Hyperseed ontology:
formal presentation and theoretical development

Ben Goertzel

March 3, 2026

Abstract

Hyperseed is a concept network intended to describe mind, experience, and reality using a compact set of mutually interdefinable primitives (e.g. occasions of experience, distinction, repetition, variety, non-duality), together with successive layers of derivative notions (e.g. effort, simplicity, pattern, emergence, habit, morphic resonance, mind-world correspondence, reflective self, reality-systems, and social/cosmic structures).

Hyperseed has earlier been presented in a semi-formalized fashion. This document aims to rebuild Hyperseed as a mathematically grounded ontology. The organizing hypothesis is that a small formal "core" can generate most of Hyperseed by composition: (i) paraconsistent truth values ("p-bits") to represent partial and conflicting evidence without explosion; (ii) a commutative quantale of "weakness" to model simplicity/generalization as (weighted) failure to make distinctions; (iii) quantale-enriched (and, where needed, $(\infty, 1)$-categorical) structure to compose contexts, processes, and approximate morphisms; and (iv) a resonance construction derived from paraconsistent evaluation dynamics, giving a principled bridge from logical conflict/coherence to dynamical coupling.

The development proceeds in several phases:

- a dependency DAG of Hyperseed concepts and a minimal formal core together with basic "sanity theorems" that anchor the core.
- a toy universe with a finite set X and a $\mathsf{p\text{-}bit}$-valued quantale, including a minimal worked example that reaches the level of morphic resonance and anti-resonance.
- a systematic crosswalk, in which every concept in the original Hyperseed ontology is assigned to a section and mapped to explicit mathematical constructions in the core.
- a series of simple "helper theorems" articulating elementary formal properties of the Hyperseed concepts, and then a series of less trivial theorems relating the concepts to each other, intended to be helpful in applying them to particular cases
- a specific, sustained theoretical development aimed at using Hyperseed to explore and formalize the ethical and cognitive properties of hypothetical AGI systems (or other intelligences) with massive amounts of cognitive and energetic resources. *A conclusion of this development is that, if a series of self-improving AGI systems starts off with a compassionate orientation, it is reasonably likely to maintain such an orientation as it becomes increasingly resource-rich and powerful.*

A (much shorter) companion paper titled *Hyperseed: A Scrutability-Style Core Ontology and a Practical Inference-Control Scaffold for Probabilistic Logic Networks* summarizes the intended use of Hyperseed within AI commonsense reasoning systems, including the potential use of Hyperseed as an initial condition for automatic learning and adaptation of ontologies.

Note on AI Co-Authoring and Co-Utilization .

- This document was primarily written by LLMs, though in a process of repeated prompting, sweeps across the whole document by scripts running prompts, and so forth. There was also human editing here and there when it was an easier way to fix things than doing prompting. Every part of the document was human-reviewed at one or more stages in the document creation process, but it can't be claimed that every part has been carefully reviewed in the final form – there may still be glitches!

- This is not a product envisioned as the subject of frequent leisure reading. It does contain a significant number of ideas, insights and conclusions that will be of interest to humans oriented toward philosophical and conceptual foundations of science, AI, and so forth; however, these are not usually presented here in the most delightfully consumable fashion, although effort has been made to include nontechnical explanations along with formalism.

- A primary use-case for this document is envisioned as: Ingestion by AI systems, which may more fully formalized the material given here, and then leverage this more formalized version for practical guidance of automated uncertain reasoning in commonsense and scientific domains. The brief companion document *Hyperseed: A Scrutability-Style Core Ontology and a Practical Inference-Control Scaffold for Probabilistic Logic Networks* outlines some ideas on how this might be done, along with some associated theoretical work elaborating "what makes a good ontology," and some ideas on how AIs may evolve even better and more useful ontologies using Hyperseed as, well, a seed.

Contents

1 Introduction

Hyperseed is an ontology – a systems of concepts – intended to serve as a basic framework for the explanation and elaboration of other concepts of interest to human beings and other intelligent systems. In more ordinary language, the aim is to have a shared "map legend": a small set of ideas and relationships that can be reused when talking about very different domains (perception, learning, ethics, culture, scientific inference, etc.). It is not intended as a set of semantic primes in a reductive sense, but rather as a universal-ish guide and toolkit, the working hypothesis being that by expressing diverse concepts in terms of this ontological core, deep and effective reasoning about the concepts and their relations and applications can often be efficiently conducted. The emphasis on "toolkit" is practical: the ontology is meant to help one build models that can be checked, compared, and composed, rather than only described informally.

