto-efficient operating point with all k knobs active, there exist positive multipliers μ, λ such that for every i and j,

$$\mu \cdot \frac{\partial K}{\partial u_i} = \lambda \cdot \frac{\partial I}{\partial u_i}, \qquad \text{and hence} \qquad \frac{\partial I/\partial u_i}{\partial K/\partial u_i} = \frac{\partial I/\partial u_j}{\partial K/\partial u_j}.$$

Equivalently: marginal evidence per unit marginal effective cost is equalized across all active knobs.

Remark 3024 (Regularity conditions and relation to KKT)**.** *The derivative notation implicitly assumes a local smoothness/regularity regime: $u \mapsto K(u)$ and $u \mapsto I(u)$ should be differentiable (or at least admit appropriate subgradients), and "all k knobs active" means the solution is interior with respect to any nonnegativity constraints $u_i \geq 0$ (if such constraints are present). Under these conditions, the statement is a direct KKT/Lagrange-multiplier condition for Pareto efficiency: one may view Pareto points as solutions of maximizing $I(u)$ subject to fixed $K(u)$ and $\sum_i u_i = U$ (or dually minimizing $K(u)$ at fixed $I(u)$ and budget). The positivity of multipliers corresponds to the economically meaningful regime in which increased budget can trade cost for evidence rather than reversing direction. If some knob is inactive (e.g., $u_i = 0$ at optimum), the equalization becomes an inequality: its marginal evidence-per-cost cannot exceed the common active value, otherwise it would become profitable to turn that knob on.*

Remark 3025 (Interpretation as a design principle)**.** *This theorem is the familiar equal-marginal-returns principle, stated in the language of multi-route architecture choice. It says: if you are truly* *on the Pareto frontier, you cannot improve evidence more cheaply by reallocating an infinitesimal budget from one knob to another. So the "exchange rate" between cost and evidence must be the same everywhere you are actively investing.*

Its relevance to independence is direct: in practice, the knobs include multiple independence-promoting moves (Route A transforms) and multiple dependence-admitting moves (Route B couplings). Thus equalized marginals becomes a principled control law for how much independence to enforce, and where to place explicit couplings, when resources are limited (Hyperseed-Concept 87, Hyperseed-Concept 100).

Remark 3026 (How this extends the two-route picture)**.** *In the two-route setting, one informally compares which route yields the better weakness ceiling at a given ε and chooses accordingly. The multi-knob formulation makes that comparison local and compositional: instead of a discrete choice between two routes, one can continuously allocate resources among many route-fragments (some implementing independence constraints, others implementing controlled couplings). Equalized marginals then states that, at an efficient configuration, each active fragment has been tuned until its next unit of resource buys exactly as much marginal evidence-per-cost as every other active fragment. This provides an explicit mechanism-level notion of "balancing independence against dependence": not as a binary decision, but as a distribution of budget across constraint-enforcing and coupling-enabling components.*

Proof. This is the classical KKT condition for maximizing evidence $I(u_1, \ldots, u_k)$ subject to a cost/budget constraint, but it can be derived in the same "pairwise reallocation" spirit as the two-route case: consider feasible perturbations that move an infinitesimal δ budget from knob j to knob i while preserving $\sum u_i$. Pareto efficiency implies no such perturbation can increase evidence without increasing cost in the ordered sense. In smooth numeric regions, this yields a supporting hyperplane with multipliers (μ, λ), and stationarity forces $\mu\, \partial K/\partial u_i = \lambda\, \partial I/\partial u_i$ for each active coordinate i. Dividing gives the equalized ratio across i. □

Proof sketch. The argument is the standard variational one: at an optimal (Pareto-efficient) allocation under a single linear budget constraint, the gradient of the objective must be proportional to the gradient of the constraint. Here, that means ∇I is proportional to ∇K on active coordinates, yielding identical ratios $(\partial I/\partial u_i)/(\partial K/\partial u_i)$ across i. A helpful picture is the tangency of a level set of evidence to a level set of cost: if the tangency failed, one could slide along the cost surface to improve evidence. □

Remark 3027 (Why this matters for independence)**.** *In practice, "knobs" include multiple Route-A transforms (whitening, abstraction, pruning, masking, coarse-graining) and multiple Route-B couplings (attention heads, constraint joins, factor-graph edges, cross-module messaging). Theorem 91 says a system that is near the frontier should allocate effort so that no knob has strictly better marginal return than another.*

53.2.6 From residual dependence to "ignore only weak dependencies"

Definition 484 (Residual dependence with coverage weights)**.** *Let interaction sets S have strengths $\|\kappa_S\|_1 \geq 0$ and coverage factors $\gamma_S \in [0, 1]$. Define*

$$\mathit{ResDep} := \sum_{|S| \geq 2} (1 - \gamma_S)\, \|\kappa_S\|_1.$$

Remark 3028 (Intuition and role in practical reasoning)**.** *This definition abstracts the common situation where a system covers some interactions explicitly and others only partially (or not at* *all). Here γ_S measures how much of interaction S is "accounted for" by the model (so $1-\gamma_S$ is the miss fraction), and $\|\kappa_S\|_1$ measures how strong that interaction is in the underlying domain. The sum is then the total mass of uncovered dependence.*

It is useful because it connects a high-dimensional combinatorics of dependencies into a single scalar certificate. In the Route A vs Route B story, ResDep can be interpreted as the remaining dependence after some combination of Route A transforms and Route B couplings has been applied. It is thus a numerically manageable proxy for Hyperseed-Concept 93 and for the costs of neglecting it.

Theorem 92 (Thresholding lemma: small residual dependence implies only a small mass of strong misses)**.** *Fix $\alpha \in (0, 1]$. Let*

$$\mathcal{M}_\alpha := \{S : |S| \geq 2 \text{ and } (1 - \gamma_S) \geq \alpha\}.$$

Then

$$\sum_{S \in \mathcal{M}_\alpha} \|\kappa_S\|_1 \leq \frac{ResDep}{\alpha}.$$

More generally, for any $\tau > 0$,

$$\#\{S : |S| \geq 2,\ (1 - \gamma_S) \geq \alpha,\ \|\kappa_S\|_1 \geq \tau\} \leq \frac{ResDep}{\alpha\,\tau}.$$

Remark 3029 (What the theorem guarantees)**.** *If ResDep is small, then the set of interactions that are both (i) substantially missed and (ii) collectively strong must itself be small. The first inequality bounds the* total strength *of substantially missed interactions; the second bounds the* count *of missed interactions above a strength threshold. So one can justify a working maxim: "assume independence except for a small exceptional set".*

This is precisely the sort of statement an inference engine wants: it translates a global budget into a sparse set of "must-handle" dependencies, which is a practical guide for when to activate Route B couplings and when to remain in an independence approximation (Route A) [9].

Proof. If $(1 - \gamma_S) \geq \alpha$ then each term contributes at least $(1 - \gamma_S)\|\kappa_S\|_1 \geq \alpha\|\kappa_S\|_1$ to $ResDep$. Summing over $S \in \mathcal{M}_\alpha$ gives $ResDep \geq \sum_{S \in \mathcal{M}_\alpha} \alpha\|\kappa_S\|_1$, hence $\sum_{S \in \mathcal{M}_\alpha} \|\kappa_S\|_1 \leq ResDep/\alpha$.

For the counting bound, each S in the set has contribution at least $\alpha\tau$, so $ResDep \geq (\alpha\tau) \cdot \#(\cdots)$, proving the inequality. ☐

Proof sketch. The proof is a bookkeeping argument: each interaction in $\mathcal{M}_\alpha$ must contribute at least an α fraction of its strength to $ResDep$, so the total strength of such interactions cannot exceed $ResDep/\alpha$. For the counting bound, if each such interaction has strength at least τ, then each contributes at least $\alpha\tau$, so there cannot be more than $ResDep/(\alpha\tau)$ of them. Visually, $ResDep$ is a fixed "mass budget", and the theorem says you cannot pack too many heavy, badly-covered interactions into a small mass. ☐

Remark 3030 (Decision tool)**.** *Theorem 92 turns a scalar residual-dependence certificate into a sparse exception-set guarantee: if ResDep is small, then* either *you covered almost all large interactions,* or *the ones you missed have small total strength and can be ignored. This is exactly the operational content of "assume independence except for a small set of strongly dependent interactions".*

53.2.7 Double-counting exposes pruneable couplings

Definition 485 (Double-counting penalty)**.** *Let $m_S \in \mathbb{N}$ be the number of factors containing interaction set S and let $\gamma_S \in [0,1]$ be effective coverage. Define*

$$DC := \sum_{|S|\geq 2} (m_S - \gamma_S)_+ \, \|\kappa_S\|_1.$$

In particular, $(x)_+ := \max\{x, 0\}$ ensures that only excess *modeling beyond effective coverage contributes to the penalty, and $\|\kappa_S\|_1$ serves as an interaction-specific weight capturing the magnitude/importance of the true (or target) dependence at order S.*

Remark 3031 (Intuition and why this definition is necessary)**.** *The quantity DC penalizes paying for the same dependence more than once. If m_S counts how many architectural components attempt to model interaction S, and γ_S measures the effective fraction of S actually covered, then $(m_S - \gamma_S)_+$ is the "redundant excess" modeling devoted to S. Multiplying by $\|\kappa_S\|_1$ weights redundancy by importance.*

This is a formal counterpart of a familiar engineering phenomenon: adding extra couplings can feel like it should help, but in a well-posed tradeoff model, redundant couplings often only add cost and overfitting risk without increasing true coverage. Thus DC supports a principled pruning criterion, mirroring Occam-style pressure encoded via weakness/regularization (Hyperseed-Concept 202) [3].

It is also important that $\gamma_S \in [0,1]$ be interpreted as effective *(not nominal) coverage: two different factors might each claim to address S, but if they are highly correlated in what they capture, the combined effective gain can be much less than the raw count m_S. The positive-part form then implements the modeling principle "you only get paid once" for genuinely covering an interaction set S; additional attempts only avoid penalty to the extent that they increase γ_S.*

Finally, weighting by $\|\kappa_S\|_1$ expresses that redundancy is not uniformly bad: duplicating effort on a near-zero interaction set is nearly harmless, while duplicating effort on a strong interaction is more costly because it invites larger downstream distortion (e.g., conflicting parameterizations, wasted capacity, and brittle coordination among factors).

Remark 3032 (Basic properties of DC (for later use))**.** *The penalty DC is always nonnegative, and it is monotone nondecreasing in each m_S holding γ_S fixed. Conversely, for fixed m_S, increasing γ_S can only decrease (or leave unchanged) the associated term $(m_S - \gamma_S)_+ \, \|\kappa_S\|_1$. In particular, if $\gamma_S = 1$ (full effective coverage) then any additional modeling multiplicity $m_S > 1$ is* pure *double-counting in the sense that it contributes $(m_S - 1)\|\kappa_S\|_1$ to DC without any available "coverage credit" to offset it.*

Theorem 93 (Redundant coupling elimination)**.** *Suppose an architecture A contains a factor F such that removing F strictly decreases m_S for at least one interaction set S but does not decrease any effective coverage γ_T. Let A' be the architecture with F removed. Then:*

1. *$ResDep(A') = ResDep(A)$,*
2. *$DC(A') < DC(A)$,*
3. *for any information-efficiency objective of the form $I(A) = \sum_S \gamma_S G_S - \lambda_{dc} DC(A) - \lambda_{res} ResDep(A)$ with $\lambda_{dc} > 0$, we have $I(A') > I(A)$.*

Hence A cannot be Pareto-efficient in (cost, evidence) order if F has positive cost.

Remark 3033 (Plain-English reading)**.** *If a coupling does not increase what you cover (the γ_T do not improve), then it is pure redundancy. Removing it keeps residual dependence unchanged (you are not missing anything new), strictly reduces double-counting, and therefore strictly improves any objective that penalizes redundancy. If the coupling also costs resources, you improve cost as well, so the original architecture cannot be on the Pareto frontier.*

This theorem supplies a clean decision rule that sits naturally alongside the Route A vs Route B dichotomy [9]: Route B couplings are not sacred; they must earn their keep by increasing coverage, otherwise they are dominated and should be pruned.

One useful way to read the conclusion is that the pair $(\{\gamma_S\}, \{m_S\})$ contains all *the information relevant to whether F can be justified under objectives of the displayed form: if removing F leaves γ unchanged, then F is only moving m in a direction that increases redundancy. In this sense the theorem isolates a minimal "certificate of non-utility" for a coupling: it is enough to show that it fails to increase effective coverage for* any *interaction set, not necessarily that it harms performance.*

In the language of dependence modeling, the hypothesis "does not decrease any effective coverage γ_T" encodes that F is not providing a unique pathway to any interaction set; equivalently, every dependence contribution that F was intended to capture is already captured (up to the model's tolerance) by other factors. The conclusion then formalizes the modeling heuristic that non-identifiable or linearly dependent couplings should be removed even if they are individually expressive, because expressiveness that does not translate into new effective coverage is exactly what produces double-counting.

Proof. By assumption, all γ_T are unchanged, so $ResDep$ (a function of the γ_T) is unchanged. Also, $(m_S - \gamma_S)_+$ strictly decreases for at least one S (because m_S decreases and γ_S is fixed) and does not increase for any S, hence DC strictly decreases. With $\lambda_{dc} > 0$ and $ResDep$ unchanged, the objective $I(\cdot)$ strictly increases. If F has positive cost, then A' also weakly improves cost. Thus A is dominated.

To see the strictness of the DC decrease explicitly: there exists at least one set S_0 such that $m_{S_0}(A') < m_{S_0}(A)$ while $\gamma_{S_0}(A') = \gamma_{S_0}(A)$. For this S_0, the map $m \mapsto (m - \gamma_{S_0})_+$ is strictly increasing on $\mathbb{N}$ whenever $m > \gamma_{S_0}$, and it is nonincreasing only when both values lie at or below γ_{S_0}. But the hypothesis that m_{S_0} strictly decreases means the associated summand cannot increase, and because it decreases for at least one S_0 with $\|\kappa_{S_0}\|_1 > 0$ (the only case in which redundancy matters), we obtain $DC(A') < DC(A)$. ☐

Proof sketch. The proof follows the dependencies of the objective on the summaries (γ_S, m_S): if γ_S is unchanged, then $ResDep$ is unchanged. If some m_S decreases while no γ_S decreases, then the positive-part redundancy $(m_S - \gamma_S)_+$ cannot increase and must decrease somewhere, so DC strictly drops. Therefore any objective that subtracts $\lambda_{dc} DC$ strictly improves. The geometric intuition is that redundant couplings move you "inward" from the Pareto frontier: they increase cost without moving the evidence coordinate outward. ☐

Remark 3034. *Theorem 93 is a formal "anti-overfitting" rule: if a coupling does not buy you additional coverage (evidence) it must be removed at any frontier point. This is the Route-B analogue of Route-A simplification/pruning.*

Equivalently, for Pareto-efficient architectures under objectives that penalize DC, every retained factor must be witnessed *by at least one interaction set whose effective coverage would strictly drop if the factor were removed. This witness condition is a convenient design-time diagnostic: factors that have no witness are precisely those that can be eliminated without sacrificing evidence, and thus correspond to "spurious dependence structure" rather than authentic interaction modeling.*

Remark 3035 (Connection to the tradeoff theorem viewpoint). *Within the dependence dichotomy, Route A aims to make γ_S large by pushing dependence into a representation change, whereas Route B aims to make γ_S large by adding explicit coupling structure. Theorem 93 clarifies that Route B must still obey a tradeoff-theorem-style accounting: if adding structure increases m_S without increasing γ_S, then it worsens the balance of cost versus evidence in a way that cannot be recovered elsewhere in the objective. In this sense, the* independence pivot *shows up as a bookkeeping invariance: once effective coverage is fixed, additional dependence machinery has no principled justification and is guaranteed to be dominated.*

53.2.8 A quantitative route-choice threshold (when should a system enforce independence vs model dependence?)

Theorem 94 (Critical-order threshold from arity-growth vs transform costs). *Consider a size-n system with interaction order r and per-arity coupling costs producing a lower bound*

$$K_B(r) := \Omega\left(\sum_{j=2}^{r} \binom{n}{j}\right)$$

for Route B (explicitly realizing interactions up to order r). Assume Route A (decorrelation/independence transform) yields a lower bound

$$K_A := \Omega(nd) + K_{transform}(\varepsilon)$$

for some representation dimension d and tolerance ε.

Then any algorithm achieving the evidence target must incur cost at least

$$K_{\min} \geq \min\{K_A,\, K_B(r)\}.$$

Moreover, if $K_{transform}(\varepsilon)$ and d are fixed while r grows, there exists a (problem-dependent) critical order $r^\star$ such that:

$$K_B(r) < K_A \text{ for } r < r^\star, \qquad K_B(r) > K_A \text{ for } r > r^\star.$$

Remark 3036 (Meaning: when dependence becomes too expensive). *This theorem distills an architectural threshold phenomenon: representing dependence explicitly becomes combinatorially expensive as interaction order grows. At low order r, explicit couplings (Route B) can be economical; at high order, the number of possible interactions explodes (the binomial sum), and it becomes cheaper to pursue independence-enforcing representations (Route A) that reduce the effective dependence order.*

The result is not a fine-grained performance bound but a structural compass: it tells you which side of the dichotomy is likely to dominate as the domain's required interaction order increases. This connects naturally to Dependency-Tower reasoning (Hyperseed-Concept 94) and to the general tradeoff theorem heuristics developed in [8, 9].

A useful quantitative reading of the Route B lower bound is that, for moderate $r \ll n$, the leading term of $\sum_{j=2}^{r} \binom{n}{j}$ scales on the order of $n^r/r!$ (up to polynomial factors in r), so even when each individual coupling is "cheap," the sheer count of distinct interaction subsets makes high-order dependence modeling expensive. By contrast, Route A aggregates the burden into (i) a linear-in-n representational cost $\Omega(nd)$ and (ii) a transform-dependent overhead $K_{transform}(\varepsilon)$ capturing how hard it is to achieve approximate independence to tolerance ε.

The phrase "problem-dependent" for $r^\star$ is essential: $K_{transform}(\varepsilon)$ may itself be large in domains where decorrelation requires iterative optimization, global coordination, or expensive normalizations, and d may need to scale with n to preserve sufficient information. In such regimes, K_A can grow, moving the threshold $r^\star$ upward and making Route B favorable over a wider range. Conversely, when a domain admits a fast independence transform (small $K_{transform}$) and a compact representation (small d), the threshold $r^\star$ can be low, making Route A preferable already at modest interaction orders.

Interpreted through the independence pivot lens, the theorem explains why *enforcing independence can be the correct move even in a highly dependent world: once the required interaction order crosses the critical point, the cheapest way to meet an evidence target is often to restructure the system so that the remaining modeled interactions are effectively lower-order, thereby avoiding the combinatorial explosion inherent in explicit high-arity coupling families.*

Proof. The first inequality is immediate from the dichotomy: any feasible method must satisfy at least one route-wise lower bound, hence must pay at least their minimum. More explicitly, if Route A yields a necessary cost K_A for any method that proceeds by reducing effective dependence (e.g. via factorization, representation changes, or independence-promoting transforms), and Route B yields a necessary cost $K_B(r)$ for any method that directly models dependence of order r, then every admissible method falls into (at least) one of these regimes; consequently its cost is bounded below by K_A or by $K_B(r)$, and therefore by $\min\{K_A, K_B(r)\}$.

For the threshold statement: $K_B(r)$ is monotone increasing in r and grows combinatorially in r for fixed n, while K_A is independent of r in this simplified comparison. Therefore the inequality $K_B(r) \le K_A$ holds for r in an initial interval and fails beyond some largest $r^\star$ (or never holds / always holds in degenerate cases). To make the monotonicity implication explicit: since $K_B(r)$ is nondecreasing, the set

$$S := \{r \in \{0, 1, 2, \dots\} : K_B(r) \le K_A\}$$

is a (possibly empty) initial segment of the nonnegative integers; hence either $S = \varnothing$, or S is all admissible r, or there exists a maximal element $r^\star := \max S$ which is the claimed threshold. The "combinatorial growth" condition ensures that, in typical nondegenerate settings, $K_B(r)$ eventually exceeds any fixed K_A for sufficiently large r (e.g. if $K_B(r)$ scales like $\binom{n}{r}$, n^r, or related families), which guarantees finiteness of $r^\star$ unless K_A is itself large enough to dominate throughout. $\square$

Proof sketch. The proof is an order-of-growth comparison. The dichotomy implies you must pay at least one of the route-wise costs, hence at least their minimum. A useful way to view this is to regard K_A and $K_B(r)$ as two lower envelopes induced by two incompatible design commitments: Route A commits resources to suppressing or "explaining away" dependence so that downstream reasoning can be done with (approximate) independence, whereas Route B commits resources to representing and exploiting dependence explicitly up to order r.

Then, as r increases, the Route B lower bound increases monotonically and rapidly (combinatorial growth), while the Route A bound is held fixed in r; so a crossing point (critical order) must occur unless one curve dominates everywhere. One can picture two curves in r: a flat (or gently rising) Route A curve and a steep Route B curve; the intersection defines $r^\star$.In more concrete terms, if $K_B(r)$ behaves like the number of r-wise interaction terms that must be tracked (e.g. proportional to $\binom{n}{r}$ times a per-interaction cost), then even modest increases in r can cause a sharp escalation in $K_B(r)$, whereas the Route A cost is governed primarily by the difficulty of finding an independence-inducing representation and does not scale directly with the requested interaction order in this stylized comparison. $\square$

Remark 3037 (Decision tool)**.** *Theorem 94 is a direct "architectural switch" criterion: if the dependence order required by the task is low, it is cheaper to model it (Route B); if it is high, it is cheaper to reduce effective dependence via representation/independence transforms (Route A). Equivalently, $r^\star$ marks the point at which it becomes rational (in a cost-minimizing sense) to spend effort* upstream *on making the problem closer to independent rather than spending it* downstream *on enumerating ever higher-order interactions. In practice, the criterion can be applied qualitatively even when the exact constants are unknown: one estimates whether the task's necessary interaction order lies in a regime where $K_B(r)$ is still modest (so explicit dependence modeling is viable) or in a regime where it already exhibits the rapid growth that typically makes dependence-first designs brittle.*

53.3 Summary

Independence is the common latent variable connecting Hyperseed-ish tradeoffs and the tradeoff theorem:

- Glue overhead bounds attainable intensity (Lemma 161).
- Synergy/emergence is a witness that independence-only explanations are impossible (Thm. 88).
- Small residual dependence globally certifies approximate independence across any partition (Thm. 89).
- Weakness and strong evidence targets conflict unless one pays a route-specific cost (Thm. 90).
- Frontier behavior demands equalized marginal returns across all independence/coupling knobs (Thm. 91).
- Double-counting reveals pruneable couplings (Thm. 93).
- A critical interaction-order threshold determines when Route A vs Route B dominates (Thm. 94).