Hyperseed is written as a "semantic stack": it starts from phenomenological primitives (occasion of experience, distinction, repetition, variety, non-duality) and builds upward via effort and simplicity into patterns and processes, then into mind-level constructs (representation, attention, control, goals, emotion, consciousness), and finally into collective and cosmological constructs (society, culture, science, mindplex/global brain, multiverse/eurycosm). The informal picture is that higher-level notions should be intelligible in terms of lower-level ones, in the same way that a complex program is built from simpler components. The stack metaphor also suggests a direction of explanation: when a high-level phenomenon is unclear, one can ask which lower-level ingredients and composition rules would generate it.

The ontology aims to be simultaneously (1) ontological (speaking about what exists), (2) phenomenological (speaking about what is given in experience), and (3) computational (speaking about what bounded agents can represent and do). These three aspects are in tension in many philosophical projects; here they are treated as constraints on the same formal objects. For example, a notion like "distinction" should have a phenomenological reading (what it is like to separate figure from ground), an ontological reading (what structures in the world support stable separation), and a computational reading (what a limited system can actually compute or store).

The Appendix contains a relatively concise list of the concepts included the ontology. Beyond the core, this is a list with some degree of arbitrariness to it – concepts may be added in future, and some could be subtracted without huge harm. But we believe this is a reasonably useful set of choices. One reason to explicitly list concepts, rather than only gesture at them, is to make the project falsifiable in a modest sense: the reader can check whether later constructions actually cover the promised vocabulary.

Remark 1. *The phrase "semantic stack" is meant quite literally: each layer is supposed to constrain (and in some cases determine) the next layer, much as in a protocol stack each level provides an interface whose regularities enable the levels above it. In a philosophical register one may hear echoes of process ontology and triadic semiotics—experience as a primitive given, distinction as the act that carves it, and habit/law as what stabilizes it across repetitions—themes congenial to various historical philosophers such as Whitehead and Peirce [15, 14]. Hyperseed's distinctive move is to insist that these are not merely poetic analogies: they are intended to admit a formal reconstruction that preserves compositional structure, limits, and approximation. In particular, "preserves compositional structure" means that if a complex situation is built by combining simpler situations, then the semantics should allow one to compute properties of the whole from properties of the parts, up to explicitly tracked approximation.*

The goal here is not to settle metaphysical debates, but to provide a rigorous scaffold that makes the Hyperseed concept network mathematically precise enough to: (1) support theorem statements and proofs; (2) enable toy and mid-scale computational models; (3) make explicit where paraconsistency, approximation, and observer-relativity enter; (4) formally derive theorems about the relationship between the concepts and their utilization in various domains. This is intended to move discussions of otherwise slippery notions (e.g. emergence, attention, selfhood) toward a setting where one can ask concrete questions like "what follows from what?" and "what fails if we weaken this assumption?"

Remark 2. *We can view Hyperseed metaphorically as a scaffold for building diverse concepts; however, a modest but important philosophical point is hidden in the word "scaffold." A scaffold is not the building; it is what allows one to test whether the building could stand. Here the "building"* *includes contested notions (e.g. consciousness, morphic resonance, non-duality), and the wager is that one can isolate a minimal algebraic/categorical substrate on which these notions can be treated with the same discipline that we apply to, say, probabilistic inference or programming language semantics. Even if one ultimately rejects the ontology as metaphysics, the scaffold may still be valuable as mathematics for graded, resource-bounded, and non-classical reasoning (cf. the general approach to cognitive formalization in [19] and the pattern/emergence framing in [5]). Concretely, one can separate two questions: (i) whether a concept is metaphysically "real," and (ii) whether there is a coherent formal object that plays the role the concept is supposed to play in reasoning and modeling.*

Method. We proceed by identifying a minimal formal "core" that can support the entire ontology. The guiding idea is to start with a small number of mathematical structures that are expressive enough to encode the recurring moves the ontology needs: making a distinction, weakening it, composing processes, and coping with conflict. The core must be able to express: (i) pairwise distinctions and their loss (weakness); (ii) composition of contexts and processes; (iii) inconsistent and incomplete knowledge without trivialization; (iv) emergent pattern intensity; and (v) resonance/morphic resonance as structure-sensitive coupling. To do this we combine a p-bit semantics (paraconsistent evidence), quantale weakness (simplicity/generalization as undistinguished pairs), and enriched-categorical composition. The intent is that later concepts are not introduced ad hoc; rather, they arise as constructions on top of this core, so that their interactions are constrained by shared algebraic laws.