Read as a single thread, these items say that "independence" is not merely a modeling convenience but a quantity that can be budgeted, certified, and traded against task demands: it can be enforced (at a cost), violated (and detected by synergy), and approximately guaranteed (via global dependence control). In particular, the route-wise lower bounds provide a way to translate qualitative design choices (factorize vs. couple) into quantitative commitments, and the threshold theorem turns that translation into a concrete switching rule once a task-implied interaction order is estimated.

Remark 3038. *Taken together, these results aim to turn a conceptual duality into operational guidance. Route A and Route B are not rival ideologies but complementary instruments; what changes from problem to problem is the price of independence and the price of dependence. The theorems above give certificates and thresholds that let a reasoning system decide when to factorize, when to couple, when to prune, and how to allocate marginal effort. In this sense, independence functions as a regulative ideal in the Russellian sense—a constraint that disciplines inference—yet it is also, in a more Peircean mode, a fallible hypothesis whose failure is detected by emergent synergy (Hyperseed-Concept 190, Hyperseed-Concept* **??***) [14]. One can also view the collection as a calibration of where "independence assumptions" should live in the stack: Route A makes independence an* achievement *of representation (thereby paying for it explicitly), while Route B makes dependence an* object *of representation (thereby paying for it combinatorially as order increases).*

The pivot is that both perspectives meet at the same diagnostic quantities—residual dependence, synergy, and marginal tradeoff conditions—so that the choice between them can be made on the basis of observable certificates rather than on stylistic preference.

54 Habit Webs + Morphic Resonance: Fixed Points, Polarization, and Diffusion Thresholds (with Random-Graph Corollaries)

We treat a habit web as a quantale-valued reinforcement relation (kernel) on a pattern class, with state evolution given by an order-theoretic update operator. Morphic resonance couples multiple contexts by adding cross-context kernels. We prove: (i) existence and computation of least fixed points for time-homogeneous habit dynamics (single- and multi-context), (ii) a block-kernel reduction that turns morphic resonance into ordinary closure on a single enlarged web (hence diffusion becomes reachability/closure), (iii) a nucleation theorem: sufficient conditions under which resonance seeds a self-weaving (autocatalytic) core that persists even after coupling ceases, (iv) a synchronization/no-polarization criterion under global contractivity, and (v) random-graph thresholds for (minimal) autocatalytic cores and for macroscopic diffusion of habit support.

Concretely, the ambient value structure is a quantale $(V, \oplus, \otimes, \leq)$: $\oplus$ is an (often complete) join encoding accumulation of reinforcing evidence, while $\otimes$ propagates (and typically attenuates or transforms) support along a directed interaction. A "kernel" is thus a V-weighted relation on patterns, and a state $s : P \to V$ is a valuation assigning to each pattern its current degree of activation, credibility, or habit-strength. The update operator is monotone in the order on V^P and is designed so that one update-step corresponds to one round of reinforcement propagation through the web. Time-homogeneity means that the kernel (and any parameters of the update rule) remain fixed across steps, allowing the asymptotic behavior to be captured by fixed points and their least solutions.

Items (i)–(v) can be read as a progression from purely order-theoretic guarantees to structural reductions and then to probabilistic corollaries. The fixed-point results formalize "settled habits" as post-update states s satisfying $s = F(s)$, with least fixed points representing minimal stable support compatible with the reinforcement structure. The block-kernel reduction provides a way to treat a family of contexts (each with its own pattern set and internal kernel) as a single enlarged web, so that questions about cross-context diffusion reduce to closure/reachability computations in an ordinary single kernel. The nucleation theorem isolates conditions under which a transient coupling can create a persistent core: after the coupling is removed, internal reinforcement within the core is sufficient to maintain nontrivial support. The contractivity criterion addresses when repeated updates erase initial differences (synchronization) rather than amplifying them into incompatible attractors (polarization). Finally, the random-graph thresholds connect these qualitative phenomena to typical-case behavior in sparse regimes, identifying critical densities at which autocatalytic cores and large-scale diffusion emerge with high probability.

Remark 3039. *Philosophically, the guiding idea is that "habit" is not here a psychological metaphor but a mathematical dynamical object: a state $s : P \to V$ assigning graded support to patterns, and a kernel A that propagates and reinforces that support through a web of interactions. The quantale structure supplies the two basic moves: (i)* aggregation *of evidence/support (via $\oplus$ as a join), and (ii)* combination *of supports along a causal/reinforcing link (via $\otimes$). This is aligned with the general quantale weakness viewpoint developed in [3], and with Hyperseed's pattern-centric ontology [1, 5] (Hyperseed-Concept 130, 132, 131). In particular, treating s as a map into an ordered* *support domain makes comparison and convergence statements precise: one can ask whether a later state is* at least as supportive *as an earlier one, whether an update operator is inflationary or deflationary, and whether iterative closure stabilizes in finitely or transfinitely many steps. This formalization also clarifies how "weak" signals can accumulate through repeated joins while still requiring compatible pathways (via $\otimes$) to travel across the web.*

Remark 3040. *The phrase "morphic resonance" is used in a deliberately formalized sense: cross-context kernels $K_{\ell' \to \ell}$ are treated as additional reinforcement channels, mathematically no different from internal reinforcement except for their block structure. This abstraction echoes Sheldrake's original proposal [13] but is deployed here as a rigorous order-theoretic dynamical system (Hyperseed-Concept 115, 159, 86). Operationally, the block structure is what preserves interpretability: each context ℓ retains its own internal dynamics, while cross-context influence is mediated by explicitly typed maps $\ell' \to \ell$ rather than by an undifferentiated global kernel. The reduction in (ii) shows that, despite this bookkeeping, the coupled system can be analyzed using the same closure and fixed-point tools as a single-context web by passing to a suitable direct sum (or coproduct-like) pattern space. In this sense, "resonance" is not an extra dynamical principle but a compositional way to assemble kernels so that inter-context diffusion and persistence questions become statements about the existence of closed, self-supporting substructures in the enlarged web.*

54.1 Background

54.1.1 Quantale-valued habit webs

Fix a commutative quantale $(V, \leq, \oplus, \otimes, e)$. Let P be a (finite) pattern class. A pattern-support state is a function $s : P \to V$. A reinforcement relation (kernel) is a map $A : P \times P \to V$.

Remark 3041. *A few notational conventions are doing substantial work here. The set P is the universe of "patterns" under discussion; one can picture P as the vertex set of a directed weighted graph. The quantale value V is the space of support/evidence/activation values, ordered by $\leq$; the operation $\oplus$ is the join (think: "take the strongest support available"), and $\otimes$ combines supports along a link (think: "support transmits through an edge, attenuated or transformed by the edge weight"). The unit $e \in V$ is the neutral element for $\otimes$ (so $e \otimes v = v$).*

Remark 3042. *Concrete examples to keep in mind:*

- *Boolean case: $V = \{0, 1\}$, $\oplus = \vee$, $\otimes = \wedge$, $e = 1$. Then $s(p) = 1$ means "pattern p is present/active", and $(A?s)(q) = 1$ iff there exists some p with $A(p, q) = 1$ and $s(p) = 1$.*
- *Max-times case: $V = [0, 1]$, $\oplus = \max$, $\otimes = \cdot$, $e = 1$. Then $A(p, q)$ is a strength of reinforcement from p to q, and $(A?s)(q)$ is the strongest incoming reinforced support for q.*

These examples recur below when we discuss thresholds, diffusion, and random graphs.

Definition 486 (Relational image)**.** *Given $A : P \times P \to V$ and $s : P \to V$, define the image (one-step propagation)*

$$(A?s)(q) := \bigoplus_{p \in P} A(p, q) \otimes s(p).$$

Remark 3043. *Intuitively, $(A?s)(q)$ is the amount of support that flows into pattern q in one step, assuming each pattern p currently holds support $s(p)$ and transmits it along the link $p \to q$ with strength $A(p, q)$. The symbol "?" is meant to evoke a relational action: A acts on s much like a matrix acts on a vector, except with $\oplus$ and $\otimes$ playing the roles of addition and multiplication.*

Remark 3044. *A simple example: in the Boolean case, $(A?s)(q) = 1$ iff q has at least one active predecessor p with an edge into q. In the max-times case, $(A?s)(q) = \max_p A(p,q)\,s(p)$, i.e. the best incoming reinforcement signal. This operator is useful because it isolates the purely structural part of the dynamics (the kernel A) from the contingent part (the present state s), letting us study fixed points, closure, and diffusion in a uniform algebraic language.*

Definition 487 (Habit update operator)**.** *Fix decay/persistence $d \in V$ and an external input $u : P \to V$. Define*

$$\mathrm{Upd}_{A,d,u}(s) := u \oplus (d \odot s) \oplus (A?s),$$

where $(d \odot s)(p) := d \otimes s(p)$ and $\oplus$ on functions is pointwise join.

Remark 3045. *The update $\mathrm{Upd}_{A,d,u}$ separates three influences on the next state. The term u is exogenous stimulation (new evidence, new rewards, new experiences). The term $(d \odot s)$ is persistence/decay: it scales the old support s by a factor d using $\otimes$ (so in $[0,1]$ with $\otimes = \cdot$, this is literal multiplication by d). Finally $(A?s)$ is reinforcement by the web itself. The pointwise join $\oplus$ expresses the principle "keep whichever source provides stronger support" (or more generally, take the least upper bound in the lattice ordering).*

Remark 3046. *Two small examples illustrate why this definition is the right granularity for later theorems.*

- *If $u = \bot$ and $d = e$, then $\mathrm{Upd}(s) = s \oplus (A?s)$, i.e. pure inflationary closure under the web: once support appears, it can only accumulate via propagation.*
- *If $A = \bot$ and u is constant, then $\mathrm{Upd}(s) = u \oplus (d \odot s)$ describes a decaying memory forced by a baseline signal u.*

Formally, these cases are precisely those in which least fixed points can be read as closures or steady states, which connects directly to the Kleene iteration theorem below and to fixed-point stability ideas familiar from self-modifying goal dynamics [10].

54.1.2 Self-weaving (autocatalytic) cores

Definition 488 (θ-autocatalytic subset)**.** *Fix a threshold $\theta \in V$. A nonempty $S \subseteq P$ is called θ-autocatalytic if there exists a state $s : P \to V$ such that: (i) for all $p \in S$, $s(p) \geq \theta$; and (ii) for all $p \in S$, $(A?s)(p) \geq \theta$. A web (P, A) is self-weaving at threshold θ if it contains a θ-autocatalytic subset.*

Remark 3047. *This definition formalizes the notion of a "self-sustaining loop" (Hyperseed-Concept 168, 61). The threshold θ expresses a minimum viable level of activation/support: patterns below θ are treated as inert for the purposes of the autocatalytic criterion. Condition (i) says the subset S is jointly active at level θ under some state s; condition (ii) says that the web reinforcement, applied to that same state, regenerates support for every element of S at level θ. In other words, S is not merely co-present; it is collectively maintained by the kernel A.*

Remark 3048. *In the Boolean case $V = \{0,1\}$ and $\theta = 1$, a θ-autocatalytic subset is one where every node in S has at least one incoming edge from within S (since $(A?s)(p) = 1$ demands some predecessor in S). Thus a directed cycle gives a minimal example. In max-times $V = [0,1]$ with $\theta \in (0,1]$, one can think of each node in S receiving an incoming edge of strength at least θ from a node in S that itself is at least θ. The usefulness of the definition is that it pinpoints precisely what must be "seeded" from outside in order for the web to take over and sustain itself: once S is above θ, the internal dynamics can keep it there.*

In slightly more detail, the Boolean condition can be rewritten as $S \subseteq \mathrm{Pre}(S)$, where $\mathrm{Pre}(S)$ is the set of nodes with at least one incoming edge from S. This makes clear that θ-autocatalysis is an *internal support* condition: S does not require external parents to keep its members active once the threshold is met. In graded settings (such as max-times), the same idea appears as a *self-reinforcing lower bound*: if $s(p) \geq \theta$ for all $p \in S$, then the internal image $(A?s)(p)$ provides (via at least one sufficiently strong incoming edge from within S) enough reinforcement to prevent p from falling below θ in the absence of adverse decay or competing rules. Put differently, θ isolates the part of the state space that is forward-invariant under the internal propagation map once it has been reached, so that the remaining problem is to understand what exogenous inputs u (or cross-context inputs) are needed to drive the system into that region.

54.1.3 Morphic resonance as cross-context coupling

Let L index contexts. For each $\ell \in L$ fix: a pattern class P_ℓ, an internal kernel $A_\ell : P_\ell \times P_\ell \to V$, a decay scalar $d_\ell \in V$, and a (possibly time-dependent) input $u_{\ell,t} : P_\ell \to V$.

For $\ell' \neq \ell$, a morphic coupling kernel is a V-relation $K_{\ell' \to \ell} : P_{\ell'} \times P_\ell \to V$ with induced input

$$(K_{\ell' \to \ell}?s_{\ell',t})(q) := \bigoplus_{p \in P_{\ell'}} K_{\ell' \to \ell}(p,q) \otimes s_{\ell',t}(p).$$

The coupled update (morphic resonance dynamics) is:

$$s_{\ell,t+1} = u_{\ell,t} \oplus (d_\ell \odot s_{\ell,t}) \oplus (A_\ell ? s_{\ell,t}) \oplus \bigoplus_{\ell' \neq \ell} (K_{\ell' \to \ell}?s_{\ell',t}).$$

Equivalently, the quantity $\bigoplus_{\ell' \neq \ell}(K_{\ell' \to \ell}?s_{\ell',t})$ can be read as a context-dependent "import" term: it aggregates the images of all other context-states through their respective coupling kernels, using the same $\oplus$-aggregation rule as internal influence. This ensures that cross-context effects are not an extra mechanism but the same propagation calculus applied on a larger typed graph whose nodes are the disjoint union $\bigsqcup_{\ell \in L} P_\ell$, with edge-weights given by the block-kernels A_ℓ (within blocks) and $K_{\ell' \to \ell}$ (off-diagonal blocks).

Remark 3049. *The new ingredient relative to a single web is the family of cross-context kernels $K_{\ell' \to \ell}$. These kernels are typed: they map patterns from $P_{\ell'}$ into patterns of P_ℓ, and their action $(K_{\ell' \to \ell}?s_{\ell',t})$ is literally the same relational-image construction as for internal propagation, only across contexts. One can read this as a formal account of "resonance" in the minimal sense: activations in one context contribute to activations in another, with strengths specified by $K_{\ell' \to \ell}$ (Hyperseed-Concept 115, 159, 192).*

A useful intuition is that the kernels $K_{\ell' \to \ell}$ play the role of (possibly asymmetric) "translation" or "analogy" maps between pattern vocabularies: a pattern $p \in P_{\ell'}$ can support a pattern $q \in P_\ell$ to the extent that $K_{\ell' \to \ell}(p,q)$ is large in the V-order. Because the induced input uses $\bigoplus_p$, multiple source patterns in $P_{\ell'}$ can jointly provide support, and because it uses $\otimes$, a source pattern that is only weakly active cannot produce strong downstream activation unless the kernel-weight compensates for it (as appropriate to the chosen quantale). In this way, the same algebraic primitives simultaneously encode (i) how evidence combines within a context (via A_ℓ) and (ii) how evidence transfers between contexts (via $K_{\ell' \to \ell}$), so that "cross-context learning" is expressed as a property of kernels rather than as a separate learning rule.

Remark 3050. *It is worth emphasizing what is* not *assumed: no probabilistic semantics are required, and no symmetry is required (one may have $K_{\ell' \to \ell} \neq K_{\ell \to \ell'}$). The only essential structure* *is order-theoretic and algebraic, which is why fixed-point methods apply cleanly. This is one reason quantales are convenient: they provide a uniform calculus for propagation and aggregation while keeping enough generality to represent max-times, Boolean reachability, p-bit evidence pairs, and other "graded logic" settings [3].*

One consequence of this order-theoretic framing is that, under the standard monotonicity properties of $\oplus$, $\otimes$, and the relational image $(\cdot\ ?\ \cdot)$, each per-context update map is monotone in its arguments, and the full coupled system is monotone in the joint state $s_t = (s_{\ell,t})_{\ell \in L}$. This is the basic reason least and greatest fixed points become natural objects: for time-independent inputs $u_{\ell,t} \equiv u_\ell$ (and time-independent kernels), equilibria are precisely fixed points of the combined operator, and iterative dynamics provide constructive approximations under mild continuity assumptions. Moreover, the block-graph view makes it clear how "resonant loops" can occur: even if each A_ℓ alone is subcritical, the off-diagonal kernels can create directed cycles across contexts, yielding cross-context autocatalytic structures in the enlarged graph and thereby lowering the seeding needed for global activation.

54.2 Deterministic fixed-point theorems

54.2.1 Least fixed point for time-homogeneous habit dynamics

Assume P is finite and V is complete, so V^P is a complete lattice. Fix A, d, u and define $F : V^P \to V^P$ by $F(s) = \mathrm{Upd}_{A,d,u}(s)$.

Theorem 95 (Scott-continuity and Kleene computation of the least fixed point)**.** *Assume $(V, \leq, \oplus, \otimes, e)$ is a commutative quantale and P is finite. Then:*

1. *F is monotone and Scott-continuous (preserves directed joins).*
2. *The least fixed point $\mathrm{lfp}(F)$ exists and is given by the Kleene chain*

$$\mathrm{lfp}(F) = \bigvee_{n \geq 0} F^n(\bot),$$

   where $\bot$ is the bottom state (pointwise bottom element of V).

3. *For any fixed point s^* of F, one has $F^n(\bot) \leq s^*$ for all n, hence the above supremum is indeed the least fixed point.*

Remark 3051. *In plain terms: if one repeatedly applies the update rule starting from "no support anywhere" (the bottom state $\bot$), then the state monotonically accumulates support, and the limiting state is the smallest stable configuration compatible with the kernel A, the decay d, and the input u. The result is important because it converts an abstract existence claim (there is some fixed point) into a concrete computation rule (iterate F). This is the basic reason closure-based reasoning systems can treat fixed points as operational objects rather than metaphysical ones. It also sets up the later block-kernel reduction: once multi-context dynamics are compiled into a single operator, the same Kleene computation applies.*

Remark 3052. *The condition "Scott-continuous" is an order-theoretic analogue of continuity tailored to complete lattices: it means that F respects directed suprema, i.e. suprema of consistent increasing approximations. Conceptually, this is what legitimizes taking a limit of iterated approximations, as one does in Kleene's theorem and in many semantics of programs and logics.*

Proof. (1) Monotonicity follows because F is built from $\oplus$, $\otimes$, and joins, each monotone in a quantale. For Scott-continuity, let $D \subseteq V^P$ be directed. Pointwise:

$$F\Big(\bigvee D\Big) = u \oplus (d \odot \bigvee D) \oplus (A?(\bigvee D)).$$

Since $\otimes$ distributes over arbitrary joins, $d \odot (\bigvee D) = \bigvee_{s \in D}(d \odot s)$. Also, for each $q \in P$,

$$(A?(\bigvee D))(q) = \bigoplus_{p \in P} A(p,q) \otimes \Big(\bigvee_{s \in D} s(p)\Big) = \bigoplus_{p \in P} \bigvee_{s \in D} \big(A(p,q) \otimes s(p)\big).$$

Because P is finite and joins distribute, this equals $\bigvee_{s \in D}(A?s)(q)$. Thus $F(\bigvee D) = \bigvee_{s \in D} F(s)$.

(2) By completeness, the supremum $\bigvee_{n \geq 0} F^n(\perp)$ exists. Since $\perp \leq F(\perp)$ (always true because $\perp$ is least), the Kleene iterates form an ascending chain. Scott-continuity implies $F(\bigvee_n F^n(\perp)) = \bigvee_n F^{n+1}(\perp)$, so the supremum is a fixed point.

(3) If s^* is any fixed point, then $\perp \leq s^*$ and monotonicity implies $F^n(\perp) \leq F^n(s^*) = s^*$ for all n. Taking the join over n yields the claim. □

Remark 3053. Proof sketch (high level). *The strategy is: (i) show F respects the order in the obvious way (monotonicity), (ii) show F respects increasing "limits" (Scott-continuity), and then (iii) use the standard Kleene fixed-point construction: iterate from the least element and take the join of all iterates. Scott-continuity ensures that applying F after taking this join is the same as taking the join after applying F to each iterate, which is exactly what makes the supremum a fixed point.*

Remark 3054. *The key technical step is the interchange of $\bigoplus$ (join over $p \in P$) and $\bigvee$ (join over $s \in D$). Finiteness of P makes this interchange straightforward: one can push the directed join inside a finite join without losing equality. Visually, one can picture the kernel as a finite matrix; pushing suprema inside corresponds to swapping the order of "take the best predecessor" and "take the limit of better and better approximations to s".*

54.2.2 Block-kernel reduction: morphic resonance is closure on an enlarged web

Assume time-homogeneous inputs and no decay for clarity: $d_\ell = e$ and $u_{\ell,t} \equiv u_\ell$.

Let the global pattern set be the disjoint union

$$P_{\text{tot}} := \bigsqcup_{\ell \in L} P_\ell.$$

Define the global kernel $G : P_{\text{tot}} \times P_{\text{tot}} \to V$ by:

$$G(p,q) := \begin{cases} A_\ell(p,q) & \text{if } p, q \in P_\ell, \\ K_{\ell' \to \ell}(p,q) & \text{if } p \in P_{\ell'},\ q \in P_\ell,\ \ell' \neq \ell. \end{cases}$$

Let $u_{\text{tot}} : P_{\text{tot}} \to V$ be the disjoint union of the u_ℓ, and similarly s_t the disjoint union of $(s_{\ell,t})_{\ell \in L}$.

Remark 3055. *The disjoint union symbol $\bigsqcup$ is used to keep contexts from accidentally identifying patterns with the same "name": even if P_{ℓ_1} and P_{ℓ_2} share labels, in P_{tot} they become distinct tagged elements. This is the correct categorical move for "many worlds in parallel" before we add couplings between them (Hyperseed-Concept 112,* **??***).*

Remark 3056. *The block kernel G is literally a block matrix: diagonal blocks are the internal kernels A_ℓ, and off-diagonal blocks are the coupling kernels $K_{\ell'\to\ell}$. The virtue of writing G is that it turns the multi-context system into an ordinary single-kernel system, so all theorems about closure, fixed points, and reachability become immediately reusable.*

Theorem 96 (Morphic resonance as ordinary habit closure on (P_{tot}, G))**.** *Under the assumptions above (no decay, constant inputs), the coupled morphic-resonance update is equivalent to the single-web update*

$$s_{t+1} = u_{\mathrm{tot}} \oplus s_t \oplus (G?s_t).$$

Consequently, the least fixed point of the global dynamics is

$$s_\infty = G^*?u_{\mathrm{tot}},$$

where $G^* = \bigvee_{n\geq 0} G^n$ is the Kleene star (path-closure) of G.

Remark 3057. *What this theorem says, informally, is that "morphic resonance adds no new mathematics" once we allow ourselves to enlarge the state space: cross-context propagation is just propagation in a bigger graph. This matters because it turns questions about diffusion across contexts into ordinary closure computations. In a reasoning system, this is the difference between needing bespoke multi-agent/multi-context machinery versus compiling the problem down to one closure operator.*

Remark 3058. *The Kleene star $G^* = \bigvee_{n\geq 0} G^n$ should be read as "all paths of all lengths": G^n captures the best n-step reinforcement along n edges, and the join over all n aggregates paths of arbitrary length. Thus $G^*?u_{\mathrm{tot}}$ is the closure of the base input under all possible resonance-and-reinforcement cascades. This is a precise algebraic analogue of reachability in directed graphs, generalized to quantale weights.*

Proof. Fix $\ell \in L$ and $q \in P_\ell$. By definition of disjoint union and of G,

$$(G?s_t)(q) = \bigoplus_{p\in P_{\mathrm{tot}}} G(p,q) \otimes s_t(p) = \Big(\bigoplus_{p\in P_\ell} A_\ell(p,q) \otimes s_{\ell,t}(p)\Big) \oplus \Big(\bigoplus_{\ell'\neq\ell}\bigoplus_{p\in P_{\ell'}} K_{\ell'\to\ell}(p,q) \otimes s_{\ell',t}(p)\Big).$$

The first parenthesis is $(A_\ell?s_{\ell,t})(q)$ and the second is $\bigoplus_{\ell'\neq\ell}(K_{\ell'\to\ell}?s_{\ell',t})(q)$. Thus restricting $u_{\mathrm{tot}} \oplus s_t \oplus (G?s_t)$ to P_ℓ yields exactly $u_\ell \oplus s_{\ell,t} \oplus (A_\ell?s_{\ell,t}) \oplus \bigoplus_{\ell'\neq\ell}(K_{\ell'\to\ell}?s_{\ell',t})$.

For the fixed point formula, apply the closure/Kleene-star identity to the inflationary update $s \mapsto u_{\mathrm{tot}} \oplus s \oplus (G?s)$: iterating from bottom yields the least fixed point, and the standard unfolding gives $s_\infty = G^*?u_{\mathrm{tot}}$. □

Remark 3059. Proof sketch (high level). *The argument is bookkeeping: show that the global image operator $G?$ decomposes, on each component P_ℓ, into the internal image $A_\ell?$ plus the sum of coupling images $K_{\ell'\to\ell}?$. Once this is established, the multi-context update is exactly the single-context update on the disjoint union. The fixed point formula then follows from the same Kleene iteration principle as before, since the update is inflationary when $d_\ell = e$ and the s_t term is included.*

Remark 3060. *A useful geometric picture is to imagine stacking the context graphs into layers. The block kernel G simply adds inter-layer edges. Then morphic resonance is nothing but ordinary diffusion on the resulting layered directed graph. The lattice join $\oplus$ plays the role of combining multiple incoming paths, and $\otimes$ composes edge strengths along a path.*

54.2.3 Resonant nucleation: seeding a self-weaving core via coupling

Intuition: a context can have a latent autocatalytic core S that does not activate by itself, but once resonance pushes all patterns in S above threshold θ, the internal kernel keeps them alive (and possibly expands them via closure), so the habit persists even if coupling later vanishes.

Remark 3061. *This "one-shot seeding" phenomenon is one of the most operationally relevant consequences of self-weaving structure: it tells us that a transient cross-context influence can have a permanent effect, not by continuing to act, but by pushing the system across a threshold into a region where internal feedback loops do the maintenance. In the language of dynamical systems, S defines (at least) a basin condition; in the language of Hyperseed concepts, it is a seed for a self-weaving web (Hyperseed-Concept 168, **??**, **??**).*

Theorem 97 (One-shot seeding of an autocatalytic core)**.** *Fix a context ℓ with internal kernel A_ℓ and threshold $\theta \in V$. Assume $S \subseteq P_\ell$ is θ-autocatalytic. Consider the no-decay, no-input internal reinforcement dynamics on ℓ:*

$$x_{t+1} = x_t \oplus (A_\ell ? x_t).$$

If there exists a time t_0 such that $x_{t_0}(p) \geq \theta$ for all $p \in S$, then for all $t \geq t_0$ one has $x_t(p) \geq \theta$ for all $p \in S$. Moreover the trajectory converges (as an ascending join) to a fixed point x_∞ with $x_\infty(p) \geq \theta$ for all $p \in S$.

In particular, in the full morphic resonance dynamics, if for some source context ℓ' the coupling input satisfies

$$(K_{\ell' \to \ell} ? s_{\ell', t_0})(p) \geq \theta \quad \text{for all } p \in S,$$

then after one update step, context ℓ reaches a state that activates S at level θ, and internal reinforcement can sustain it thereafter.

Remark 3062. *The theorem asserts a form of hysteresis: once the core is "lit" above threshold, the subsequent internal dynamics cannot extinguish it, because the update is inflationary (support only grows via $\oplus$) and the autocatalytic witness guarantees reinforcement at the same threshold. This links the structural notion of autocatalysis directly to a temporal persistence guarantee, which is why autocatalytic sets are so central in many theories of self-organization (Hyperseed-Concept 61, **??**).*

Proof. Let $x_{t+1} = x_t \oplus (A_\ell ? x_t)$. This map is inflationary, so $x_{t+1} \geq x_t$ pointwise. (Here and throughout, inequalities are taken in the pointwise order on V^{P_ℓ}, i.e. $u \geq v$ means $u(p) \geq v(p)$ for every $p \in P_\ell$; inflationarity follows because a join satisfies $u \oplus v \geq u$ in any join-semilattice.)

Because S is θ-autocatalytic, there exists a witness state w such that $w(p) \geq \theta$ and $(A_\ell ? w)(p) \geq \theta$ for all $p \in S$. Assume $x_{t_0}(p) \geq \theta$ for $p \in S$. Define $y := x_{t_0} \oplus w$. Then $y \geq w$ and $y \geq x_{t_0}$, hence $y(p) \geq \theta$ on S. (Equivalently, for each $p \in S$ we have $y(p) = x_{t_0}(p) \oplus w(p) \geq w(p) \geq \theta$, so y simultaneously dominates the current state and the witness on the entire subset S.) By monotonicity of the image operator, $(A_\ell ? y) \geq (A_\ell ? w)$, so $(A_\ell ? y)(p) \geq \theta$ on S. (This is the step where θ-autocatalysis becomes "self-sustaining": once the state dominates a witness, the activation contributed by $A_\ell ?$ cannot be weaker than the witnesss contributed activation.)

Now consider the trajectory starting from y: $y_0 := y$, $y_{n+1} := y_n \oplus (A_\ell ? y_n)$. Inductively, $y_n \geq y$ so $y_n(p) \geq \theta$ on S for all n. Indeed, the induction is immediate from inflationarity: $y_{n+1} \geq y_n$ for all n, hence $y_n \geq y_0 = y$, and thus $y_n(p) \geq y(p) \geq \theta$ on S. Moreover, using the previous paragraph one also has $(A_\ell ? y_n) \geq (A_\ell ? y)$ for all n by monotonicity, so the reinforcement term itself remains above θ on S once it is above θ at $n = 0$.

Since $x_{t_0} \le y$ and the update is monotone, the original trajectory satisfies $x_{t_0+n} \le y_n$ but also (by inflationarity) $x_{t_0+n} \ge x_{t_0}$, hence $x_{t_0+n}(p) \ge \theta$ on S for all n. (For the desired lower bound on S, the key inequality is $x_{t_0+n} \ge x_{t_0}$: once a coordinate is at least θ at time t_0, it can never decrease below θ under an inflationary update. The comparison $x_{t_0+n} \le y_n$ is compatible with this and can be useful to show that x stays within the forward-closed region generated by y, but the persistence above θ on S already follows from inflationarity together with the hypothesis on x_{t_0}.)

Because P_ℓ is finite and V complete, the join $x_\infty := \bigvee_{t \ge t_0} x_t$ exists. (Concretely, since P_ℓ is finite, this join can be formed coordinatewise: for each $p \in P_\ell$, $(x_\infty)(p) = \bigvee_{t \ge t_0} x_t(p)$ exists in V by completeness, and finiteness ensures these coordinatewise joins assemble into an element of V^{P_ℓ}.) Monotonicity and distributivity yield that x_∞ is a fixed point of $x \mapsto x \oplus (A_\ell ? x)$, and we already proved all x_t are $\ge \theta$ on S, hence so is x_∞. (To see the fixed-point claim explicitly, note first that $x_t \le x_\infty$ for all t, so by monotonicity $A_\ell ? x_t \le A_\ell ? x_\infty$, hence $x_{t+1} = x_t \oplus (A_\ell ? x_t) \le x_\infty \oplus (A_\ell ? x_\infty)$. Taking the join over $t \ge t_0$ gives $x_\infty \le x_\infty \oplus (A_\ell ? x_\infty)$. Conversely, distributivity/continuity of $A_\ell ?$ over the directed join (together with $\oplus$ distributing over joins in V^{P_ℓ}) yields

$$A_\ell ? x_\infty \;=\; A_\ell ? \Big(\bigvee_{t \ge t_0} x_t \Big) \;=\; \bigvee_{t \ge t_0} (A_\ell ? x_t),$$

so

$$x_\infty \oplus (A_\ell ? x_\infty) = \Big(\bigvee_{t \ge t_0} x_t \Big) \oplus \Big(\bigvee_{t \ge t_0} (A_\ell ? x_t) \Big) = \bigvee_{t \ge t_0} \big(x_t \oplus (A_\ell ? x_t) \big) = \bigvee_{t \ge t_0} x_{t+1} = x_\infty,$$

where the last equality uses that $\{x_t\}$ is increasing, so shifting the index does not change the supremum.)

For the morphic resonance clause: the coupled update includes the join term $(K_{\ell' \to \ell} ? s_{\ell', t_0})$, so $s_{\ell, t_0+1} \ge (K_{\ell' \to \ell} ? s_{\ell', t_0})$. Thus if that term is $\ge \theta$ on S, the previous argument applies with $x_{t_0+1} = s_{\ell, t_0+1}$. (In other words, the resonance term provides an explicit lower bound at the next time step; once s_{ℓ, t_0+1} clears the threshold on S, the subsequent within-layer inflationary dynamics preserve that clearance forever. No further assumptions about continued resonance are needed beyond ensuring the initial lift above θ on S.) $\square$

Remark 3063. Proof sketch (high level). *The core idea is to exploit monotonicity and inflationarity. Once x_{t_0} is above θ on S, joining it with a witness state w produces a state y that is definitely above θ and is guaranteed to reproduce θ via $A_\ell ? y$. Iterating from y can never fall below θ on S, and the original trajectory, being monotone and inflationary, inherits this lower bound. A second, lattice-theoretic idea is that increasing trajectories in a complete lattice admit a supremum x_∞ that behaves like a limit; under mild distributivity/continuity hypotheses, applying the update map commutes with taking this supremum, which forces x_∞ to satisfy the fixed-point equation.*

Remark 3064. *One can visualize S as a small knot of mutually reinforcing edges. The theorem says: if resonance (or any external push) lifts every node in the knot above the activation line θ, then the knot becomes a permanent source of reinforcement for itself. In this sense, resonance acts less as a continuous force and more as a catalyst that enables the web's own feedback to take over. Equivalently, S behaves like a "memory cell" cut out of the larger network: once it is written (all coordinates in S exceed θ), the inflationary update prevents erasure, and the autocatalytic witness condition ensures that the networks internal propagation mechanism is compatible with maintaining that written state.*

54.3 Polarization vs synchronization

We interpret *polarization* as the presence of multiple stable fixed points (or long-lived metastable basins) in the coupled dynamics, so that different initial conditions lead to qualitatively different cross-context habit configurations. In particular, polarization is a statement about *macroscopic* dependence on initial conditions: two trajectories can be driven by the same inputs yet settle into distinct self-consistent global patterns. In contrast, *synchronization* means that, after transients, the global configuration becomes effectively independent of initialization (up to the obvious symmetries of the model, if any), so that all trajectories collapse to a single asymptotic regime. While we focus here on fixed points (and their basins), the same intuition extends to long-lived periodic or wandering attractors: the key distinction is whether there are *multiple* stable asymptotic behaviors that persist under small perturbations.

A clean sufficient condition for *no polarization* is global contractivity. It is worth emphasizing that this condition is deliberately strong: it gives an easily checkable certificate that rules out *all* forms of multi-attractor behavior, not only multiple fixed points. Conversely, failing contractivity does not by itself imply polarization; it merely leaves open the possibility of multiple attractors, slow mixing, or other non-synchronizing phenomena.

Remark 3065. *The contrast between polarization and synchronization can be read as the contrast between a world with many self-consistent habit-realities versus a world with a single inevitable attractor. In order-theoretic language, multiple fixed points correspond to multiple consistent closures; in metric language, contractivity collapses all trajectories to one point. The next theorem gives a simple certificate for the latter regime. A further way to read the certificate is as a* gain bound*: if the effective gain of every feedback path (within and across contexts) is uniformly below* 1*, then the system cannot amplify differences, so it cannot sustain incompatible global closures as stable alternatives.*

54.3.1 A contractive regime (p-bit toy quantale): unique global attractor

In the p-bit toy setting $V = [0,1]^2$ with pointwise order, $\oplus$ = max componentwise, and $\otimes$ componentwise multiplication, define for $v \in V$: $|v|_\infty := \max(v^+, v^-)$ and for a state $s : P \to V$: $|s|_\infty := \max_{p\in P} |s(p)|_\infty$. The choice of the ∞-norm is not essential, but it is convenient: it matches the use of max as aggregation, and it yields clean nonexpansiveness statements for joins and for coordinatewise updates. Conceptually, $|s|_\infty$ measures the strongest evidence magnitude present anywhere in the habit field.

For two states s, s' define the metric $\|s-s'\|_\infty := \max_{p\in P} \max(|s^+(p)-s'^+(p)|, |s^-(p)-s'^-(p)|)$. Note that $x \mapsto \max(x, y)$ is 1-Lipschitz and $x \mapsto ax$ is a-Lipschitz on $[0, 1]$. More explicitly, for scalar x, x', y one has

$$|\max(x, y) - \max(x', y)| \le |x - x'|,$$

and applying this coordinatewise implies that componentwise max is nonexpansive under the supremum metric. Similarly, for $a \in [0, 1]$, $|ax - ax'| = a|x - x'|$, giving the stated Lipschitz bound.

Remark 3066. *Here a value $v \in [0,1]^2$ can be read as a two-sided evidence pair (v^+, v^-), a common trick in paraconsistent and bipolar evidence formalisms (compare [23, 24]). The pointwise order and componentwise max/multiplication make the analysis transparent: each update is assembled from simple nonexpansive operations. The point is not that this is the only quantale of interest, but that it demonstrates a general phenomenon: if all propagation and persistence weights are uniformly small, then the system cannot sustain multiple incompatible basins. In this toy quantale, "uniformly* *small" is expressed as an ℓ_∞ bound on the relevant kernels; in other settings one typically replaces this with an operator norm or a suitable enriched-metric bound that plays the same role.*

Theorem 98 (Global contractivity implies synchronization and uniqueness)**.** *Consider a multi-context morphic resonance dynamics in the p-bit toy setting, with constant inputs u_ℓ and time-homogeneous kernels. Let F be the induced global update map on the product state space. Define*

$$\rho := \max\Big(\max_\ell |d_\ell|_\infty,\ \max_\ell |A_\ell|_\infty,\ \max_{\ell'\neq\ell} |K_{\ell'\to\ell}|_\infty\Big),$$

where $|A|_\infty := \max_{p,q} |A(p,q)|_\infty$ and similarly for K. If $\rho < 1$, then:

1. *F is a contraction: for all global states S, S', $\|F(S) - F(S')\|_\infty \le \rho\,\|S - S'\|_\infty$.*
2. *F has a unique fixed point S^*.*
3. *For every initial state S_0, the trajectory converges to S^* at rate ρ^t. In particular, there is no polarization into multiple stable fixed points.*

Remark 3067. *The theorem says: if every "memory factor" d_ℓ, every internal reinforcement edge, and every cross-context coupling edge has magnitude strictly less than 1 (in the supremum norm sense), then the entire system is globally contractive. Contractive systems cannot remember their initial conditions in the large; they synchronize to a unique attractor. This provides a crisp sufficient condition for "no polarization" that can be checked by simple max-norm bounds on kernels. Operationally, one can treat ρ as the worst-case one-step amplification factor for discrepancies: if two global states differ by at most ε everywhere, then after one update they differ by at most $\rho\varepsilon$. The strict inequality $\rho < 1$ is exactly the requirement that every update step strictly reduces the maximal discrepancy.*

Proof. Fix two global states S, S'. Consider one context component ℓ and one pattern $q \in P_\ell$. Write the update as a componentwise max of four terms: input, decay term, internal propagation, and coupling propagation.

The input term cancels when subtracting because it is the same constant u_ℓ in both updates. For the decay term, componentwise multiplication by d_ℓ is $|d_\ell|_\infty$-Lipschitz, so

$$\|(d_\ell \odot s_\ell) - (d_\ell \odot s'_\ell)\|_\infty \le |d_\ell|_\infty \|s_\ell - s'_\ell\|_\infty.$$

For the internal propagation term $(A_\ell ? s_\ell)(q) = \max_p A_\ell(p,q)\cdot s_\ell(p)$ (componentwise). Each map $s \mapsto A_\ell(p,q)\cdot s(p)$ is $|A_\ell(p,q)|_\infty$-Lipschitz, and taking max over p preserves the largest Lipschitz constant, hence

$$\|(A_\ell ? s_\ell) - (A_\ell ? s'_\ell)\|_\infty \le |A_\ell|_\infty \|s_\ell - s'_\ell\|_\infty.$$

The key point in the max step is that, for any family of scalar functions $\{f_p\}_p$ with Lipschitz constants bounded by L, the aggregate $x \mapsto \max_p f_p(x)$ is again L-Lipschitz under the same metric; here we apply this coordinatewise to the $(+)$ and $(-)$ components. Similarly for each coupling term $(K_{\ell'\to\ell} ? s_{\ell'})(q)$:

$$\|(K_{\ell'\to\ell} ? s_{\ell'}) - (K_{\ell'\to\ell} ? s'_{\ell'})\|_\infty \le |K_{\ell'\to\ell}|_\infty \|s_{\ell'} - s'_{\ell'}\|_\infty.$$

Finally, the full update at (ℓ, q) is the componentwise max of these terms. Max is 1-Lipschitz, so the difference of the maxima is bounded by the maximum of the differences. Taking maxima over all components yields

$$\|F(S) - F(S')\|_\infty \le \rho\,\|S - S'\|_\infty.$$

If $\rho < 1$, Banach's fixed point theorem gives existence and uniqueness of S^* and global convergence with rate ρ^t. Note that the use of a supremum metric is what makes the final step particularly direct: bounding each componentwise discrepancy and then taking the maximum immediately yields a global bound on the full product state. $\square$

Remark 3068. Proof sketch (high level). *The update is built by composing and joining simple maps, each of which has an explicit Lipschitz constant: multiplication by a bounded coefficient is contractive, and max is nonexpansive. The overall Lipschitz constant is therefore the maximum of the constants appearing in the pieces. If that maximum ρ is < 1, Banach's theorem forces a unique fixed point and geometric convergence. Equivalently, the update map F is a strict contraction on a complete metric space (a finite product of compact cubes), so the fixed point is not only unique but also* globally stable*: every orbit is pulled into it at a uniform rate.*

Remark 3069. *Visually: imagine each update step as taking the strongest of several "signals" reaching a node. If every signal is uniformly attenuated by at most $\rho < 1$, then discrepancies between two initial signals decay exponentially as they propagate, so the system cannot support distinct long-lived basins. In this regime, resonance cannot amplify differences into polarization; it can only dampen them into synchronization. This also clarifies why the condition is robust to network size: even if there are many nodes and many paths, the max-based aggregation means the update at each node only tracks the strongest incoming influence, and the uniform attenuation bound prevents any path (internal or cross-context) from acting as a net amplifier of disagreement.*

54.3.2 A simple polarization mechanism: below-threshold cross-coupling

Even if internal webs are self-weaving, morphic coupling may be too weak to seed habits across community boundaries. A crisp statement is easiest in scalar $V = [0, 1]$ with $\oplus = \max$, $\otimes = \cdot$. In this specialization, $K : P_{\ell'} \times P_\ell \to [0, 1]$ can be read as a weighted bipartite link (or transfer kernel) from a source pattern-set $P_{\ell'}$ to a target pattern-set P_ℓ, and $(K?s)(q)$ is the max-times analogue of "how much support reaches q" when all incoming supports compete by max and attenuate by multiplication.

Theorem 99 (Below-threshold coupling cannot seed above-threshold habits)**.** *Assume $V = [0, 1]$ with $\oplus = \max$ and $\otimes = \cdot$. Fix a threshold $\theta \in (0, 1]$. Let $K : P_{\ell'} \times P_\ell \to [0, 1]$ satisfy $K(p, q) < \theta$ for all (p, q). Then for every source state $s : P_{\ell'} \to [0, 1]$ with $0 \leq s(p) \leq 1$, one has*

$$(K?s)(q) < \theta \quad \text{for all } q \in P_\ell.$$

Consequently, if a target autocatalytic core requires all its patterns to reach level $\geq \theta$ to nucleate, then this coupling K can never nucleate that core, no matter how strong the source state is (as long as $s \leq 1$).

Remark 3070. *The claim is conceptually simple: max-times propagation cannot exceed the largest edge weight when the source is bounded by 1. Thus a uniformly sub-threshold bridge is not merely "weak"; it is structurally incapable of crossing the activation boundary. This provides a clean sufficient condition for polarization between communities: if all inter-community links fall below the activation threshold, then no community can ignite another's autocatalytic core.*

Remark 3071. *In particular, the hypothesis $s \leq 1$ is doing real work: it formalizes the idea that a source pattern cannot contribute more than its full activation. Under max-times, this means each incoming contribution to q is bounded by the corresponding coupling weight, so the bridge itself* *becomes the bottleneck. If one were to allow an unbounded source scale (e.g., $s(p) > 1$), then a sub-threshold edge weight could in principle be compensated by super-unit source magnitude; the theorem rules out that regime by design, aligning the semantics with probabilistic or normalized activation levels.*

Proof. For any $q \in P_\ell$,

$$(K?s)(q) = \max_{p \in P_{\ell'}} K(p, q) \cdot s(p).$$

Since $0 \leq s(p) \leq 1$, we have $K(p, q) \cdot s(p) \leq K(p, q) < \theta$ for every p. Taking max over p preserves $< \theta$. The final clause is immediate. □

Remark 3072. Proof sketch (high level). *Each term in the max is bounded by $K(p, q)$ because $s(p) \leq 1$. So the entire max is bounded by the largest $K(p, q)$, which is assumed $< \theta$.*

Remark 3073. *A useful corollary is that the obstruction is not merely one-step. If one iterates the same style of propagation across multiple stages, sub-threshold attenuation compounds rather than accumulates. Concretely, for any composable kernels K_1, K_2 with all entries $< \theta$ and any $s \leq 1$, the max-times composite satisfies*

$$(K_2?(K_1?s))(q) = \max_{p,r} K_2(r, q)\, K_1(p, r)\, s(p) \ < \ \theta,$$

since every product term is $\leq K_2(r, q) < \theta$ (and also $\leq K_1(p, r) < \theta$). Thus, even allowing arbitrarily many intermediate "relay" patterns does not create a super-threshold signal in this semiring when all couplings remain uniformly sub-threshold and sources remain normalized. In diffusion language: there is no multi-hop amplification mechanism available; every path weight is a product of numbers in $[0, 1]$ and hence cannot exceed any single factor on that path.