Remark 3. *Several technical terms appear here that will be defined carefully later, but it is helpful to state the intended reading now. The symbol* p-bit *denotes a paraconsistent evidence unit: rather than assigning each proposition a single truth value, we allow a* pair *(support, opposition), so that both can be nonzero simultaneously without the system collapsing into triviality. This is the formal counterpart of taking value conflict and ambiguous boundaries as first-class phenomena (Hyperseed-Concepts 198 and 165). Logically, this draws on the general tradition of non-explosive semantics (see also [23]) and is developed in a resonance-oriented direction in [24]. An informal example is a dataset or social situation where there is strong evidence for and against a claim (or for and against a boundary between "self" and "other") that does not disappear merely by collecting more of the same kind of evidence; the pair representation records both pressures explicitly.*

Remark 4. *"Quantale weakness" is the second pillar: a* quantale *is an algebraic structure that behaves like a lattice of grades together with an associative "multiplication" (a way to compose grades). In this paper, weakness measures (Hyperseed-Concept 202) will be aggregated and composed using such a structure, enabling the slogan "loss of distinctions composes." This line of thought is elaborated in [3], and the broader cognitive motivation for taking "weakness" as primitive (rather than error-free crispness) is consonant with the perspective in [2]. We will also connect this with patterns and emergence (Hyperseed-Concept* **??***) as treated in [5]. The key conceptual point is that blur is not just a nuisance: if two distinctions are each slightly unreliable, then the combined distinction produced by chaining them should be predictably (and quantifiably) weaker, rather than treated as either perfectly valid or completely broken.*

Remark 5. *Finally, "enriched-categorical composition" indicates the following: instead of treating contexts merely as labels, we treat translations between contexts as morphisms whose quality/strength is graded (by the same sort of quantale used for weakness). This provides a disciplined language for observer-/context-indexing (Hyperseed-Concept 86) and for composing approximate correspondences rather than exact equalities. The resulting structure is meant to serve as the backbone for later* *discussions of mind–world correspondence (Hyperseed-Concept 112) and transfer-like phenomena (Hyperseed-Concepts 192 and 193; see [7] for related mathematical motivations). Informally, this is a way to say: two observers (or two models) may not match perfectly, but there can still be a structured, composable notion of "translation" between them, and the translation can carry a measured degree of fidelity.*

Remark 6. *The mention of "resonance/morphic resonance" (Hyperseed-Concepts 159 and 115) signals a specific ambition: to model coupling not as a generic diffusion term, but as a structure-sensitive propagation whose strength depends on pattern-alignment. The phrase "morphic resonance" is historically associated with Sheldrake's speculative proposal [13]; here it is treated as a name for a mathematically specifiable operator that can be studied independently of any particular metaphysical interpretation. The modeling goal is to make room for the idea that some influences propagate preferentially along shared structure (similar organization, similar habits, similar representations), which is a common motif in cognitive science and machine learning even when the specific term "morphic resonance" is not used.*

What counts as success. A successful mathematical Hyperseed should make it easy to answer questions of the form:

- "Given an observer with limited representational capacity, what distinctions can it make?"
- "How do patterns emerge from compositional simplicity?"
- "When do habits stabilize, reverse, or transmit via morphic resonance?"
- "How do self-models and reflective will arise as fixed points or higher morphisms?"

Even if one disagrees with Hyperseed's philosophical stance, this reconstruction should still be valuable as a modular formal toolkit for paraconsistent, resource-sensitive modeling of cognition. For early-stage AGI learning, these are exactly the kinds of questions that recur: an agent must decide what to represent, how to compress experience into patterns, how to remain stable under self-modification, and how to coordinate or transfer knowledge across contexts.