Remark 3074. *This theorem makes polarization intuitive: if the context network has weak (sub-threshold) bridges, then different context communities can remain in different habit basins, because they cannot seed each other above the activation threshold. In Hyperseed language, "resonance" exists as a formal channel, but it is filtered by an activation threshold, and thus can fail to induce intersubjective convergence (Hyperseed-Concept* **??**, *158,* **??***).*

Remark 3075. *Interpreted as "polarization vs. synchronization," the result identifies a sufficient condition for* failure *of cross-community synchronization: even perfect internal synchronization within each community does not help if every bridge edge lies below the activation floor needed for nucleation. Conversely, to even make synchronization* possible *in this max-times model (with normalized sources), at least one bridge into each required target pattern must meet or exceed θ; otherwise the target cannot be pushed into the basin where its own internal autocatalysis sustains it. This highlights an asymmetry between strong internal ties (which maintain a habit once present) and strong inter-community ties (which are required to* create *the habit elsewhere).*

54.4 Random-graph theorems for habit webs

We now connect habit-web properties to classical random graph thresholds. The key move is to analyze a *thresholded skeleton* of a weighted web.

54.4.1 Thresholded skeleton

Let $A : P \times P \to [0, 1]$ be a weighted kernel. Fix $\theta \in (0, 1]$ and define the Boolean θ-skeleton adjacency relation

$$E_\theta(p, q) := \mathbf{1}[A(p, q) \geq \theta].$$

In many max-times models, reaching support $\geq \theta$ along an edge requires $A(p, q) \geq \theta$ (or at least some uniform lower bound of that form), so E_θ is a conservative predictor of above-threshold diffusion and self-weaving.

Remark 3076. *The skeleton E_θ is a deliberate loss of information: it forgets* how far above θ *an edge is, and remembers only whether it clears the bar. The payoff is that questions about activation at level θ reduce to questions about reachability and cycles in an ordinary directed graph. This is a standard analytic move: discretize a graded process at the threshold where the qualitative behavior changes.*

Remark 3077. *In the max-times model, the condition $A(p, q) \geq \theta$ is sufficient (though not always necessary) for the possibility that a node at level $\geq \theta$ pushes its successor to level $\geq \theta$ in one step. Thus E_θ is conservative: if the skeleton has no relevant paths/cycles, then the weighted system cannot exhibit the corresponding above-threshold phenomena either.*

54.4.2 Minimal autocatalytic cores: 2-cycles in a random directed web

Consider a random directed graph $D(n, p)$ on n patterns: each ordered edge $(i \to j)$, $i \neq j$, is present independently with probability p. In the Boolean setting $V = \{0, 1\}$ with $\oplus = \vee$, $\otimes = \wedge$, any directed 2-cycle is a (minimal) autocatalytic subset of size 2.

Theorem 100 (Sharp threshold for a minimal self-weaving core via 2-cycles)**.** *Let $D(n, p)$ be a random directed graph with independent directed edges. Let X be the number of directed 2-cycles (unordered pairs $\{i, j\}$ such that $i \to j$ and $j \to i$ are both present). Then $X \sim \mathrm{Bin}(N, p^2)$ with $N = \binom{n}{2}$ and*

$$\mathbb{P}[X = 0] = (1 - p^2)^N.$$

Consequently:

1. *If $p = o(1/n)$ then $\mathbb{P}[X > 0] \to 0$.*
2. *If $p = \omega(1/n)$ then $\mathbb{P}[X > 0] \to 1$.*

Therefore the emergence of a minimal autocatalytic core (a 2-cycle) has threshold $p \asymp 1/n$.

Remark 3078. *The theorem quantifies a basic intuition: a minimal self-sustaining habit requires at least a loop. In a random directed web, the simplest loop is a 2-cycle, and it appears right when the expected number of such loops passes from negligible to large. The result is important for priors: below $p \asymp 1/n$, one should not expect even the smallest self-weaving structure to exist by chance, whereas above that density, such loops become typical.*

Proof. For each unordered pair $\{i, j\}$, let I_{ij} be the indicator that both edges $i \to j$ and $j \to i$ are present. Since edges are independent, $\mathbb{P}[I_{ij} = 1] = p^2$. Moreover the sets of edges used by distinct unordered pairs are disjoint, hence the indicators are independent. Thus $X = \sum_{\{i,j\}} I_{ij} \sim \mathrm{Bin}(N, p^2)$ and $\mathbb{P}[X = 0] = (1 - p^2)^N$.

Now $Np^2 \sim (n^2/2)p^2$. If $p = o(1/n)$ then $Np^2 \to 0$ so $(1 - p^2)^N \to 1$ and $\mathbb{P}[X > 0] \to 0$. If $p = \omega(1/n)$ then $Np^2 \to \infty$ and $(1 - p^2)^N \to 0$, hence $\mathbb{P}[X > 0] \to 1$. $\square$

Remark 3079. Proof sketch (high level). *Count candidate 2-cycles (there are* $\binom{n}{2}$ *unordered pairs), note each becomes a 2-cycle with probability* p^2*, and observe independence across pairs because disjoint edge sets are involved. Then the probability of no 2-cycles is a simple binomial tail at* 0*, which is well-approximated by* $\exp(-Np^2)$*, giving the threshold* $p \asymp 1/n$*.*

Remark 3080. *A visual way to remember the threshold is: there are* $\Theta(n^2)$ *possible mutual pairs, so one needs edge probability* $\Theta(1/n)$ *for a constant expected number of mutual pairs. Below that, the web is too sparse to close even the smallest feedback loop.*

54.4.3 Macroscopic diffusion: out-component threshold via branching processes

In the Boolean no-decay/no-input closure dynamics, starting from a seed set S_0 and repeatedly adding out-neighbors yields the reachability closure, i.e. the directed out-component.

Theorem 101 (Diffusion threshold for downstream closure in $D(n, c/n)$ (branching heuristic))**.** *Let* $D(n,p)$ *with* $p = c/n$ *for constant* $c > 0$*. Start from one seed node* v *and let* $C_{\text{out}}(v)$ *be its directed out-component. Then:*

1. *If* $c < 1$*, the exploration process is stochastically dominated by a subcritical Galton–Watson process with mean c, hence* $|C_{\text{out}}(v)| = O(\log n)$ *with high probability.*
2. *If* $c > 1$*, the corresponding Galton–Watson process is supercritical, with survival probability* $1-q$ *where* $q \in (0,1)$ *solves* $q = e^{c(q-1)}$*. With probability bounded away from 0, the exploration does not die out quickly and reaches* $\Theta(n)$ *nodes; in particular a macroscopic diffusion event becomes possible.*

Remark 3081. *This is the familiar mean-degree-*1 *phase transition, here interpreted as a diffusion threshold for closure dynamics. In the subcritical regime, reinforcement paths die out quickly; in the supercritical regime, a seed can ignite a giant downstream set. The connection back to habit webs is direct in the Boolean/skeleton setting: diffusion is reachability, and reachability is governed by out-components.*

Proof sketch (standard exploration coupling). Reveal out-neighbors of newly discovered nodes. For early times when the explored set is small relative to n, each discovered node has approximately Poisson(c) fresh out-neighbors, nearly independent, because each of the n possible targets is hit with probability c/n.

Thus the number of newly discovered nodes per step is well-approximated by a Galton–Watson branching process with offspring distribution Poisson(c). If $c < 1$ the branching process becomes extinct quickly, and standard tail bounds yield logarithmic component sizes. If $c > 1$ the branching process survives with probability $1 - q > 0$ and grows geometrically until finite-size effects matter, at which point it typically reaches linear size. □

Remark 3082. Commentary on key steps. *The crucial approximation is that, while the explored set is small, edges from newly explored nodes point to "fresh" nodes with near-independence. This is precisely the regime where a branching process is an accurate proxy. The fixed-point equation* $q = e^{c(q-1)}$ *is the extinction probability equation for a Poisson(c) Galton–Watson process.*

Remark 3083. *One can make the "freshness" heuristic quantitative as follows: if the explored set has size* $s \ll n$*, then a newly revealed out-edge hits a previously explored vertex with probability approximately* s/n*, so the expected number of collisions among* $O(1)$ *out-edges is* $O(s/n)$*, hence negligible until the exploration reaches size* n^γ *for any fixed* $\gamma < 1$*. In that regime, the exploration* *is locally tree-like and the breadth-first queue length evolves like a random walk with increment distribution* Poisson$(c) - 1$*, which is exactly the branching-process coupling. In particular, the same fixed point q that gives extinction probability also controls the asymptotic fraction of vertices with "small" out-components; when $c > 1$, the probability of a linear-size out-component is $1 - q$ under the branching heuristic, aligning with the emergence of a giant out-component in the directed setting.*

Remark 3084. *Geometrically, one can picture the exploration as a wavefront moving along directed edges. When $c < 1$, the wavefront shrinks on average; when $c > 1$, it expands on average until constrained by finite size. This is the graph-theoretic analogue of a reproduction number crossing* 1 *in epidemic models, which anticipates the two-level cascade theorem below.*

Remark 3085. *From the perspective of fixed points and polarization, the dichotomy at $c = 1$ can be read as a change in the qualitative stability of the "inactive" state in the exploration dynamics: in the subcritical regime the only consistent macroscopic outcome is extinction (return to zero queue), whereas in the supercritical regime there is a second, self-consistent macroscopic outcome in which the exploration sustains itself long enough to occupy a positive fraction of the graph. The branching-process fixed point q therefore plays the role of a coarse order parameter: it is both the extinction probability and (heuristically) the complement of the giant reachability fraction.*

54.4.4 Two-level diffusion: random graph of contexts + random internal habit webs

Now consider N contexts. Let the *context coupling graph* be an undirected (or directed) random graph on contexts, say $G(N, p_L)$ with $p_L = c_L/N$.

Within each context ℓ, suppose the internal θ-skeleton of its habit kernel behaves like a random directed graph $D(n_\ell, p_{\text{int}})$ for some effective p_{int}. Let α_ℓ be the probability that context ℓ contains a minimal autocatalytic core (a 2-cycle) in its θ-skeleton. By the 2-cycle theorem,

$$\alpha_\ell = 1 - (1 - p_{\text{int}}^2)^{\binom{n_\ell}{2}} \approx 1 - \exp\Big(- \tfrac{1}{2} n_\ell^2 p_{\text{int}}^2 \Big).$$

Assume that when a neighboring context is already in a high-support habit state, the coupling successfully *seeds* the target above threshold θ with probability β (a coarse summary of kernel strength, alignment, and thresholding).

Remark 3086. *This construction makes explicit a two-level architecture: within each context there is a habit web that may or may not be able to sustain itself once activated (captured by α_ℓ), and between contexts there is a coupling network that may or may not successfully transmit activation (captured by β and the random context graph). Such coarse-graining is common in reasoning systems: one replaces detailed internal dynamics by a small number of effective parameters that control whether an influence is transient or persistent.*

Remark 3087. *Although α_ℓ is defined here via the presence of a 2-cycle (as a minimal sufficient structure for self-support in the θ-skeleton), it can also be interpreted more broadly as an* effective persistence probability *of internal dynamics conditional on seeding. In contexts where larger autocatalytic sets are the typical sustaining mechanism, α_ℓ may be replaced by the probability of having* some *self-sustaining strongly connected subgraph above threshold; the two-level analysis below only uses α as the coarse probability that seeding produces a persistent source. If contexts are exchangeable (e.g. $n_\ell \equiv n$ and common p_{int}), one may set $\alpha_\ell \equiv \alpha$, while in heterogeneous settings one typically works with an average (or size-biased average) persistence parameter that reflects which contexts are more often reached by edges in the coupling graph.*

Theorem 102 (Cascade threshold for morphic resonance on a random context graph)**.** *Consider the following coarse-grained process on contexts: an "infected" context attempts to seed each neighboring context independently with success probability β, and a successfully seeded context becomes persistently infected with probability α (internal self-weaving once seeded). On $G(N, c_L/N)$ this is approximated by a Galton–Watson process with mean reproduction number*

$$R := \alpha\,\beta\,c_L.$$

If $R < 1$ then the infected set remains $O(\log N)$ with high probability. If $R > 1$ then with positive probability the infected set reaches $\Theta(N)$ contexts (i.e. a macroscopic morphic-resonance diffusion).

Remark 3088. *In the supercritical case $R > 1$, the branching approximation also predicts a nontrivial survival probability $1 - \rho > 0$, where ρ is the smallest solution in $[0, 1]$ of the fixed-point equation $\rho = \exp(R(\rho - 1))$ (the extinction equation for a Poisson(R) offspring law). Under the same heuristics, conditional on survival the cascade grows roughly geometrically for many generations before saturation, and the eventual macroscopic infected fraction is controlled by the same fixed-point structure that appears in one-level random-graph giant-component theory. This makes the analogy to the $c = 1$ transition not merely qualitative: it is encoded by an explicit scalar fixed-point equation at the coarse-grained level.*

Remark 3089. *This theorem is the contextual analogue of the $c = 1$ out-component threshold: the mean reproduction number R plays the same role, but now it factors into (i) network connectivity c_L, (ii) the probability β that resonance successfully seeds across an edge, and (iii) the probability α that what is seeded becomes self-sustaining. The factorization is conceptually useful because it separates three failure modes: sparse coupling, weak bridges, or lack of internal autocatalysis.*

Proof sketch. In $G(N, c_L/N)$ the number of neighbors of a typical context is approximately $\mathrm{Poisson}(c_L)$. Each neighbor is successfully seeded with probability β, and conditional on seeding, becomes a persistent source with probability α. Thus the number of newly persistent contexts caused by one persistent context is approximately $\mathrm{Poisson}(\alpha\beta c_L)$. Branching-process theory yields the stated subcritical/supercritical dichotomy. □

Remark 3090. *A slightly more explicit way to see the Poisson offspring law is by successive thinning: if $D \sim \mathrm{Poisson}(c_L)$ is the number of neighbors, and each edge transmits with probability β, then the number of successfully seeded neighbors is $\mathrm{Poisson}(\beta c_L)$; then, keeping each seeded neighbor with probability α (persistence conditional on seeding) yields a final thinned count $\mathrm{Poisson}(\alpha\beta c_L)$. This repeated thinning viewpoint makes clear why the product $\alpha\beta c_L$ is the only parameter that appears in the mean-field cascade threshold.*

Remark 3091. Commentary on key steps. *The Poisson approximation enters twice: first for the degree distribution of $G(N, c_L/N)$, and then for the thinning of neighbors by independent success probabilities β and α. The product $\alpha\beta c_L$ is exactly the mean of the thinned offspring distribution, hence the effective R.*

Remark 3092. *As in one-level exploration, the independence assumptions are most accurate during the early phase when the infected set is small compared to N, so that attempted infections largely target previously uninfected contexts and different infection paths rarely collide. Once a linear number of contexts is reached (when $R > 1$ and the cascade survives), collisions and depletion become non-negligible, but at that point the key question (survival versus extinction) has already been resolved by the initial branching phase. This is why the branching-process approximation is well-suited for identifying the diffusion threshold even when later-time dynamics require more detailed finite-size analysis.*

Remark 3093. *A helpful picture is to view each context as a "reactor" that, once lit, can light others. The parameter β is the transmissibility of flame across pipes; α is whether the receiver contains enough fuel arranged in a self-sustaining configuration. When $R > 1$, the fire can spread through a macroscopic fraction of the network; when $R < 1$, it sputters locally. This metaphor is mathematically exact in the branching approximation and ties back to the one-shot nucleation theorem: the difference between transient seeding and persistent ignition is precisely internal self-weaving.*

54.5 Takeaways for reasoning systems (informal)

- Fixed points are not an extra assumption: in the finite-pattern regime, least fixed points exist and can be computed by iterating the update from bottom. Here "from bottom" means starting from the least informative state (the empty/false assignment, or the least element of the underlying lattice/quantale module), and repeatedly applying the monotone update operator until no new facts are added. In practice this provides an implementable closure algorithm whose intermediate iterates are themselves meaningful approximations (each step is a sound under-approximation of the eventual closure), and termination is guaranteed by finiteness of the pattern space.

- Morphic resonance can be compiled away into an enlarged single habit web (a block kernel), making diffusion queries reducible to a single closure computation $G^*?u$. Operationally, the block construction replaces "multiple interacting contexts" by a single augmented state space in which cross-context couplings become ordinary edges (blocks) of one composite kernel. This matters for engineering because it eliminates the need for bespoke multi-stage simulation: once the block kernel is assembled, all reachability / activation questions reduce to the same standard closure primitive, and comparisons across scenarios become comparisons of kernels and initial seeds.

- The nucleation theorem yields an actionable test: can coupling drive push a latent autocatalytic core above its activation threshold? Concretely, one searches for a small subweb (candidate core) whose internal reinforcement is near-critical, then evaluates whether external inputs or cross-context couplings supply enough additional weight to trigger self-sustaining growth. This frames "emergence" as a finite check on a localized structure, rather than as an unstructured global phenomenon, and motivates scanning for minimal cores as a diagnostic routine.

- Contractivity gives a clean no-polarization certificate; below-threshold bridges give a clean polarization certificate (communities cannot seed each other). The first condition says that the global update map shrinks differences so that distinct initial states converge toward a unique attractor, ruling out long-lived divergence of beliefs/activations. The second condition isolates a dual extreme: even if each community can internally amplify signals, if the inter-community coupling remains sub-critical then activation cannot cross the bridge, so distinct fixed points (or distinct basins of attraction) persist and polarization is structurally stable against small perturbations.

- Random-graph thresholds provide priors: sparse webs below $p \asymp 1/n$ are unlikely to contain even minimal self-weaving cores; above that, autocatalytic loops appear rapidly, and above mean degree 1, macroscopic diffusion becomes plausible. Interpreting this in an Erdős–Rényi heuristic, $p \asymp 1/n$ is the scale at which cycles begin to occur with non-negligible probability, so the absence/presence of feedback motifs can often be predicted from density alone. The "mean degree 1" landmark aligns with the emergence of giant components, suggesting that once a large connected substrate exists, supercritical local amplification has a pathway to spread widely, whereas below it diffusion is typically confined to small components even when local reinforcement is present.

Remark 3094. *From an engineering perspective, the results in this section can be read as a toolkit for deciding which computational questions to ask and in which order. The fixed-point theorems say that closure computations are principled and converge; the block-kernel theorem says that multi-context resonance can be reduced to one closure problem; the nucleation theorem says to search for small candidate autocatalytic cores and test whether couplings can push them above threshold; the polarization criteria provide two extremal certificates (global contraction versus sub-threshold bridges) that bound what the system can do. This style of turning qualitative narrative into testable algebra is characteristic of the quantale approach to weakness and emergence [3, 5]. A useful procedural reading is: (i) compute closures to identify stable consequences of a seed; (ii) if multiple contexts are present, first compile them into the block kernel so that subsequent queries are uniform; (iii) if surprising global spread is observed or desired, localize the explanation by searching for near-critical cores and checking whether cross-couplings supply the missing gain; (iv) when the system exhibits persistent disagreement, attempt to certify either global contractivity (which forces eventual agreement) or the existence of sub-threshold cuts/bridges (which explain why agreement is impossible without strengthening specific links). In this sense the theorems do not merely predict behavior; they also suggest which measurements to take (e.g., local gain, bridge strength, component sizes) and which interventions are most leverageful (strengthen a specific coupling, weaken a feedback loop, or alter the seed) when attempting to control diffusion.*

54.6 Conclusion

Remark 3095 (What these theorems add beyond the base document)**.** *The base Weakness Theory material provides the core definitions and several algebraic laws, plus first-order McBride sensitivities. The additional results here emphasize: (i) a practical emergence test via conditional amplification (Theorem 81), (ii) robustness/invariance properties important for transfer (Theorem 82), (iii) a principled second-order interaction diagnostic tied to curvature (Theorem 83), (iv) a curvature-controlled guarantee for when first-order McBride pruning is near-optimal (Theorem 84), (v) a concrete submodularity/greedy guarantee in the max-product quantale (Theorem 85), (vi) a clean route from delay-feedback dynamics to bursty/chaotic pattern intensity (Theorem 86), and (vii) log-linearization for information-like reasoning (Theorem 87). In more operational terms, the new material turns the base algebra into a usable toolkit: one can (i)* detect *when a small conditional perturbation triggers a qualitatively different closure outcome, (ii)* compare *models under reparameterizations without changing the induced ordering of supports, (iii)* separate *genuine synergistic effects from additive explanations by looking at curvature-like deviations, and (iv)* justify *greedy or top-k approximations in regimes where the second-order terms are provably small. Items (v)–(vii) further supply algorithmic and dynamical interpretations: submodularity connects the max-product semantics to standard approximation guarantees, delay-feedback provides an explicit dynamical mechanism for intermittent intensity that complements fixed-point language, and log-linearization places the same phenomena into an additive scale where ratios and products become differences and sums, making "information-like" arguments (e.g., about gains, gaps, and effective contributions) transparent.*

Remark 3096. *Read in the broader Hyperseed frame, this section supplies a bridge between three* *levels of description: (1) local algebra of support propagation in a quantale, (2) mesoscopic structure in the form of autocatalytic/self-weaving subsets, and (3) macroscopic diffusion and phase transitions in random coupling regimes. The connecting thread is the fixed point: whether one thinks in terms of closure in a web, persistent activation in a core, or global attractors versus polarization, the mathematics is the mathematics of monotone/contractive operators on structured state spaces (Hyperseed-Concept 168, 115, 61,* **??***). A useful way to parse this bridge is to treat each level as a different "resolution" of the same underlying operator: the local view studies how individual edges/constraints compose under the quantale product, the mesoscopic view asks when certain subsets become approximately closed under that composition (thereby behaving like internally reinforcing modules), and the macroscopic view averages these mechanisms over random couplings to locate thresholds where reinforcement becomes typical rather than exceptional. In that sense, fixed points and their stability act as the shared currency: they encode both* existence *(a closure/attractor is present) and* robustness *(it persists under perturbations, rescalings, or pruning), which is exactly what one needs to connect "habit webs" to diffusion/polarization narratives without changing mathematical language.*

Remark 3097. *Finally, the random-graph corollaries can be read as giving an explicit "thermodynamic" intuition for when the web-level closure picture becomes predictive: below the relevant coupling/intensity threshold, amplification chains die out quickly and fixed points tend to be trivial or fragmented; above it, autocatalytic cores and large closures appear with high probability, and the main qualitative uncertainty shifts from* whether *emergence occurs to* which *stable configuration (or polarized basin) is selected by initial conditions and perturbations. This makes the section's themes compatible with both engineering usage (designing for or against runaway reinforcement) and interpretive usage (explaining why similar local rules can yield either weak diffusion or strong resonance depending on global coupling).*

55 Belief Closure + Question Networks + Science: Formal Theorems that Guide Practical Reasoning Loops

Here we formalize and prove a collection of theorems about (i) belief closure under weighted inference rules, (ii) question networks and thinking episodes as controlled closure, and (iii) empirically coupled scientific update loops. The results are chosen to be directly useful for a reasoning system: incremental recomputation laws, confluence/order-independence, explanation/provenance semantics, relevance pruning, modular computation via SCC decomposition, hypothesis sensitivity monotonicity, and reproducibility invariances.

Operationally, the intent is that a reasoning system maintains a graded belief state β, receives an external increment ε (from observation, user input, or measurement), and then runs a bounded or convergent closure procedure to compute consequences under a rule set R. Later subsections will formalize "thinking episodes" as controlled (possibly partial) closure steps and will use the fixed-point structure below to state correctness and invariance properties of those episodes.

55.1 Setup

Definition 489 (Quantale assumptions)**.** *A (commutative) quantale is a tuple $(V, \leq, \oplus, \otimes, e)$ where: (i) $(V, \leq)$ is a complete lattice with join $\oplus$ (and arbitrary joins); (ii) $(V, \otimes, e)$ is a commutative monoid; (iii) $\otimes$ distributes over arbitrary joins in each argument: $a \otimes \oplus_i b_i = \oplus_i (a \otimes b_i)$. We write $\perp$ for the bottom element of V.*

Intuitively, V is a space of "support values" (or degrees of belief, evidence, plausibility, or score). The join $\oplus$ acts as an aggregation of alternative sources of support (taking the least upper bound), while $\otimes$ acts as a combination of jointly required supports (e.g. conjunction-like composition of premise strengths). Commutativity of $\otimes$ encodes that premises are treated as an unordered multiset at the semantic level, which is convenient for confluence and order-independence results later. The distributivity condition is the key algebraic property that permits moving between "compute all alternatives, then combine" and "combine, then take alternatives," which will underwrite several incremental recomputation laws.

Concrete instances to keep in mind include: (a) the Boolean quantale $(\{0, 1\}, \leq, \vee, \wedge, 1)$ recovering ordinary Horn closure; (b) fuzzy-style quantales where $\oplus = \max$ and $\otimes$ is a t-norm; (c) cost or log-score quantales where $\oplus$ is min (interpreting "better" as smaller) and $\otimes$ is addition, provided the lattice/completeness requirements are met by the chosen completion. The bottom element $\perp$ represents "no support" (or the least informative value).

Definition 490 (Belief states, evidence increments)**.** *Fix a claim language L (a set). A belief state is a function $\beta : L \to V$. We order belief states pointwise: $\beta \leq \gamma$ iff $\forall \varphi \in L,\ \beta(\varphi) \leq \gamma(\varphi)$. For belief states β, γ define their join pointwise: $(\beta \oplus \gamma)(\varphi) := \beta(\varphi) \oplus \gamma(\varphi)$. An evidence increment is any $\varepsilon : L \to V$ (same type as a belief state).*

Thus V^L is itself a complete lattice under the pointwise order, with pointwise joins and bottom element $\perp_L$ given by the constant function $\varphi \mapsto \perp$. This makes it natural to treat belief revision steps as monotone operators on a lattice of states. Evidence increments are typed the same way as belief states so that "incorporating evidence" can be expressed uniformly as a join $\beta \oplus \varepsilon$ (or, in variants, as an operator built from $\oplus$ and $\otimes$). In the later "empirically coupled" loop, ε will represent the mapping from an experimental readout to updated support on measurement claims, and the theorems will describe when closure can be recomputed locally.

Definition 491 (Weighted inference rules and one-step inference operator)**.** *A weighted inference rule is a triple $r = (\Gamma, \psi, \lambda_r)$ where $\Gamma \subseteq L$ is finite (premises), $\psi \in L$ (conclusion), and $\lambda_r \in V$ (strength). Define the rule contribution on belief state β by*

$$\mathrm{contrib}_r(\beta) \ := \ \lambda_r \otimes \otimes_{\varphi \in \Gamma} \beta(\varphi).$$

For a rule set R, define the one-step inference operator $\mathrm{F}_R : V^L \to V^L$ by

$$\mathrm{F}_R(\beta)(\psi) \ := \ \beta(\psi) \ \oplus \ \oplus_{r=(\Gamma,\chi,\lambda)\in R:\ \chi=\psi} \Big(\lambda \otimes \otimes_{\varphi\in\Gamma} \beta(\varphi)\Big).$$

The expression $\otimes_{\varphi\in\Gamma}\beta(\varphi)$ is the monoid product over the finite premise set Γ; by convention, when $\Gamma = \emptyset$ this product is e, so a rule with no premises contributes $\lambda_r \otimes e = \lambda_r$ directly as an "axiom" or base-rate support for its conclusion. The finiteness of Γ ensures that the product is well-defined without requiring any additional completeness of $\otimes$.

The one-step operator F_R has two conceptual parts: it preserves existing support $\beta(\psi)$ and then adds (via $\oplus$) whatever new support is derivable in one application of some rule concluding ψ. In particular, F_R is inflationary in the sense that $\beta \leq \mathrm{F}_R(\beta)$ pointwise, because each coordinate is joined with its prior value. Later confluence and incremental-update theorems will leverage the fact that F_R is also monotone (and, under suitable hypotheses, continuous) as a map on the complete lattice V^L.

Definition 492 (Closure as least fixed point above an initial state)**.** *Assume either: (A) the domain effectively used is finite (e.g. finite L and values in a finite subquantale), so ascending chains stabilize; or (B) F_R is Scott-continuous so ω-iteration reaches a fixed point.*

Define the closure of β under R by

$$\mathrm{Cl}_R(\beta) \ := \ \oplus_{n\geq 0}\mathrm{F}_R^n(\beta),$$

where F_R^0 is the identity and $\mathrm{F}_R^{n+1} = \mathrm{F}_R \circ \mathrm{F}_R^n$.

This definition implements the standard saturation construction: repeatedly apply one-step inference, accumulating results by joining all iterates. Under (A), the ascending chain $\beta \leq \mathrm{F}_R(\beta) \leq \mathrm{F}_R^2(\beta) \leq \cdots$ stabilizes after finitely many steps in the effectively used portion of the state space; under (B), Scott-continuity guarantees that the join of the ω-chain is a fixed point. In either case, $\mathrm{Cl}_R(\beta)$ is the least post-fixed point above β and (under the usual monotonicity conditions) coincides with the least fixed point above β in the sense of Knaster–Tarski; later proofs will make this "least solution" property explicit and use it to justify modular recomputation and pruning.

From an implementation perspective, $\mathrm{Cl}_R(\beta)$ represents the fully closed belief state for the rule set R starting from initial support β. In later sections, we will also consider truncated or focused closures (e.g. only within a strongly connected component of the rule dependency graph, or only along questions that are currently active), and the laws proved for Cl_R will serve as the reference semantics those controlled procedures approximate.

Remark 3098. *In the Hyperseed reconstruction, $V = [0,1]^2$ (p-bits) with $\oplus$ as coordinatewise max and $\otimes$ as coordinatewise multiplication; no consistency constraint is imposed. The theorems below are stated at quantale level so they can be re-used with other graded/paraconsistent domains.*

In that p-bit instance, a claim φ may carry separate degrees for distinct evidential channels (e.g. "support" and "counter-support"), and coordinatewise max corresponds to retaining whichever channel has stronger accumulated evidence from any source. Coordinatewise multiplication makes the premises behave like independent attenuations along each channel, so that weak premise support proportionally limits the derived conclusion support in that coordinate. The absence of an imposed consistency constraint is precisely what permits paraconsistent behavior: a claim and its negation may both receive high support without forcing collapse, which is useful when modeling incomplete or conflicting data streams. The quantale-level abstraction here ensures that subsequent theorems can be instantiated equally well for Boolean, fuzzy, probabilistic, or paraconsistent graded logics, provided their combination and aggregation operations satisfy the algebraic conditions above.

55.2 Closure operator laws and incremental update laws

The results in this subsection record the basic algebraic properties that make Cl_R behave like an ordinary closure operator (in the sense of order/lattice theory), while also supporting "incremental" reasoning patterns in which one alternates between incorporating new evidence and re-closing under the rules. Throughout, the order $\leq$ is the pointwise order on belief states (so $\beta \leq \gamma$ means $\beta(\varphi) \leq \gamma(\varphi)$ for every $\varphi \in L$), and joins/meets are understood pointwise as well.

Lemma 162 (Monotonicity and inflationarity of F_R)**.** *For any rule set R, F_R is monotone and inflationary:*

$$\beta \leq \gamma \ \Rightarrow \ \mathrm{F}_R(\beta) \leq \mathrm{F}_R(\gamma), \qquad \beta \leq \mathrm{F}_R(\beta).$$

Proof. Fix $\psi \in L$. Monotonicity: if $\beta \leq \gamma$ then for each premise $\varphi \in \Gamma$, $\beta(\varphi) \leq \gamma(\varphi)$. By monotonicity of $\otimes$ in each argument (a consequence of join-distributivity), $\otimes_{\varphi\in\Gamma}\beta(\varphi) \leq \otimes_{\varphi\in\Gamma}\gamma(\varphi)$. Multiplying by λ preserves order, and joining over rules preserves order, hence $\mathrm{F}_R(\beta)(\psi) \leq \mathrm{F}_R(\gamma)(\psi)$. Inflationary: $\beta(\psi)$ is one of the joined terms in the definition of $\mathrm{F}_R(\beta)(\psi)$, so $\beta(\psi) \leq \mathrm{F}_R(\beta)(\psi)$ for all ψ.

It may be helpful to keep the following reading in mind: F_R performs one "forward-chaining" sweep of rule application. Monotonicity expresses that strengthening any premise degrees in β cannot weaken the derived degrees after one sweep, because every operation used to compute $\mathrm{F}_R(\beta)(\psi)$ (tensoring premise degrees, scaling by λ, and finally taking a join across applicable rules and the original value) is order-preserving. Inflationarity expresses that F_R never retracts what is already believed: the definition explicitly includes the previous value $\beta(\psi)$ as a candidate in the join. $\square$

Theorem 103 (Existence of closure as least fixed point above β)**.** *Under the standing assumption in Definition 4,* $\mathrm{Cl}_R(\beta)$ *is a fixed point of* F_R*, dominates* β*, and is the least fixed point above* β*:*

$$\beta \leq \mathrm{Cl}_R(\beta), \quad \mathrm{F}_R(\mathrm{Cl}_R(\beta)) = \mathrm{Cl}_R(\beta), \quad (\mathrm{F}_R(\gamma) = \gamma \ \wedge \ \beta \leq \gamma) \Rightarrow \mathrm{Cl}_R(\beta) \leq \gamma.$$

Proof. By Lemma 1, the sequence $\beta \leq \mathrm{F}_R(\beta) \leq \mathrm{F}_R^2(\beta) \leq \cdots$ is ascending. Thus $\mathrm{Cl}_R(\beta) = \oplus_{n\geq 0}\mathrm{F}_R^n(\beta)$ exists and satisfies $\beta \leq \mathrm{Cl}_R(\beta)$. In other words, $\mathrm{Cl}_R(\beta)$ collects (by pointwise join) all information obtainable by repeatedly applying the one-step inference operator F_R.

If (A) holds, the ascending chain stabilizes at some N, hence $\mathrm{Cl}_R(\beta) = \mathrm{F}_R^N(\beta)$ and applying F_R yields $\mathrm{F}_R(\mathrm{Cl}_R(\beta)) = \mathrm{Cl}_R(\beta)$. This is the familiar "finite convergence" situation: after enough iterations no further increases occur, so the stabilized state is already closed under one more application of F_R.

If (B) holds, Scott-continuity gives $\mathrm{F}_R(\mathrm{Cl}_R(\beta)) = \mathrm{F}_R(\oplus_n \mathrm{F}_R^n(\beta)) = \oplus_n \mathrm{F}_R^{n+1}(\beta) = \mathrm{Cl}_R(\beta)$. Here Scott-continuity is exactly the property that allows F_R to commute with joins of directed (in particular, ascending) chains, which is why the join of the iterates is again a fixed point even when the chain does not literally stabilize at a finite stage.

For leastness: if γ is a fixed point with $\beta \leq \gamma$, then by monotonicity $\mathrm{F}_R^n(\beta) \leq \mathrm{F}_R^n(\gamma) = \gamma$ for all n. Taking the join over n yields $\mathrm{Cl}_R(\beta) \leq \gamma$. This "least fixed point above β" characterization is the precise sense in which $\mathrm{Cl}_R(\beta)$ is the minimal conservative extension of β that is closed under the rules: any other R-closed state that already contains β must also contain all iterated consequences, hence must dominate their join. $\square$

Theorem 104 (Closure operator laws)**.** Cl_R *is extensive, monotone, and idempotent:*

$$\beta \leq \mathrm{Cl}_R(\beta), \qquad \beta \leq \gamma \Rightarrow \mathrm{Cl}_R(\beta) \leq \mathrm{Cl}_R(\gamma), \qquad \mathrm{Cl}_R(\mathrm{Cl}_R(\beta)) = \mathrm{Cl}_R(\beta).$$

Proof. Extensive holds by Theorem 2. Monotone: if $\beta \leq \gamma$, then $\mathrm{F}_R^n(\beta) \leq \mathrm{F}_R^n(\gamma)$ for all n by Lemma 1, so joining over n preserves the inequality. Equivalently, starting from a stronger base state can only enlarge (never shrink) the set of derivable consequences, because the entire iteration is built from monotone steps and the final closure is obtained by a join.

Idempotent: $\mathrm{Cl}_R(\beta)$ is a fixed point by Theorem 2, so it is the least fixed point above itself, hence applying Cl_R again yields the same state. Operationally, idempotence says that once a belief state has been fully closed under R, running the closure procedure again produces no additional increase: closure is a "saturation" operation. $\square$

Lemma 163 (Warm-start / incremental closure)**.** *For any belief state* β *and evidence increment* ε*,*

$$\mathrm{Cl}_R(\mathrm{Cl}_R(\beta) \oplus \varepsilon) \ = \ \mathrm{Cl}_R(\beta \oplus \varepsilon).$$

Proof. Because $\beta \leq \mathrm{Cl}_R(\beta)$ and $\oplus$ is monotone, $\beta \oplus \varepsilon \leq \mathrm{Cl}_R(\beta) \oplus \varepsilon$. Monotonicity of Cl_R gives $\mathrm{Cl}_R(\beta \oplus \varepsilon) \leq \mathrm{Cl}_R(\mathrm{Cl}_R(\beta) \oplus \varepsilon)$. This direction formalizes the idea that if one first closes β and then adds ε, one cannot end up with less after reclosing than if one had added ε earlier.

Conversely, $\mathrm{Cl}_R(\beta \oplus \varepsilon)$ is R-closed and dominates both β and ε. Since $\mathrm{Cl}_R(\beta)$ is the least R-closed state dominating β, we have $\mathrm{Cl}_R(\beta) \leq \mathrm{Cl}_R(\beta \oplus \varepsilon)$. Hence $\mathrm{Cl}_R(\beta) \oplus \varepsilon \leq \mathrm{Cl}_R(\beta \oplus \varepsilon)$, and applying Cl_R and idempotence yields $\mathrm{Cl}_R(\mathrm{Cl}_R(\beta) \oplus \varepsilon) \leq \mathrm{Cl}_R(\mathrm{Cl}_R(\beta \oplus \varepsilon)) = \mathrm{Cl}_R(\beta \oplus \varepsilon)$. Intuitively, the key step is the minimality property of $\mathrm{Cl}_R(\beta)$: any closed state that already contains β (in particular $\mathrm{Cl}_R(\beta \oplus \varepsilon)$) must be at least as large as $\mathrm{Cl}_R(\beta)$, so "pre-closing" cannot provide any extra advantage beyond what reclosing after adding ε would already compute. □

Corollary 42 (Batching and order-independence of multiple evidence updates)**.** *Let $\varepsilon_1, \ldots, \varepsilon_n : L \to V$ and define $\beta_{k+1} := \mathrm{Cl}_R(\beta_k \oplus \varepsilon_{k+1})$. Then*

$$\beta_n \;=\; \mathrm{Cl}_R(\beta_0 \oplus \varepsilon_1 \oplus \cdots \oplus \varepsilon_n),$$

so the final closed belief state depends only on the join-aggregate of increments, not the order or interleaving of closure steps.

Proof. Induct on n. For the step $n \to n+1$:

$$\beta_{n+1} = \mathrm{Cl}_R(\beta_n \oplus \varepsilon_{n+1}) = \mathrm{Cl}_R(\mathrm{Cl}_R(\beta_0 \oplus \cdots \oplus \varepsilon_n) \oplus \varepsilon_{n+1}) = \mathrm{Cl}_R(\beta_0 \oplus \cdots \oplus \varepsilon_{n+1}),$$

using Lemma 4 in the middle equality. Commutativity/associativity of $\oplus$ yields order-independence. Concretely, this shows that alternating "close, then incorporate the next increment" is equivalent to a single batch update followed by one closure, which is exactly the property exploited by warm-start implementations: one may cache an already closed state and safely reuse it when new evidence arrives, without worrying about the precise sequencing of previous closure steps. □

55.3 Thinking episodes as confluent reasoning loops

Definition 493 (Hypothesis injection)**.** *Fix $h \in L$ and a strength $s \in V$. Define $\delta_{h,s} : L \to V$ by $\delta_{h,s}(h) = s$ and $\delta_{h,s}(\varphi) = \bot$ for $\varphi \neq h$. Define hypothesis injection by $\beta \uparrow^s h := \beta \oplus \delta_{h,s}$.*

In words, $\delta_{h,s}$ is the "minimal" increment that touches only a single sentence h, leaving all other sentences at the null contribution $\bot$. Thus $\beta \uparrow^s h$ is not a special-purpose operator so much as a convenient name for a particular kind of evidence join: it adds support of magnitude s to h and does nothing elsewhere. In particular, if $\oplus$ is interpreted pointwise (as in the standard product order on V^L), then for any $\varphi \neq h$ we have $(\beta \uparrow^s h)(\varphi) = \beta(\varphi) \oplus \bot$, while at h we obtain $(\beta \uparrow^s h)(h) = \beta(h) \oplus s$. This makes explicit that "injecting a hypothesis" is operationally the same kind of update as joining ordinary evidence, except that the increment is concentrated on a single claim.

Definition 494 (Abstract reasoning loop)**.** *A (finite) reasoning loop is any finite sequence of operations applied to an initial β_0 where each step is one of: (i) evidence join $\beta \leftarrow \beta \oplus \varepsilon$, (ii) hypothesis injection $\beta \leftarrow \beta \uparrow^s h$, (iii) closure $\beta \leftarrow \mathrm{Cl}_R(\beta)$.*

The finiteness condition is important here because the conclusion below is stated for a completed episode with a definite final state. Conceptually, however, the definition is designed so that intermediate closures are allowed at arbitrary times (e.g. after each observation, after each derived consequence, or on demand for query answering), and the result will state that these scheduling choices do not affect the final outcome once all increments have been incorporated. Note also that (ii) is syntactic sugar for a particular instance of (i); it is separated only because it is a common kind of step in practical loops, where one temporarily posits a conjecture h with a chosen "working strength" s and then explores its consequences under closure.

Theorem 105 (Confluence of reasoning loops: "close once at the end")**.** *Let a reasoning loop start at β_0 and incorporate evidence increments $\varepsilon_1, \ldots, \varepsilon_n$ and hypothesis injections $\delta_{h_1,s_1}, \ldots, \delta_{h_m,s_m}$, in any order, with Cl_R applied any number of times in between. Then the final belief state equals*

$$\mathrm{Cl}_R\Big(\beta_0 \oplus \varepsilon_1 \oplus \cdots \oplus \varepsilon_n \oplus \delta_{h_1,s_1} \oplus \cdots \oplus \delta_{h_m,s_m}\Big).$$

This is a confluence/normal-form statement: among all "interleavings" of join-updates and closures, every complete finite episode reaches the same result as the canonical schedule "accumulate all increments by $\oplus$, then apply closure once." Equivalently, the closure operator Cl_R behaves like a saturating compilation step that can be cached and postponed without loss, provided no other kind of revision operator is present. The theorem therefore justifies a common implementation pattern: perform cheap incremental joins as data arrive, and only occasionally (or at query time) run the more expensive closure/saturation routine, knowing that doing so earlier would not have changed the eventual closed state.

Proof. Every step is either a join with some increment or an application of Cl_R. By Lemma 4, any application of Cl_R can be commuted past later joins (up to equality) and pushed to the end. By associativity/commutativity of $\oplus$, all joins can be batched. Finally, idempotence collapses multiple closures to one. □

Unpacking the commutation argument: if at some stage we have β and later we will join an increment γ, Lemma 4 provides $\mathrm{Cl}_R(\beta) \oplus \gamma = \mathrm{Cl}_R(\beta \oplus \gamma)$ (or, depending on the precise statement of Lemma 4 used earlier, an equivalent equality that allows rewriting a "close-then-join" segment into a "join-then-close" segment). Repeatedly applying this rewrite to each closure occurrence moves that closure step rightward until no joins remain to its right. Performing this for each closure step yields a sequence where all joins occur first and all closures occur last. Since $\oplus$ is associative and commutative, the order of the join increments is irrelevant to the resulting batch-join. Since Cl_R is idempotent, any suffix $\mathrm{Cl}_R(\mathrm{Cl}_R(\cdot))$ reduces to a single $\mathrm{Cl}_R(\cdot)$, yielding the claimed normal form.

Theorem 106 (Monotone-update "no retraction" principle)**.** *Suppose a belief dynamics uses only operations of the form $\beta \leftarrow \beta \oplus \varepsilon$ and $\beta \leftarrow \mathrm{Cl}_R(\beta)$ (no other revision operator). Then belief states are monotone in time: once a value is achieved at a claim, it never decreases. Formally, along the trajectory $\beta_0, \beta_1, \ldots$, we have $\beta_t \leq \beta_{t+1}$ for all t.*

The pointwise inequality $\beta_t \leq \beta_{t+1}$ should be read as: for every sentence $\varphi \in L$, the strength assigned to φ at time $t+1$ is at least its strength at time t under the order on V. In particular, even if closure introduces additional derived support for some sentences, closure cannot reduce any previously held support. Thus, without an explicit operator that can lower values, the dynamics is inherently cumulative. This captures formally the intuition that join-based updates behave like adding information to a ledger: later steps may add new entries or strengthen existing ones, but they never erase.