Remark 7. *These questions already hint at the kinds of mathematics that will appear later. "Limited representational capacity" anticipates explicit capacity/constraint functionals and the associated notion of what an observer can stably discriminate (Hyperseed-Concepts 98, 82, 181). "Habits stabilize, reverse, or transmit" points toward dynamical notions (Hyperseed-Concepts 189, 188, and 115) and their interaction with paraconsistent evidence accumulation. And "fixed points or higher morphisms" foreshadows the use of order-theoretic fixed point theorems to express reflective stability conditions for goal systems and self-modification (Hyperseed-Concept 110; see [10] for a closely related application pattern). The informal moral is that "reflective agency" is treated as something one can characterize by invariance or stability properties, rather than only by narrative description.*

Remark 8. *The intended notion of "observer" here is not merely a human subject but any system that (i) makes distinctions, (ii) carries representations, and (iii) allocates attention and control under resource constraints (Hyperseed-Concepts 157, 60, 87). This explicitly permits both biological and engineered instances (Hyperseed-Concepts 68 and* **??***) and aligns with an engineering-oriented stance toward general intelligence [19]. In later sections, when consciousness is discussed more directly, one may also connect this observer-relativity with formal "locations" for individuals and collectives (Hyperseed-Concepts* **??** *and 75; see [4, 12] for related perspectives). This broad notion* *of observer is useful for AGI research because it lets one apply the same definitions to, say, a single model, a team of models, or a model interacting with tools and institutions, while keeping track of which capacities and contexts are doing the explanatory work.*

Organization of the paper. Sections 2–5 cover the "first sprint": concept DAG, formal core with sanity theorems, and a finite toy model (including morphic resonance). Sections 6–26 then map the full Hyperseed ontology into rigorous constructions. Appendix C contains a complete checklist of Hyperseed concepts and where they are treated. The division is meant to help the reader separate foundational commitments (the core machinery) from downstream elaborations (the larger vocabulary), so that one can reuse pieces even if one does not adopt the full stack.

Remark 9. *The phrase "first sprint" is meant to set expectations: early sections aim for a small set of definitions and compositional laws that are strong enough to support meaningful theorems, yet weak enough to remain applicable across many domains (cognition, culture, science, cosmology). In particular, the appearance of "sanity theorems" is meant to reassure the reader that the algebraic choices are not merely aesthetic: they enforce non-trivial constraints on how approximation and composition can interact. Later, when the discussion turns toward wu wei and least-effort style principles (Hyperseed-Concepts 206 and 207), it will be useful to have already fixed the underlying graded-compositional apparatus (see [21] for a related development). One can think of these sanity theorems as the analogue of type-safety or soundness results in programming languages: they prevent certain pathologies and clarify what constructions are legitimate.*

Scope notes. Throughout, "ontology" is used in a technical sense: a typed vocabulary with axioms, composition rules, and semantics. Many Hyperseed notions are observer-relative (e.g. distinction, simplicity, uncertainty) and some are intrinsically paraconsistent (e.g. value conflict, self/other boundaries). These are not bugs; they are treated as explicit design requirements. In particular, the goal is not to eliminate context dependence or conflict, but to represent them explicitly so that one can reason about them and measure their effects.

Remark 10. *In particular, observer-relativity is not taken to mean "arbitrary subjectivism." Rather, it is treated as the claim that many predicates are best understood as* indexed *(by observer, context, or both), and that the mathematics should track how such indices compose when observers communicate, aggregate, or form collectives (Hyperseed-Concepts 86,* **??***, 170, 91). This stance is compatible with a social-computational-probabilistic view of scientific practice [20], and it also sets the stage for later efficiency claims about prosocial coordination in multi-agent settings [6]. A simple motivating example is that two agents can disagree not only about facts but about which distinctions are salient; indexing helps separate "disagreeing about the world" from "using different coordinate systems for describing it."*

Remark 11. *Paraconsistency is likewise not a license for confusion; it is a discipline for representing situations where evidence genuinely supports incompatible conclusions (Hyperseed-Concept 198) without forcing an explosion of entailments. The practical motivation is clear in cognitive and ethical modeling: minds (and groups of minds) often must act under persistent conflict, not merely transient uncertainty. The formal aim is to make such conflict compositional, so that one can ask when it localizes, when it propagates, and when it is resolved by additional structure rather than by fiat. From an AGI-safety and alignment perspective, this matters because real agents must integrate competing objectives, inconsistent testimony, and shifting self-model boundaries without degenerating into either paralysis or arbitrary collapse.*

1.1 Use of Hyperseed for Guiding AI Reasoning

A (much shorter) companion paper titled *Hyperseed: A Scrutability-Style Core Ontology and a Practical Inference-Control Scaffold for Probabilistic Logic Networks* summarizes the intended use of Hyperseed within AI commonsense reasoning systems, including the potential use of Hyperseed as an initial condition for automatic learning and adaptation of ontologies.