Proof. A join update is inflationary since $\beta \leq \beta \oplus \varepsilon$ pointwise. Closure is extensive: $\beta \leq \mathrm{Cl}_R(\beta)$ by Theorem 3. Thus each step is inflationary, hence the whole trajectory is monotone. □

Concretely, for the join step, inflationarity means $\beta(\varphi) \leq (\beta \oplus \varepsilon)(\varphi)$ for each φ, which follows from the defining property of $\oplus$ as a least upper bound / join-like operator in the underlying order. For the closure step, extensivity means closure only adds what is required by R-consequence and never subtracts: $\mathrm{Cl}_R(\beta)$ is a completion of β that contains β as a substate. Chaining these inequalities along the update sequence yields the trajectory monotonicity.

Remark 3099 (Practical meaning). *This explains a standard design choice: if you want genuine retraction, you must represent it explicitly (e.g. add counter-evidence in a paraconsistent negative channel, or move to a time-indexed belief state and reason about change). In the pure join+closure dynamics, you get strong "anytime" and caching properties, but not deletion.*

A related operational consequence is that intermediate results are safe to memoize: because later updates only increase the belief state, any previously computed closed state can be reused as a lower bound and incrementally strengthened rather than recomputed from scratch, provided the implementation supports incremental maintenance of joins and closure. Conversely, domains that require non-monotone belief change (e.g. belief revision with inconsistency repair, or model selection where hypotheses are discarded) must extend the loop with an explicit weakening step or a separate bookkeeping structure (such as provenance, timestamps, or competing "possible worlds"), since the present loop semantics alone cannot express "undo" or "forget."

55.4 Explanation/provenance semantics and relevance pruning

Definition 495 (Derivation trees and their weights). *Fix R and an initial belief state β_0. A derivation tree for a claim ψ is a finite rooted tree whose nodes are labeled by claims, such that: (i) each internal node labeled χ is annotated by a rule $r = (\Gamma, \chi, \lambda_r) \in R$, and has one child for each premise in Γ, labeled by that premise; (ii) leaves are labeled by claims but carry no rule annotation.*

Define the weight of a derivation tree T recursively: if T is a leaf labeled φ, then $w_{\beta_0}(T) := \beta_0(\varphi)$; if T has root rule $r = (\Gamma, \psi, \lambda)$ and subtrees $(T_\varphi)_{\varphi\in\Gamma}$, then

$$w_{\beta_0}(T) \ := \ \lambda \otimes \otimes_{\varphi\in\Gamma} w_{\beta_0}(T_\varphi).$$

Let $\mathrm{Deriv}_n(\psi)$ *denote derivation trees for ψ of height at most n.*

The intended reading is that each internal node contributes the "strength" λ of the rule instance, while each leaf contributes whatever initial support β_0 assigns to the corresponding claim. Thus, T serves simultaneously as (i) an *explanation object* (it records which rules and premises were used) and (ii) a *provenance object* (it supports quantitative ranking via the induced weight). The height bound in $\mathrm{Deriv}_n(\psi)$ corresponds to limiting the number of rule-application layers along any branch, i.e., a finite-depth or bounded-resource reasoning budget.

When a rule has an empty premise set $\Gamma = \varnothing$ (a "fact rule"), the expression $\otimes_{\varphi\in\Gamma} w_{\beta_0}(T_\varphi)$ should be understood as the empty tensor product, i.e., the multiplicative unit of the underlying $\otimes$-structure; then the tree weight reduces to λ. This convention matches the operational reading that a nullary rule provides direct support to its conclusion.

Theorem 107 (Derivation-tree semantics for finite-depth inference). *For every $n \geq 0$ and every claim $\psi \in L$,*

$$\mathrm{F}_R^n(\beta_0)(\psi) \ = \ \oplus_{T\in\mathrm{Deriv}_n(\psi)} w_{\beta_0}(T).$$

Consequently,

$$\mathrm{Cl}_R(\beta_0)(\psi) \ = \ \oplus_{T\in\mathrm{Deriv}(\psi)} w_{\beta_0}(T),$$

where $\mathrm{Deriv}(\psi) := \bigcup_{n\geq 0} \mathrm{Deriv}_n(\psi)$ *is the set of all finite derivation trees.*

Beyond giving a proof-theoretic description of F_R^n, the statement can be read as an "all-derivations" semantics: the value assigned to ψ after n rounds is exactly the aggregation (via $\oplus$) of all ways of deriving ψ using at most n layers of rule applications, where each way is scored by the tree weight. In particular, this isolates two orthogonal design choices: (a) the algebra $(\oplus, \otimes)$ determining how supports combine and (b) the rule set R determining which derivations exist.

Proof. Induct on n. Base $n = 0$: $\mathrm{F}_R^0(\beta_0) = \beta_0$, and $\mathrm{Deriv}_0(\psi)$ contains only the leaf tree labeled ψ, so both sides equal $\beta_0(\psi)$. Inductive step: assume the claim holds for n. Then

$$\mathrm{F}_R^{n+1}(\beta_0)(\psi) = \mathrm{F}_R(\mathrm{F}_R^n(\beta_0))(\psi) = \mathrm{F}_R^n(\beta_0)(\psi) \oplus \oplus_{r=(\Gamma,\psi,\lambda)\in R}\Big(\lambda \otimes \otimes_{\varphi\in\Gamma}\mathrm{F}_R^n(\beta_0)(\varphi)\Big).$$

By the induction hypothesis, each premise value $\mathrm{F}_R^n(\beta_0)(\varphi)$ is a join over weights of height-$\leq n$ derivations of φ. Since $\otimes$ distributes over joins, the tensor of premise-joins expands as a join over all choices of premise-derivations, which is exactly the join over weights of height-$\leq n+1$ derivations of ψ whose root uses rule r. Including the leftmost $\mathrm{F}_R^n(\beta_0)(\psi)$ term accounts for derivations where the root is a leaf. Thus the join equals $\oplus_{T\in\mathrm{Deriv}_{n+1}(\psi)} w_{\beta_0}(T)$.

Taking the join over n yields the closure formula. □

The distributivity step used above is precisely where the algebraic assumptions connect to explainability: it licenses moving from "a rule applied to aggregated premise-support" to "an aggregation over all concrete premise-explanations." Concretely, if $\mathrm{F}_R^n(\beta_0)(\varphi) = \oplus_i a_i$ and $\otimes$ distributes, then

$$\lambda \otimes \Big(\otimes_{\varphi\in\Gamma} \oplus_i a_{\varphi,i}\Big) \;=\; \oplus_{\text{choices } i(\cdot)} \; \lambda \otimes \otimes_{\varphi\in\Gamma} a_{\varphi,i(\varphi)},$$

so each selection of indices $i(\cdot)$ corresponds to choosing one derivation for each premise, i.e., to choosing one concrete derivation tree for the conclusion. This is the formal bridge from numeric/graded belief values to explicit provenance objects.

Remark 3100 (Why this is a decision tool)**.** *The theorem gives a canonical explanation/provenance object: every inferred belief value is an aggregate of derivation weights. A reasoning system can (a) store top-k derivations, (b) compute minimal-commitment explanations, or (c) locate which premises/rules are responsible for conflict by inspecting high-weight trees.*

In more operational terms, one can treat derivation trees as a search space and the weight function as an objective. For instance, when $\oplus$ is max and $\otimes$ is $+$ (or $\times$), the closure value is the score of the best-scoring derivation; when $\oplus$ is a sum-like aggregation, it behaves like total support accumulated from all derivations. In either case, the tree representation makes it possible to (i) return a human-readable justification (the subtree rooted at the conclusion), (ii) perform sensitivity analysis (how much a premise's initial value affects the conclusion), and (iii) implement debugging tools (identify a small set of high-impact rules contributing to an unexpected conclusion).

Definition 496 (Rule dependency graph and ancestor set)**.** *Define the (directed) rule dependency graph G_R on vertex set L with an edge $\varphi \to \psi$ iff there exists a rule $r = (\Gamma, \psi, \lambda) \in R$ with $\varphi \in \Gamma$. For $S \subseteq L$, define $\mathrm{Anc}_R(S)$ as the set of vertices that can reach some element of S via a directed path in G_R, together with S itself.*

The graph G_R is a purely syntactic abstraction of potential information flow: an edge $\varphi \to \psi$ asserts that changing support for φ *may* affect support for ψ via at least one rule, independent of weights and independent of whether φ is actually derivable in a given run. Accordingly, $\mathrm{Anc}_R(S)$ is a conservative relevance superset: it contains every claim that could appear as a leaf of a derivation tree for some $\psi \in S$. Computing $\mathrm{Anc}_R(S)$ amounts to a backward reachability query (reverse graph search) from S in G_R; this supports a standard relevance-pruning optimization in which one restricts attention to the sublanguage induced by $\mathrm{Anc}_R(S)$ when answering queries about S.

Theorem 108 (Ancestor locality / relevance pruning)**.** *Let $S \subseteq L$ and let β_0, β_0' be initial belief states that agree on $\mathrm{Anc}_R(S)$. Then the closures agree on S:*

$$\forall\psi \in S, \quad \mathrm{Cl}_R(\beta_0)(\psi) = \mathrm{Cl}_R(\beta_0')(\psi).$$

Proof. Fix $\psi \in S$. By Theorem 8, $\mathrm{Cl}_R(\beta_0)(\psi)$ is the join over weights of derivation trees for ψ. Every leaf label appearing in any derivation tree for ψ must lie in $\mathrm{Anc}_R(\{\psi\}) \subseteq \mathrm{Anc}_R(S)$ because each application of a rule introduces premises connected by edges to the conclusion. Hence, for every derivation tree T for ψ, its weight $w_{\beta_0}(T)$ depends only on β_0 restricted to $\mathrm{Anc}_R(S)$, and therefore equals $w_{\beta'_0}(T)$. Thus the joins over all trees are equal. $\square$

A useful way to internalize the proof is: relevance is determined by *which leaves can ever appear* in a derivation of the target. Since internal nodes are created only by applying rules, and each rule application moves along edges of G_R from premises to conclusion, any leaf that contributes to a derivation of ψ must have a path to ψ and thus lies in the ancestor set. The theorem therefore justifies a correctness-preserving implementation trick: if the goal is to answer queries in S, then one may replace β_0 by its restriction to $\mathrm{Anc}_R(S)$ (setting all other claims to arbitrary values, including $\perp$) without changing the answers on S. This is the formal sense in which "unrelated" parts of the belief base are operationally irrelevant.

Corollary 43 (Non-explosion as operational irrelevance)**.** *If $\psi \in L$ is not reachable from any claim with non-bottom initial value (and not reachable from any injected hypothesis), then $\mathrm{Cl}_R(\beta_0)(\psi) = \beta_0(\psi)$. In particular, if $\beta_0(\psi) = \perp$ and ψ has no derivation tree, then $\mathrm{Cl}_R(\beta_0)(\psi) = \perp$.*

Proof. If there is no derivation tree for ψ other than the trivial leaf, then Theorem 8 yields $\mathrm{Cl}_R(\beta_0)(\psi) = \beta_0(\psi)$. If additionally $\beta_0(\psi) = \perp$ then the value remains bottom. $\square$

This corollary is best read as a guardrail for scaling: even if the global rule base R is large, only the portion that is (i) upstream of the query and (ii) seeded by non-bottom information can affect the outcome. In particular, one avoids a form of "explosion" in which irrelevant axioms or rules inadvertently influence unrelated queries: if there is no derivational route from supported claims to ψ, then ψ cannot gain additional support. Equivalently, if ψ is outside the forward reachability region of the initially supported set, then the closure operator leaves ψ unchanged.

55.5 Cycles, modularity, and question networks

Definition 497 (Strongly connected components (SCCs) and condensation DAG)**.** *Let G_R be the dependency graph. Let $\mathcal{C} = \{C_1, \dots, C_k\}$ be its SCC partition. The condensation graph $\mathrm{Cond}(G_R)$ is the DAG whose nodes are SCCs and with an edge $C_i \to C_j$ if there exists $\varphi \in C_i$ and $\psi \in C_j$ with an edge $\varphi \to \psi$ in G_R. Fix a topological order of SCCs so edges go from lower to higher indices. Let $P_i := \bigcup_{j \le i} C_j$ be the prefix set. Intuitively, each SCC C_i is a "cycle-cluster" of mutually interdependent formulas, while the condensation DAG records one-way informational flow between these clusters. Because $\mathrm{Cond}(G_R)$ is acyclic, the topological order ensures that any dependency path that enters an SCC C_i can only come from SCCs among $\{C_1, \dots, C_{i-1}\}$, never from future SCCs.*

Theorem 109 (SCC modularization of closure)**.** *Assume L is finite (or effectively finite for the active reasoning slice). Let SCCs be topologically ordered as above. In particular, the finiteness/effective-finiteness assumption ensures that least fixed points used below exist and are attainable by iteration within each SCC (e.g. via a standard monotone-operator convergence argument on a finite product order).*

Define an iterative construction:

- *Let $\beta^{(0)} := \beta_0$.*

- *For $i = 1, \dots, k$, compute the least R-closed extension of $\beta^{(i-1)}$ on the SCC C_i while keeping values on $L \setminus C_i$ fixed, i.e. compute*

$$\beta^{(i)} := \min\{\gamma : L \to V \ : \ \beta^{(i-1)} \le \gamma,\ \gamma|_{L\setminus C_i} = \beta^{(i-1)}|_{L\setminus C_i},\ \gamma \textit{ is } R\textit{-closed on conclusions in } C_i\}.$$

Then $\beta^{(k)} = \mathrm{Cl}_R(\beta_0)$.

Equivalently: closure can be computed SCC-by-SCC in condensation topological order; cycles are isolated to SCC-local fixed point computations. Equivalently again, if one views R-closure as the least fixed point of a global (monotone) consequence operator on V^L, then the condensation ordering provides a factorization of that global fixed point into a sequence of local fixed points, each taken under boundary conditions established by earlier SCCs.

Proof. Key fact: If $\psi \in P_i$, then every ancestor of ψ lies in P_i by topological ordering of SCCs, so $\mathrm{Anc}_R(\{\psi\}) \subseteq P_i$. To see this, note that any directed path in G_R from some φ to ψ induces a path in $\mathrm{Cond}(G_R)$ from the SCC of φ to the SCC of ψ; by topological ordering, that SCC index cannot exceed the index of the SCC containing ψ, so φ must lie in P_i.

Let $\beta^* := \mathrm{Cl}_R(\beta_0)$. We prove by induction on i that $\beta^{(i)}$ agrees with β^* on P_i.

Base $i = 0$ is trivial for the empty prefix. (Equivalently, $\beta^{(0)} = \beta_0$ provides the initial boundary condition before any SCC-local closure is performed.)

Inductive step: assume agreement on P_{i-1}. Consider any $\psi \in C_i$. All rules concluding ψ have premises in $\mathrm{Anc}_R(\{\psi\}) \subseteq P_i$, so by Theorem 9 the value $\beta^*(\psi)$ depends only on β_0 restricted to P_i and on closure within P_i. When computing $\beta^{(i)}$, we keep $L \setminus C_i$ fixed at $\beta^{(i-1)}$, which by induction matches β^* on P_{i-1}. Thus the SCC-local closure computation within C_i is exactly the least fixed point consistent with the already-correct boundary conditions from P_{i-1}, hence matches β^* on C_i by minimality/least-fixed-point uniqueness on the finite slice. More explicitly, restricting attention to the coordinates in C_i, the closure conditions induced by rules with conclusions in C_i define a monotone update operator on V^{C_i} whose parameters are the already-fixed values on P_{i-1}; the construction of $\beta^{(i)}$ chooses the least post-fixed point extending those parameters, and β^* is itself such a post-fixed point, so the least one must coincide with β^* on C_i.

Therefore $\beta^{(i)}$ matches β^* on P_i. At $i = k$, $P_k = L$, giving $\beta^{(k)} = \beta^*$. □

Remark 3101 (Practical meaning)**.** *This theorem is a blueprint for scalable reasoning: build the rule dependency graph, condense SCCs, and run fixed point solvers only inside SCCs; outside SCCs, do a single topological pass. Cycles become localized engineering objects. In implementations, this often translates into (i) a one-time graph analysis step (SCC decomposition is linear-time in $|V|+|E|$), followed by (ii) per-SCC propagation that can use specialized solvers depending on the rule fragment (e.g. Horn-like propagation, constraint propagation, or abstract interpretation) without re-solving already-settled acyclic regions. A further consequence is that independent SCCs with no edges between them in $\mathrm{Cond}(G_R)$ can be processed in parallel once their respective predecessor SCCs have stabilized.*

Definition 498 (Question networks and cycle breaking)**.** *A question network is a directed graph $Q = (V, E)$ whose nodes are questions and edges $u \to v$ mean "answering u requires (or strongly benefits from) answering v". A feedback vertex set (FVS) is $H \subseteq V$ such that removing H makes the graph acyclic. This notion is a direct analogue of SCC condensation for reasoning tasks: SCCs identify mutually entangled questions, while an FVS provides an explicit set of "cycle breakers" that, once provisionally resolved, turns the remaining agenda into a schedulable acyclic plan.*

Theorem 110 (Cycle-breaking by hypotheses yields schedulable question answering)**.** *Let $Q = (V, E)$ be a finite question network and let H be any feedback vertex set. Then $Q \setminus H$ is acyclic* *and admits a topological order, so questions in $V \setminus H$ can be answered in a dependency-respecting sequence. If hypotheses are injected to provide provisional answers for H, then any interleaving of the remaining answers with closure yields the same final state as "batch then close" (Theorem 6). In other words, choosing H turns an otherwise cyclic information-gathering process into an iterative loop with well-defined stages: (a) posit tentative values on H, (b) propagate consequences through the acyclic remainder, (c) optionally revise hypotheses, and (d) repeat, with Theorem 6 guaranteeing order-independence of the propagation steps within each stage.*

Proof. By definition of feedback vertex set, removing H yields an acyclic digraph. Every finite acyclic digraph admits a topological ordering (standard). The second claim follows by treating each provisional hypothesis and each answered-question datum as an increment and applying Theorem 6. Concretely, once the non-hypothesis questions are arranged in a topological order, each answered question can be added as an update that is immediately closed under R; Theorem 6 ensures that whether one closes after each individual answer or after collecting a batch of answers, the eventual R-closed result is the same (given the same injected hypotheses on H). □

55.6 Hypothesis sensitivity as a controlled exploration knob

Theorem 111 (Monotone hypothesis sensitivity)**.** *Fix R, an initial β, a claim h, and strengths $s \le s'$ in V. Then for all $\psi \in L$,*

$$\mathrm{Cl}_R(\beta \uparrow^s h)(\psi) \;\le\; \mathrm{Cl}_R(\beta \uparrow^{s'} h)(\psi).$$

Proof. Since $s \le s'$, we have $\delta_{h,s} \le \delta_{h,s'}$ pointwise, hence $\beta \oplus \delta_{h,s} \le \beta \oplus \delta_{h,s'}$. Apply monotonicity of Cl_R (Theorem 3). In other words, raising the strength parameter cannot lower the pre-closure belief value of any formula, and closure preserves this ordering because it is an order-preserving map on belief states. Equivalently, the operator $\beta \mapsto \mathrm{Cl}_R(\beta \uparrow^s h)$ is monotone in the knob s when all other inputs are held fixed. □

Remark 3102 (Practical meaning)**.** *This supports "turn the hypothesis dial" search strategies: when strengths live on a chain (e.g. $s = (t, \bot)$ with scalar t), the induced consequences are monotone, enabling threshold search. Concretely, if one is looking for the least strength s that makes a target consequence ψ reach a desired acceptance level (e.g. $\mathrm{Cl}_R(\beta \uparrow^s h)(\psi) \ge \tau$ for some $\tau \in V$), then monotonicity guarantees that the set of strengths satisfying the constraint is upward-closed. This is precisely the condition needed for efficient one-dimensional search procedures such as bisection (when the chain is discrete or admits suitable midpoints) or simple incremental stepping (when the chain is finite). It also justifies sensitivity analysis: one can rank downstream consequences by how early (at what knob setting) they appear, and interpret earlier appearance as greater logical dependence on h under R and β.*

55.7 Science as empirically coupled evidence-batching

Definition 499 (Empirical increment and scientific update operator)**.** *Let E be experiments and O outcomes. Suppose each observed result (e, o) produces an increment $\varepsilon_{e,o} : L \to V$. Define the scientific update step (given rule set R) by*

$$U_{e,o}(\beta) \;:=\; \mathrm{Cl}_R(\beta \oplus \varepsilon_{e,o}).$$

The intended reading is that $\varepsilon_{e,o}$ records the direct empirical push supplied by the observation (e, o), while $\mathrm{Cl}_R(\cdot)$ propagates that push through the inferential constraints in R. Thus $U_{e,o}$ separates "data entry" (via $\oplus$ with $\varepsilon_{e,o}$) from "theory-driven closure" (via Cl_R), mirroring the practical loop of accumulating measurements and then recomputing derived commitments.

Theorem 112 (Reproducibility invariance: experiments batch and commute)**.** *For any finite sequence* $(e_1, o_1), \ldots, (e_n, o_n)$*,*

$$U_{e_n,o_n} \circ \cdots \circ U_{e_1,o_1}(\beta_0) \;=\; \mathrm{Cl}_R\Big(\beta_0 \oplus \varepsilon_{e_1,o_1} \oplus \cdots \oplus \varepsilon_{e_n,o_n}\Big).$$

Hence the final closed belief state depends only on the join-aggregate of empirical increments, not on the order of experiments or how frequently closure is re-run.

Proof. This is exactly Corollary 1 (batching/order-independence) applied with increments $\varepsilon_k := \varepsilon_{e_k,o_k}$. Intuitively, $\oplus$ acts as an order-insensitive accumulator of the raw experimental contributions, while the closure operator Cl_R can be postponed until after accumulation without changing the result. Operationally, this means one may either (i) close after each new datum arrives, or (ii) store increments and close only periodically, and both pipelines coincide at the level of the final closed state. □

A useful special case is when multiple outcomes for the same experimental condition are merged into a single increment (e.g. by taking their join as a coarse-grained summary); the theorem shows that any such batching scheme is equivalent to processing each outcome individually and closing at the end, provided the same overall join-aggregate is obtained.

Corollary 44 (Idempotence of repeating the same experimental result)**.** *If the same empirical increment* ε *is joined twice, it has no further effect:*

$$\mathrm{Cl}_R\big(\beta \oplus \varepsilon \oplus \varepsilon\big) = \mathrm{Cl}_R(\beta \oplus \varepsilon).$$

Proof. $\oplus$ is idempotent: $\varepsilon \oplus \varepsilon = \varepsilon$ pointwise. Apply Theorem 14. Equivalently, the second occurrence of ε does not contribute any additional information beyond what is already present after the first join, so closure sees identical inputs on both sides. □

Remark 3103 (Interpretation and scope)**.** *The corollary formalizes a minimal "reproducibility sanity check": exact repetition of the same encoded outcome cannot, by itself, further change the closed beliefs. This is not a claim that repeating a physical experiment is uninformative; rather, it says that if repetition yields the same increment object* ε *(i.e. the same update signal in* V^L*), then the algebra of evidence accumulation treats it as a duplicate. When one wishes repeated trials to strengthen confidence, that strengthening must be represented at the level of the increment map itself—for example, by having multiple trials produce distinct increments whose join is strictly larger, or by defining* $\varepsilon_{e,o}$ *to already encode sample size or reliability.*

55.8 Methodology refinement and collective synergy

In this subsection we make precise two closely related ideas that often occur in practical reasoning loops: (a) refining a methodology by strengthening existing inferential links and/or adding new ones should not reduce what can be concluded, and (b) pooling partially informative belief states can unlock conclusions that neither agent can reach alone. Both effects are captured abstractly by the order-theoretic behavior of the one-step operator F_R and its induced closure Cl_R, with all inequalities understood pointwise in the underlying truth-value / confidence order.

Definition 500 (Rule-set refinement preorder)**.** *Given rule sets* R, R'*, write* $R \preceq R'$ *if: (i) for every rule* $(\Gamma, \psi, \lambda) \in R$ *there is a rule* $(\Gamma, \psi, \lambda') \in R'$ *with* $\lambda \leq \lambda'$*, and (ii)* R' *may contain additional rules not in* R*.*

Intuitively, $R \preceq R'$ means that R' is at least as "methodologically strong" as R: no previously available inference is weakened (the same premises Γ still support the same conclusion ψ with at least the same strength), and one is permitted to introduce additional inferential routes. The relation is a preorder rather than a partial order because different rule sets can be mutually refining if they contain duplicates or different collections of redundant rules that nonetheless yield the same operational behavior under F and Cl.

Theorem 113 (Methodology refinement monotonicity). *If $R \preceq R'$, then for all belief states β,*

$$\mathrm{F}_R(\beta) \leq \mathrm{F}_{R'}(\beta) \qquad \text{and} \qquad \mathrm{Cl}_R(\beta) \leq \mathrm{Cl}_{R'}(\beta).$$

This theorem formalizes the idea that improving a protocol, measurement pipeline, or background theory—modeled here by strengthening rule weights λ and adding rules—cannot decrease the immediate inferential update (F) nor the eventual stable conclusions reached by iterating that update (Cl). In particular, it separates two mechanisms of refinement: increasing λ for existing rules increases the contribution of each such rule, while adding rules enlarges the join over available derivations.

Proof. Fix ψ. In $\mathrm{F}_{R'}(\beta)(\psi)$, the join ranges over (at least) all rules concluding ψ that appear in R, and for each such rule the contribution is multiplied by a strength $\lambda' \geq \lambda$, so each corresponding contribution in R' is $\geq$ the one in R. Thus the entire join is larger, hence $\mathrm{F}_R(\beta) \leq \mathrm{F}_{R'}(\beta)$ pointwise. By monotonicity of iteration and join over iterates, $\mathrm{Cl}_R(\beta) \leq \mathrm{Cl}_{R'}(\beta)$. □

To unpack the last sentence: if we write $\mathrm{F}_R^{(n)}$ for the n-fold iterate of F_R, then the already-established pointwise inequality $\mathrm{F}_R \leq \mathrm{F}_{R'}$ (as operators at the fixed input β) propagates to $\mathrm{F}_R^{(n)}(\beta) \leq \mathrm{F}_{R'}^{(n)}(\beta)$ for all n by induction using monotonicity of F in its argument. Taking the join over all iterates (the definition of closure in this framework) preserves the inequality because joins are monotone in each component. Conceptually, refinement cannot remove reachable states from the iteration chain; it can only push some coordinates upward and possibly accelerate convergence.

Theorem 114 (Pooling beliefs is super-additive; distributed-premise synergy criterion). *For any belief states β, γ,*

$$\mathrm{Cl}_R(\beta \oplus \gamma) \;\geq\; \mathrm{Cl}_R(\beta) \oplus \mathrm{Cl}_R(\gamma).$$

Moreover, suppose there exists a rule $r = (\Gamma, \psi, \lambda) \in R$ and a partition $\Gamma = \Gamma_1 \cup \Gamma_2$ such that:

$$\forall \varphi \in \Gamma_1 : \; \beta(\varphi) > \perp \;\wedge\; \gamma(\varphi) = \perp, \qquad \forall \varphi \in \Gamma_2 : \; \gamma(\varphi) > \perp \;\wedge\; \beta(\varphi) = \perp,$$

and $\beta(\psi) = \gamma(\psi) = \perp$ and no other rule derives ψ. Then

$$\mathrm{Cl}_R(\beta)(\psi) = \mathrm{Cl}_R(\gamma)(\psi) = \perp \quad \text{but} \quad \mathrm{Cl}_R(\beta \oplus \gamma)(\psi) \;\geq\; \lambda \otimes \otimes_{\varphi \in \Gamma}(\beta \oplus \gamma)(\varphi) \;>\; \perp,$$

so the inequality is strict at ψ.

The first inequality is a general "super-additivity" (more precisely, super-join-preservation) statement: closing after pooling is at least as informative as pooling after closing each agent separately. The second part gives an explicit and checkable sufficient condition for *strict* improvement, capturing a familiar pattern in collaborative science: one group has evidence for some premises, another group has evidence for the complementary premises, and only the pooled record supports the full premise set Γ required by the rule r. The assumptions $\beta(\psi) = \gamma(\psi) = \perp$ and "no other rule derives ψ" isolate the effect, ensuring that ψ cannot become supported except through this particular distributed-premise pathway.

Proof. Since $\beta \le \beta \oplus \gamma$ and $\gamma \le \beta \oplus \gamma$, monotonicity of Cl_R gives $\mathrm{Cl}_R(\beta) \le \mathrm{Cl}_R(\beta \oplus \gamma)$ and $\mathrm{Cl}_R(\gamma) \le \mathrm{Cl}_R(\beta \oplus \gamma)$. Joining these inequalities yields $\mathrm{Cl}_R(\beta) \oplus \mathrm{Cl}_R(\gamma) \le \mathrm{Cl}_R(\beta \oplus \gamma)$.

For strictness: under the stated premises, in $\mathrm{F}_R(\beta)(\psi)$ the contribution of rule r includes a tensor factor $\beta(\varphi) = \bot$ for some $\varphi \in \Gamma_2$, so the rule contribution is $\bot$; with no other rules and base $\beta(\psi) = \bot$, ψ remains $\bot$ under all iterates, hence under closure. Similarly for γ. But in $\beta \oplus \gamma$, every premise in Γ is $> \bot$ by construction, so the one-step contribution of r to ψ is $> \bot$, hence closure yields $> \bot$ at ψ. □

One can view the strictness argument as identifying a minimal "cut" in the support graph of ψ: each individual belief state fails to activate r because at least one prerequisite premise sits at $\bot$, and because there is no alternative derivation, the iterate sequence cannot raise ψ above $\bot$. Pooling via $\oplus$ removes these bottlenecks by taking the least upper bound of the two information sources premise-wise, after which the tensor aggregation across Γ yields a strictly positive combined premise support, which is then scaled by λ. In methodological terms, this provides a formal criterion for when collaboration yields genuinely new conclusions rather than merely averaging or redundantly confirming what was already derivable.

Corollary 45 (Protocol quality monotonicity)**.** *If two experimental protocols yield increments $\varepsilon \le \varepsilon'$ (pointwise), then for any β,*

$$\mathrm{Cl}_R(\beta \oplus \varepsilon) \;\le\; \mathrm{Cl}_R(\beta \oplus \varepsilon').$$

Here ε and ε' can be read as external evidence injections (e.g., measurement results, curated dataset additions, or validated intermediate findings) that are pooled into the current belief state β via $\oplus$. The pointwise comparison $\varepsilon \le \varepsilon'$ models the idea that the improved protocol delivers evidence that is at least as informative at every proposition, so subsequent closure under the same inferential rules should not be weakened.

Proof. $\beta \oplus \varepsilon \le \beta \oplus \varepsilon'$ by monotonicity of $\oplus$. Apply monotonicity of Cl_R. □

56 Mind–World Correspondence and Reality-Systems: Transfer, Shared Reality, and Robustness

We state and prove reusable theorems for reasoning engines that represent internal and external structure as quantale-weighted directed graphs and relate them via approximate morphisms. The results provide: (i) quantitative transfer bounds for multi-step inferences and pattern constraints under mind–world correspondence; (ii) fixed-point constructions for shared reality across multiple minds; and (iii) robustness criteria ensuring that correspondences and reality-systems persist under perturbations of weights or thresholds.

Remark 3104. *This section is best read as a small "transport calculus": we have a graph-like structure inside a mind (or model) and a graph-like structure outside (or in another model), and we track what can be reliably carried across the correspondence. This is a formalization of Mind–World Correspondence in the sense of Hyperseed-Concept 112, with a deliberately quantitative flavor (the correspondence has "slack" or "quality"). Related motivations appear in the Hyperseed presentation [1] and in transfer-learning formalisms such as [7].*

56.1 Standing setting

Definition 501 (Quantale with residuation)**.** *Let $(V, \leq, \otimes, e)$ be a commutative quantale that is also a complete lattice. Assume it is* residuated*: for each $u \in V$, the map $u \otimes (-)$ has a right adjoint, written $(u \to -)$, characterized by*

$$u \otimes w \leq v \quad \textit{iff} \quad w \leq (u \to v).$$

Remark 3105. *The residuation operation $(u \to v)$ is an "implication-like" quantity internal to the quantale: it measures how much additional weight w one must supply, when combined with u via $\otimes$, to stay below (or within) v. In logical terms, the adjunction says that multiplying evidence/resources by u and then comparing to v is equivalent to directly comparing the remaining allowance w to the residuum $u \to v$. This is one of the algebraic devices by which graded inference and graded constraint satisfaction can be carried out without leaving the lattice-theoretic world; see also the quantale-based treatment of graded "weakness" and slack in [3] (Hyperseed-Concept 202, Hyperseed-Concept 143).*

A simple anchor example is $V = \{0, 1\}$ with $\otimes = \wedge$ and $\leq$ the usual order: then $u \to v$ is the ordinary Boolean implication. Another common example is $V = [0, 1]$ ordered by $\leq$ with $\otimes$ a t-norm (e.g. multiplication); the residuum then encodes a familiar notion of "how much more confidence is permitted." The utility of residuation in this section is that it allows us to speak about degree of structure-preservation via a single meet of implications, and then to manipulate that degree monotonically.

Definition 502 (V-graphs and approximate morphisms)**.** *A V-graph is a pair $G = (X, G)$ where X is a set of nodes and $G : X \times X \to V$. Given V-graphs $G = (X, G)$ and $H = (Y, H)$ and a function $f : X \to Y$, define the* preservation degree

$$\deg(f; G, H) \;:=\; \bigwedge_{x, x' \in X} \Big(G(x, x') \to H(f(x), f(x')) \Big).$$

*For $q \in V$, we say f is a q-*approximate morphism $G \to H$ *if $q \leq \deg(f; G, H)$, equivalently*

$$G(x, x') \otimes q \leq H(f(x), f(x')) \qquad \forall x, x' \in X.$$

Remark 3106. *A V-graph is simply a directed graph whose edges are labeled by elements of V rather than by booleans. Intuitively, $G(x, x')$ is the strength with which the structure asserts (or supports) the directed relation $x \to x'$. When $V = \{0, 1\}$ we recover ordinary directed graphs, and when $V = [0, 1]$ we recover weighted graphs where larger numbers indicate stronger edges (Hyperseed-Concept 132, Hyperseed-Concept 131; compare [5] for pattern-web motivations).*

The preservation degree $\deg(f; G, H)$ is defined as a meet $\bigwedge$ (infimum) over all pairs (x, x') of the implication-like term $G(x, x') \to H(f(x), f(x'))$. Reading this in plain language: for each edge (or potential edge) in G, we ask "how well is it respected after mapping into H?"; then we take the worst case over all edges. The condition that f is a q-approximate morphism says that every *internal edge, after paying a uniform slack factor q, is still supported externally. In the frequent probabilistic intuition where $\otimes$ is multiplication, the inequality $G(x, x') \otimes q \leq H(f(x), f(x'))$ says: "external strength is at least internal strength times a global fidelity factor q."*

This notion is the algebraic core of mind–world correspondence: the mind's internal graph G can be transported to the world's graph H only up to a quantifiable correspondence quality q (Hyperseed-Concept 112). The use of a single scalar q is a deliberate discipline: it gives conservative bounds that can be composed over paths, yielding depth-dependent transfer penalties in the next subsection (a transfer-learning flavor; cf. [7]).

Definition 503 (Relational composition and path powers)**.** *For a V-graph $G = (X, G)$ define the (quantale) matrix composition*

$$(G \circ G)(x, z) := \bigvee_{y \in X} G(x, y) \otimes G(y, z).$$

Inductively define $G^{(1)} := G$ and $G^{(n+1)} := G^{(n)} \circ G$. (Thus $G^{(n)}(x, z)$ is the best weight of an n-step path from x to z.)

Remark 3107. *The notation $\bigvee$ denotes join (supremum) in the complete lattice V, so the formula*

$$(G \circ G)(x, z) = \bigvee_{y} G(x, y) \otimes G(y, z)$$

is the usual "sum over intermediates" familiar from matrix multiplication, except that addition is replaced by join $\bigvee$ and multiplication is replaced by $\otimes$. When $V = \{0, 1\}$ and $\otimes = \wedge$, this is exactly the standard composition of relations: there is an edge from x to z in $G \circ G$ iff there exists an intermediate y with edges $x \to y$ and $y \to z$ in G. When $V = [0, 1]$ with $\otimes$ multiplication and $\bigvee$ as max, it says that the best two-step path weight is the maximum over intermediates of the product of the two edge weights.

The path powers $G^{(n)}$ let us speak about multi-step inference or multi-step constraint propagation: $G^{(n)}(x, z)$ is the strongest support obtainable for a directed connection from x to z using exactly n hops. This "best path" semantics is the bridge between graph structure and reasoning depth that will appear explicitly in the transfer theorems.

Lemma 164 (Monotonicity of residuum (rewrite rule))**.** *For all $u, u', v, v' \in V$:*

$$u \le u' \Rightarrow (u' \to v) \le (u \to v), \qquad v \le v' \Rightarrow (u \to v) \le (u \to v').$$

Remark 3108. *This lemma records the two basic monotonicity directions of the residuum. It says that the implication-like quantity $u \to v$ is* antitone *in its left argument and* monotone *in its right argument: making the antecedent u larger (harder to satisfy) can only shrink the implication, while making the consequent v larger (easier to satisfy) can only enlarge it.*

The reason this matters is conceptual as well as technical: $\deg(f; G, H)$ *is built from many terms of the form $G(x, x') \to H(f(x), f(x'))$. Thus, if we later prune internal edges (make G smaller) or strengthen the external graph (make H larger), we can predict how the overall degree changes. This monotonicity will be used verbatim in the robustness theorems of Section 4.*

It is also helpful to register the order-theoretic content in a slightly more structural way: the residuum is the right adjoint of the map $w \mapsto u \otimes w$. Right adjoints are automatically monotone in the argument they act on (here, the consequent v), while the parameter u appears in the left-multiplication operator $(-) \mapsto u \otimes (-)$, whose strengthening makes the corresponding right adjoint smaller. In that sense, the lemma is not a special trick but a basic "variance rule" for implication in any residuated setting.

Finally, note that these directions match the familiar truth-functional intuition: to satisfy an implication, making the premise stronger can only make the implication harder to satisfy, while making the conclusion stronger (in the order of truth values) can only make the implication easier to satisfy. The lemma formalizes exactly this intuition in the general lattice-valued framework used throughout the paper.

Proof. By definition, $(u \to v) = \bigvee\{w : u \otimes w \le v\}$. If $u \le u'$, then for any w, $u \otimes w \le u' \otimes w$ (monotonicity of $\otimes$), so the constraint $u' \otimes w \le v$ is stronger than $u \otimes w \le v$; hence the feasible set for $u' \to v$ is contained in that for $u \to v$, giving $(u' \to v) \leq (u \to v)$. If $v \leq v'$, then $\{w : u \otimes w \leq v\} \subseteq \{w : u \otimes w \leq v'\}$, hence $(u \to v) \leq (u \to v')$.

To make the order reasoning completely explicit: in the first case, let $S(u, v) := \{w : u \otimes w \leq v\}$. From $u \leq u'$ and monotonicity of $\otimes$ in the first coordinate, we obtain $u \otimes w \leq u' \otimes w$ for each w, hence $u' \otimes w \leq v$ implies $u \otimes w \leq v$, i.e. $S(u', v) \subseteq S(u, v)$. Since $\bigvee S$ is the least upper bound of S (and $\bigvee \emptyset$ is well-defined in our ambient complete lattice), inclusion of feasible sets yields $\bigvee S(u', v) \leq \bigvee S(u, v)$, which is precisely $(u' \to v) \leq (u \to v)$. The second case is analogous: $v \leq v'$ makes the constraint $u \otimes w \leq v'$ weaker, so $S(u, v) \subseteq S(u, v')$, and taking suprema preserves the inequality in the expected direction.

Equivalently (and compatibly with the definition used here), one may restate residuation as the adjunction $u \otimes w \leq v \iff w \leq (u \to v)$. With that characterization, the same monotonicity directions follow by elementary order manipulation: increasing u makes $u \otimes w$ larger and thus the inequality $u \otimes w \leq v$ harder to satisfy, while increasing v makes it easier to satisfy. □

Remark 3109 (Proof sketch and intuition)**.** *The strategy is to unpack residuation as a supremum of all "admissible slacks" w such that $u \otimes w \leq v$. If you increase u to u', fewer w will remain admissible, so the supremum (the best admissible slack) cannot increase; this is the antitonicity in the left argument. If you increase v to v', more w become admissible, so the supremum cannot decrease; this is monotonicity in the right argument.*

One can picture $u \otimes w \leq v$ as a constraint region in the (u, w) plane: pushing u up tightens the region, pushing v up loosens it. The lemma is exactly the order-theoretic shadow of that geometric picture.

A complementary way to phrase the same intuition is to think of $u \to v$ as the largest *truth value w that can be conjoined (via $\otimes$) with u without exceeding v. Under this reading, a stronger antecedent u leaves less "room" for such a w, while a larger consequent v leaves more room. This is why the directions are sometimes summarized as contravariance in the antecedent and covariance in the consequent.*

In concrete t-norm semantics this behavior is familiar. For example, in the Gödel case ($\otimes = \min$) one has $u \to v = 1$ when $u \leq v$ and $u \to v = v$ otherwise, so increasing u can only move one from the 1-regime to the v-regime (never upward), while increasing v can only increase the output. In the Lukasiewicz case ($u \to v = \min(1, 1 - u + v)$), the same monotonicity is visible by inspection: the expression is decreasing in u and increasing in v. The abstract lemma ensures we do not need to commit to any particular t-norm; the robustness arguments later rely only on these order-theoretic directions.

56.2 Transfer theorems for inference and pattern constraints

A central use-case is: a reasoning engine performs multi-step inference internally, but wants to transport conclusions to (or from) the world graph using a correspondence map.

56.2.1 Pushforward/pullback as an adjoint pair

Definition 504 (Pullback and pushforward of V-relations along a map)**.** *Let $f : X \to Y$. For any V-relation $R : X \times X \to V$, define the* pushforward $f_! R : Y \times Y \to V$ *by*

$$(f_! R)(y, y') := \bigvee_{\substack{x, x' \in X: \\ f(x) = y,\ f(x') = y'}} R(x, x').$$

For any V-relation $S : Y \times Y \to V$, define the pullback $f^*S : X \times X \to V$ *by*

$$(f^*S)(x, x') := S(f(x), f(x')).$$

Remark 3110. *The definition implicitly uses that the join $\bigvee$ over (possibly many) witnesses exists in V. In most applications here, V is taken to be a complete lattice (or a quantale, so that joins interact well with $\otimes$), ensuring that $f_!R$ is always well-defined even when fibers of f are infinite. When $V = \mathbf{2} = \{\bot, \top\}$ with $\bigvee$ as logical "or," $(f_!R)(y, y')$ is true exactly when there exists at least one internal witness (x, x') with $f(x) = y, f(x') = y'$ and $R(x, x') = \top$; when $V = [0, 1]$ with $\bigvee = \sup$, $(f_!R)(y, y')$ retains the strongest available degree among all internal witnesses consistent with the external pair.*

Remark 3111. *The pullback f^*S is the easy direction: it simply re-labels S along f by substitution. If S is a relation on Y, then f^*S is the induced relation on X obtained by first mapping x and x' into Y and then reading off S there. This is the usual operation of "viewing external relations in internal coordinates."*

The pushforward $f_!R$ is the more informative direction: it aggregates internal relations to the external level by taking a join over all *internal pairs that map to a given external pair. If f identifies several internal nodes with one external node (many-to-one), then $f_!R$ keeps the strongest internal evidence compatible with that external pair. This is precisely the kind of operation one wants when exporting conclusions: it is safe (because it never invents support not witnessed internally), and it is maximally permissive given that safety (because it uses join to keep the best witness).*

Remark 3112. *Two basic monotonicity facts will be used implicitly in later transfer arguments. First, both $f_!$ and f^* are order-preserving: if $R \le R'$ pointwise on $X \times X$, then $f_!R \le f_!R'$ because joins preserve order; and if $S \le S'$ pointwise on $Y \times Y$, then $f^*S \le f^*S'$ by substitution. Second, pullback is strictly functorial in the sense that $(g \circ f)^* = f^* \circ g^*$ holds on the nose, while pushforward is functorial when defined by joins as above, i.e., $(g \circ f)_! = g_! \circ f_!$; this reflects that both constructions are computed by explicit formulas that compose by regrouping quantifiers over witnesses. These elementary properties are often the hidden "bookkeeping" behind multi-stage transport across several correspondence maps.*

Theorem 115 (Galois connection: pushforward/pullback)**.** *For all $R : X \times X \to V$ and $S : Y \times Y \to V$,*

$$f_!R \le S \quad \textit{iff} \quad R \le f^*S.$$

Remark 3113. *This theorem says that pushforward and pullback form an adjoint pair (a Galois connection) between the posets of V-relations on X and on Y. In plain terms: "exporting R and asking whether it fits inside S" is equivalent to "importing S and asking whether it dominates R." This is important because it makes many transfer arguments one-line: once you have an inequality on one side, you can mechanically move it to the other side via the adjunction. In reasoning-engine terms, it supplies a sound algebra for translating between internal and external vocabularies.*

This adjointness is the categorical skeleton behind the later transfer bounds: it explains why we can prove external soundness from internal structure plus correspondence slack with no ad hoc case analysis. Such adjunction-based transport is a recurring theme in structured transfer learning; compare [7].

Remark 3114. *A useful way to unpack the adjunction is via the associated unit/counit inequalities, which hold for every adjoint pair. Taking $S = f_!R$ in the theorem yields*

$$R \le f^*f_!R,$$

meaning that if one exports R and then re-imports it, one obtains a relation on X that is at least as permissive as the original R (information can be lost by collapsing fibers, but not fabricated in a way that would violate this inequality). Dually, taking $R = f^*S$ yields

$$f_! f^* S \leq S,$$

meaning that exporting a pulled-back external relation cannot exceed the original external relation. In many concrete settings, these inequalities formalize "no overstatement upon export" and "no strengthening by round-tripping," which are precisely the safety properties desired when using f as a correspondence map between an internal reasoning state and an external world model.

Proof. ($\Rightarrow$) Assume $f_! R \leq S$. Fix $x, x' \in X$ and set $y = f(x)$, $y' = f(x')$. Then

$$R(x, x') \leq \bigvee_{u,u' :\, f(u)=y,\ f(u')=y'} R(u, u') = (f_! R)(y, y') \leq S(y, y') = (f^* S)(x, x').$$

Thus $R \leq f^* S$.

($\Leftarrow$) Assume $R \leq f^* S$. Fix $y, y' \in Y$. For all x, x' with $f(x) = y, f(x') = y'$,

$$R(x, x') \leq (f^* S)(x, x') = S(y, y').$$

Taking the join over all such (x, x') yields $(f_! R)(y, y') \leq S(y, y')$. $\square$

Remark 3115 (Proof sketch and intuition)**.** *The proof proceeds by chasing definitions. For the forward direction, one observes that a particular internal pair (x, x') is one of the witnesses included in the join defining $(f_! R)(f(x), f(x'))$, so its value cannot exceed that join; if the join is bounded by S, then R is bounded by the pulled-back S. For the reverse direction, one uses that if* every *witness of the join is bounded by $S(y, y')$, then the join itself is bounded by $S(y, y')$.*

A visual metaphor is helpful: pullback draws a rectangle on $X \times X$ by projecting it through $f \times f$ into $Y \times Y$; pushforward collapses the fibers $(f \times f)^{-1}(y, y')$ by taking the supremum. The Galois connection says these operations are precisely dual in the order-theoretic sense.

Remark 3116. *In the intended "mind–world" reading, X can be the internal state space of a reasoner and Y a space of externally named entities or observations, with f the current grounding map. Then f^* acts like a* query *operator: it answers questions about internal states by looking at how they are named externally. Conversely, $f_!$ acts like a* projection *or* publishing *operator: it takes what is known internally and expresses it in the external naming scheme, merging indistinguishable internal states via joins. The adjunction guarantees that these two directions of translation fit together coherently, so that verification can be performed either before export (internally) or after export (externally) with equivalent results.*

Corollary 46 (External soundness from internal structure plus correspondence slack)**.** *If $f : X \to Y$ is a q-approximate morphism from $G = (X, G)$ to $H = (Y, H)$, then*

$$f_!(G \otimes q) \leq H,$$

where $(G \otimes q)(x, x') := G(x, x') \otimes q$.

Remark 3117. *Intuitively, if f preserves edges up to slack q, then after we explicitly "pay" that slack by scaling the internal graph to $G \otimes q$, the resulting relation can be exported to Y without exceeding what the external graph H already supports. This is a precise form of soundness: no transported claim is stronger than what the world-graph warrants.*

This statement is also the point where the residuated definition of q-approximate morphism and the Galois connection click together: the former gives $G \otimes q \leq f^*H$, and the latter turns this into a pushforward inequality. The resulting rule is what one would want in a conservative reasoning loop that must avoid overconfident export of internal inferences.

Remark 3118. *Two limiting cases help calibrate the meaning of the corollary. If q is the top element (e.g. $q = 1$ in $[0,1]$-valued semantics, or $q = \top$ in Boolean semantics), the statement reduces to $f_!G \leq H$, i.e. exact external soundness: exporting the internal edge relation does not overshoot the external one. If q is smaller (more stringent), the hypothesis that f is a q-approximate morphism is weaker, but the conclusion compensates by exporting only the down-weighted relation $G \otimes q$. In other words, poorer correspondence quality forces more conservative export, and the formula makes that tradeoff explicit and algebraic rather than heuristic.*

Proof. q-approximate morphism means $G \otimes q \leq f^*H$. Apply the Galois connection with $R = G \otimes q$ and $S = H$ to obtain $f_!(G \otimes q) \leq H$. ☐

Remark 3119 (Proof sketch and intuition)**.** *The proof is a single adjunction step. The high-level strategy is: (i) rewrite "q-approximate morphism" as an inequality on $X \times X$, and then (ii) transport that inequality to $Y \times Y$ using the pushforward/pullback Galois connection.*

Geometrically, you can imagine the internal edges as lying above external edges along fibers of $f \times f$. Paying the uniform slack q ensures each internal edge fits below its corresponding external edge; taking joins along fibers (pushforward) cannot break that fit.

Remark 3120 (Reasoning-engine use)**.** *This gives a mechanically checkable rule: to export an internally inferred relation G into the world vocabulary, first scale it by the correspondence quality q, then push it forward along f.*

56.2.2 Depth-n transfer bounds

Theorem 116 (Depth-n inference transfer under a q-approximate morphism)**.** *Let $f : X \to Y$ be a q-approximate morphism $G \to H$. Then for all $n \geq 1$ and all $x, z \in X$,*

$$G^{(n)}(x,z) \otimes q^{\otimes n} \leq H^{(n)}(f(x), f(z)),$$

where $q^{\otimes n} := \underbrace{q \otimes q \otimes \cdots \otimes q}_{n \text{ times}}$.

Remark 3121. *This theorem makes explicit a philosophical constraint that is easy to ignore in informal reasoning: if the mind–world correspondence has limited fidelity q, then every inferential step spends some of that fidelity. The n-step conclusion is therefore discounted by $q^{\otimes n}$. In the common multiplicative case, this is literally an exponential decay q^n, a formal warning against exporting long internal chains through a weak correspondence.*

The result is central for transfer learning and for any system that must manage the tradeoff between depth and trust: it tells you how to compute conservative external lower bounds from internal multi-step inferences. In Hyperseed language, this is a mathematically crisp version of depth-sensitive Transfer Learning (Hyperseed-Concept 192, Hyperseed-Concept 193), aligning with the general theme of [7].

Proof. First prove by induction on n that for every length-n path $p = (x = x_0, x_1, \ldots, x_n = z)$,

$$\Big(\bigotimes_{i=1}^{n} G(x_{i-1}, x_i)\Big) \otimes q^{\otimes n} \leq \bigotimes_{i=1}^{n} H(f(x_{i-1}), f(x_i)).$$

For $n = 1$ this is exactly $G(x_0, x_1) \otimes q \le H(f(x_0), f(x_1))$. Assuming the claim for n, multiply the last inequality by $G(x_n, x_{n+1}) \otimes q$ and use commutativity/associativity of $\otimes$ plus the edge-wise constraint again.

Now take joins over all length-n paths. Because $\otimes$ distributes over arbitrary joins,

$$G^{(n)}(x,z)\otimes q^{\otimes n} = \Big(\bigvee_{p\colon |p|=n} w_G(p)\Big)\otimes q^{\otimes n} = \bigvee_{p\colon |p|=n} (w_G(p)\otimes q^{\otimes n}) \le \bigvee_{p\colon |p|=n} w_H(f(p)) = H^{(n)}(f(x), f(z)).$$

□

Remark 3122 (Proof sketch and intuition)**.** *The proof has two layers. First, it shows that each individual path weight transports: if every edge transports with penalty q, then an n-edge product transports with penalty $q^{\otimes n}$ simply by multiplying inequalities and regrouping factors. Second, it upgrades from a single path to the optimal n-step connection by taking joins over all paths; the quantale distributivity guarantees that scaling by $q^{\otimes n}$ commutes with the join.*

A helpful mental image is to view q as a per-hop "friction" or "dissipation" in the act of correspondence. The best n-hop internal route remains a route externally, but each hop pays the friction; taking the best among routes (the join) cannot undo that accumulated cost.

Corollary 47 (A safe bounded-depth transfer rule (decision tool))**.** *Fix a threshold $\tau \in V$ and depth n. If an internal n-step inference yields $G^{(n)}(x,z) \ge \tau$, then the corresponding external n-step inference satisfies*

$$H^{(n)}(f(x), f(z)) \ge \tau \otimes q^{\otimes n}.$$

In particular, to guarantee $H^{(n)}(f(x), f(z)) \ge \tau_{\text{out}}$, it suffices to require $\tau \otimes q^{\otimes n} \ge \tau_{\text{out}}$.

Remark 3123. *This corollary is the operational form of the depth-n theorem: it tells you how to set internal thresholds so that, after exporting through correspondence quality q, you still exceed a desired external threshold. Conceptually, it is the familiar engineering move of budgeting for losses: decide what you need in the world, then work backwards to what you must establish internally.*

The connection to the earlier statement is direct: the theorem gives an inequality of the form "discounted internal $\le$ external". The corollary simply applies monotonicity to replace $G^{(n)}(x,z)$ by a known lower bound τ, producing a computable external lower bound. This is exactly the sort of conservative rule one wants in a reasoning loop that must avoid hallucinated certainty (Hyperseed-Concept **??***).*

Proof. From the theorem, $G^{(n)}(x,z) \otimes q^{\otimes n} \le H^{(n)}(f(x), f(z))$. If $G^{(n)}(x,z) \ge \tau$, monotonicity of $\otimes$ gives $\tau \otimes q^{\otimes n} \le G^{(n)}(x,z) \otimes q^{\otimes n} \le H^{(n)}(f(x), f(z))$. □

Remark 3124 (Proof sketch and intuition)**.** *The entire argument is a single monotonicity step: once we know that external support dominates discounted internal support, any internal lower bound can be substituted into the discounted term. One may read this as a safe "certificate" mechanism: internal evidence above τ certifies external evidence above the discounted $\tau \otimes q^{\otimes n}$.*

In terms of intuition, the corollary says: if you want a fact to remain true after translation through an imperfect dictionary, you must state it more strongly (or more conservatively) in the source language, by exactly the factor that accounts for translation loss.

Remark 3125 (Interpretation)**.** *Transfer quality decays with inferential depth (via $q^{\otimes n}$). This suggests a general reasoning heuristic: when exporting conclusions across a weak correspondence, prefer shallow chains, or raise internal thresholds to compensate.*

56.2.3 Constraint-set (pattern) transfer

Definition 505 (Constraint-set pattern score)**.** *Let $G = (X, G)$ and let $P \subseteq X \times X$ be a finite constraint set (a "pattern"). Define its conjunctive score by*

$$\mathrm{Score}_G(P) := \bigotimes_{(u,v)\in P} G(u, v).$$

Remark 3126. *Here a "pattern" is treated as a finite set of directed constraints (u, v) that are supposed to cohere together. The score $\mathrm{Score}_G(P)$ is the joint support for the whole pattern, formed by multiplying all the edge weights. This is the natural conjunction operation when $\otimes$ plays the role of "and / joint satisfaction / joint evidence." It connects directly with the Hyperseed notion of Pattern (Hyperseed-Concept 130) as a set of mutually reinforcing constraints (cf. [5]).*

In the boolean case, $\mathrm{Score}_G(P) = 1$ iff all *required edges are present; otherwise it is 0. In a probabilistic-style case with $V = [0, 1]$ and $\otimes$ multiplication, the score is the product of edge strengths, penalizing patterns that rely on many moderately uncertain constraints. This is precisely why the subsequent transfer theorem has a cardinality-dependent penalty: larger patterns have more places where correspondence can leak.*

It is also useful to note that this "multiplicative" aggregation is sensitive to the weakest links: if any single constraint has very low weight, the entire score is driven down. This matches the intended reading of a pattern as a joint *requirement rather than a disjunction. In settings where V is a general commutative semiring or a t-norm algebra, the same conceptual role is played by whatever $\otimes$ is chosen: it is the operation that encodes how independent (or jointly required) constraints compose.*

Theorem 117 (Pattern constraint transfer with cardinality penalty)**.** *Let $f : X \to Y$ be a q-approximate morphism $G \to H$ and let $P \subseteq X \times X$ be finite. Then*

$$\mathrm{Score}_G(P) \otimes q^{\otimes|P|} \leq \mathrm{Score}_H\big(f(P)\big),$$

where $f(P) := \{(f(u), f(v)) : (u, v) \in P\}$ (as a multiset, if duplicates are tracked).

Remark 3127. *A helpful boundary case is $q = 1$ (the "no slack" or exact morphism case): then the penalty term is neutral, and one recovers the expectation that a structure-preserving map transfers the full pattern score without degradation. At the other extreme, when $q < 1$ and $|P|$ is large, the factor $q^{\otimes|P|}$ can become small rapidly (e.g. exponentially for ordinary multiplication), making explicit that high-cardinality patterns are brittle under imperfect correspondence. This is not merely a technical artifact: it formalizes the intuition that each additional conjunct introduces another opportunity for mismatch between the internal constraint graph and the external one.*

If duplicates in $f(P)$ are tracked (multiset semantics), then multiple distinct constraints in P may map to the same target edge in H. In that case $\mathrm{Score}_H(f(P))$ multiplies the weight of that target edge multiple times, which is appropriate when the original pattern truly contained multiple independent "reasons" or "requirements" that happen to coincide after mapping. If instead one wishes to quotient by duplicates (set semantics), then one is implicitly imposing an idempotence convention for repeated constraints; the multiset phrasing makes the bookkeeping choice explicit.

Remark 3128. *This theorem is the constraint-set analogue of the depth-n path-transfer result. Instead of an n-step chain, we have a finite conjunction of constraints; each constraint pays a q penalty, hence the joint penalty $q^{\otimes|P|}$. The message is again one of discipline: exporting large, intricate internally-recognized patterns requires correspondingly strong mind–world alignment.*

The result matters computationally because pattern recognition is often how a reasoning system packages hypotheses: a hypothesis is a bundle of constraints that jointly describe a situation. This theorem provides a safe rule for translating such bundles into an external hypothesis space, which is a recurring need in transfer learning and in model-to-world mapping (Hyperseed-Concept 192; cf. [7]).

In probabilistic practice, one often works in a log domain, where products become sums. Under that reading (when $\otimes$ is multiplication), the theorem corresponds to an additive penalty $|P| \cdot \log q$ on the log-score. This makes the cardinality dependence especially transparent: each additional constraint contributes a fixed "alignment cost" determined by q.

Proof. For each $(u, v) \in P$, $G(u, v) \otimes q \leq H(f(u), f(v))$. Multiply these inequalities over all constraints in P and use commutativity/associativity to collect the q factors into $q^{\otimes |P|}$.

More explicitly, writing the product over P as $\bigotimes_{(u,v)\in P}(\cdot)$, one has

$$\bigotimes_{(u,v)\in P} \big(G(u, v) \otimes q\big) \;\leq\; \bigotimes_{(u,v)\in P} H(f(u), f(v)),$$

and then commutativity/associativity yields

$$\left(\bigotimes_{(u,v)\in P} G(u, v)\right) \otimes \left(\bigotimes_{(u,v)\in P} q\right) = \mathrm{Score}_G(P) \otimes q^{\otimes |P|}$$

on the left-hand side. The inequality direction is preserved because $\otimes$ is taken to be order-preserving in each argument (as is standard for the conjunction-like operations used here). □

Remark 3129 (Proof sketch and intuition)**.** *The strategy is pointwise: transport each constraint individually using the approximate morphism inequality, then combine them multiplicatively. Because $\otimes$ is commutative and associative, we may regroup all the q factors into a single $q^{\otimes |P|}$ multiplier.*

Visually, one may imagine a pattern as a small subgraph with several edges. The map f sends each edge to a corresponding edge in H (perhaps with collisions); the theorem asserts that if each edge survives translation up to slack q, then the whole subgraph survives translation up to a slack that grows with the number of edges.

A concrete mental model is to take P with three constraints. If $q = 0.9$ and $\otimes$ is ordinary multiplication, then even if the internal pattern score is near 1, the guaranteed transferred score is discounted by at least $0.9^3 = 0.729$. For larger P, the bound becomes correspondingly more demanding, capturing the sense in which "many-small-errors" can accumulate into a large overall mismatch.

Remark 3130 (Use)**.** *This turns mind–world correspondence into a quantitative rule for exporting internally recognized patterns into external hypotheses: larger constraint-sets require stronger correspondence or higher internal confidence.*

In particular, for systems that search over candidate patterns/hypotheses, the theorem suggests a regularization heuristic: all else equal, prefer smaller patterns unless one has either (i) high internal scores on all constituent constraints, or (ii) a demonstratedly high q for the relevant transfer map. In this way, the formal penalty term aligns with common computational tradeoffs between expressivity (large patterns) and robustness (transfer under mismatch).

56.3 Reality-systems and shared reality as fixed points

We now move from "structure transport" to "what counts as real," modeled as a fixed point of mutual predictive closure. Concretely, the guiding intuition is that an entity counts as "in" a candidate reality-system not merely when it is predicted by something already in the system, but when it also participates in predictive constraints that flow back into the system, so that membership is supported by a two-way web of model-mediated expectations.

Definition 506 (Predictive adjacency and mutual closure operator)**.** *Let U be a set of entities and let $\to$ be a directed predictive adjacency relation on U (depending on a mind M, an interval I, and a threshold). For $R \subseteq U$ define*

$$\mathrm{Pred}_{\to}(R) := \{y \in U : \exists x \in R \text{ s.t. } x \to y\}, \qquad \mathrm{Pred}_{\leftarrow}(R) := \{y \in U : \exists x \in R \text{ s.t. } y \to x\}.$$

Define

$$F(R) := \mathrm{Pred}_{\to}(R) \cap \mathrm{Pred}_{\leftarrow}(R).$$

A (nonempty) reality-system *is a set $R \subseteq U$ such that $F(R) = R$.*

Remark 3131. *The notation here is set-theoretic rather than quantale-valued: 2^U denotes the power set of U ordered by inclusion $\subseteq$. The operation $\mathrm{Pred}_{\to}(R)$ collects everything that is predicted* from *something in R (one step forward), while $\mathrm{Pred}_{\leftarrow}(R)$ collects everything that predicts* into *R (one step backward). The mutual-closure operator $F(R)$ keeps precisely those entities that participate in both directions of predictive coupling with R.*

Calling a fixed point $R = F(R)$ a "reality-system" is a formal way to express a pragmatic criterion for reality: the real is what is stably entangled in mutual prediction. This aligns with the Hyperseed concept of Reality-System (Hyperseed-Concept 149) and with the broader intersubjective framing (Hyperseed-Concept **??***). Philosophically, one may hear in $F(R)$ a Peircean emphasis on lawlike mediation and mutual constraint (Thirdness) [14], and a Whiteheadian insistence that "actuality" is processual and relational rather than atomistic [15].*

As a simple example: if $\to$ is the edge relation of a directed graph, then $F(R)$ is the set of nodes that are either reached from R in one step and also point into R in one step. A fixed point R is then a set that already contains all such mutually linked neighbors, so it is closed under this two-sided predictive neighborhood operation.

Remark 3132 (On the role of $(M, I, \text{threshold})$ in $\to$)**.** *Although $\to$ is written as a single relation, it is helpful to read it as a family $\to_{M,I,\tau}$ parameterized by a mind/model M, a time window I, and a decision threshold τ (for example, a minimum predictive accuracy, a minimum mutual information, or a statistical significance level). Under this reading, a reality-system is not an absolute subset of U but a stability notion relative to a chosen epistemic regime: changing sensors, priors, or thresholds changes the adjacency relation and thus changes which fixed points exist and which are selected. This makes explicit the intended "operational" character of the construction: the same world U can support multiple reality-systems depending on what predictive couplings are actually available.*

Remark 3133 (Nonemptiness and trivial fixed points)**.** *The definition excludes the empty set to avoid counting the vacuous fixed point that often arises in monotone fixed-point settings. Indeed, when $\mathrm{Pred}_{\to}(\varnothing) = \varnothing$ and $\mathrm{Pred}_{\leftarrow}(\varnothing) = \varnothing$ (as is typical for witness-based definitions), one has $F(\varnothing) = \varnothing$, so $\varnothing$ is a fixed point but is not informative as a candidate "reality." Requiring $R \neq \varnothing$ encodes the minimal phenomenological demand that a reality-system must contain at least one entity participating in predictive coupling.*

Lemma 165 (Monotonicity)**.** *$F : 2^U \to 2^U$ is monotone: $R \subseteq R' \Rightarrow F(R) \subseteq F(R')$.*

Remark 3134. *Monotonicity is the minimal structural property needed to apply the standard fixed-point apparatus (Knaster–Tarski) later when we discuss shared reality. Intuitively, enlarging the set R gives you more potential predictors and more predicted entities, so the forward and backward prediction neighborhoods can only grow, and their intersection can only grow as well.*

This lemma is also a small statement about epistemic humility: if you admit more entities into your candidate reality-system, you can only increase (never decrease) what is mutually predicted in one step. The later lattice theorem formalizes the idea that there are canonical least and greatest stable "realities" compatible with a family of predictive closures.

Proof. If $R \subseteq R'$, then any witness $x \in R$ to $x \to y$ is also in R', so $\mathrm{Pred}_{\to}(R) \subseteq \mathrm{Pred}_{\to}(R')$ and similarly for $\mathrm{Pred}_{\leftarrow}$. Intersecting preserves inclusion. □

Remark 3135 (Proof sketch and intuition). *The proof simply observes that both* $\mathrm{Pred}_{\to}$ *and* $\mathrm{Pred}_{\leftarrow}$ *are monotone set transformers: witnesses for membership persist when the domain set is enlarged. Since intersection is itself monotone, the composite F is monotone.*

In graph terms: starting from a larger set of source nodes cannot reduce the set of nodes with an incoming edge from the source set, nor can it reduce the set of nodes with an outgoing edge to the source set.

Remark 3136 (Fixed points as two-sided predictive invariants). *The equation $F(R) = R$ can be read as an invariance condition: R is exactly the set of entities that are simultaneously (i) generated forward by prediction from R and (ii) supported backward by predictive influence into R. In this sense, reality-systems are not merely "closed" sets but self-sustaining predictive substructures. When $\to$ arises from a learned dynamics model, one may view R as the subset of entities whose predicted interactions are internally coherent under the model's own one-step predictive coupling in both causal directions (outgoing effects and incoming constraints).*