2 Hyperseed at a glance: concept inventory and dependency DAG

2.1 Purpose and reading conventions

Hyperseed is presented (in its original form) as a tightly interlinked concept-network rather than as a linear theory [1]. Many concepts are intended to be mutually definable or at least mutually constraining, so there is no unique "correct" topological ordering. In particular, what counts as "basic" in Hyperseed is often a matter of which questions one wants the formalism to answer first: one can start from distinctions and build upward toward agency-like notions, or start from process and build toward stable patterns, or start from value-laden notions and work backward toward representational constraints. The reconstruction strategy adopted here is therefore pragmatic: we choose primitives and dependencies so that the resulting definitions are checkable (in the ordinary mathematical sense) and reusable across later sections without reintroducing implicit circularity.

Remark 12. *It is worth pausing over what it means, mathematically, for an ontology to be "interlinked." In an ordinary axiomatic theory one expects a small set of primitives and a long chain of definitions; but in a concept network one expects a kind of mutual illumination, where definitions are less like one-way reductions and more like constraints that cut down a space of possible meanings. Hyperseed leans into this latter style: concepts such as* distinction *(Hyperseed-Concept 98),* pattern *(Hyperseed-Concept 130), and* process *(Hyperseed-Concept 140) are not merely "introduced" and then used; they are repeatedly refined by their relations to effort, simplicity, emergence, and resonance. In technical terms, one may think of the "meaning" of a concept as the collection of constraints it imposes on admissible models: a formal model of Hyperseed is not merely a set-theoretic structure with extra operations, but a structure satisfying a web of compatibility conditions that jointly determine which interpretations are coherent. This way of proceeding is familiar in areas where definitions are stabilized by the role they play (e.g. universal properties, adjunctions, or fixed-point characterizations), even if Hyperseed's motivating vocabulary is not usually presented in that language.*

Nevertheless, a mathematically grounded reconstruction benefits from an explicit *expository orientation*: we choose a directed acyclic graph (DAG) whose edges represent "is used in the formal definition of" or "is a prerequisite for the cleanest formalization of". This DAG should be read as a *build order* rather than a metaphysical claim. Concretely, the DAG functions as a promise that each later object can be defined in terms of earlier ones in a way that can be verified line-by-line, even if (conceptually) Hyperseed intends later notions to feed back and refine earlier intuitions. The build order is thus an editorial device: it is a compromise between the networked character of the source material and the linear constraints of a written proof-oriented exposition.

Remark 13. *The phrase "build order" is doing real work. It signals that the DAG is a discipline of exposition: it tells the reader what must be* already fixed *so that later definitions are not silently circular. In particular, it separates definitional dependence (what you need in order to write down a definition) from causal or dynamical dependence (what influences what in time) and from explanatory dependence (what helps us understand what). Hyperseed will later return to feedback,* *heterarchy, and closure (Hyperseed-Concept* **??***, 168), but those will be treated as* structures within *the already-defined mathematical universe rather than as reasons to permit circular definitions at the foundational level. A useful analogy is the difference between (i) allowing mutually recursive* equations *inside a system once the ambient semantics is fixed (e.g. via least fixed points in a complete lattice), and (ii) allowing mutually recursive* definitions *without any semantic grounding. The former can be made precise and non-pathological; the latter typically produces ambiguity. The DAG is meant to keep us in the former regime: when Hyperseed-like closure is formalized, it will appear as a theorem or as a definable construction (often a fixed point, an invariant, or a limit), not as a tacit permission to define objects by appealing to themselves.*

Throughout the paper we will use two recurring indexing ideas: these are not merely notational conveniences, but design constraints on the formal core, since they force many predicates to be typed and parameterized rather than treated as absolute, global properties. The intent is that whenever an informal Hyperseed statement appears to be unconditional, the reader should ask whether it is actually conditional on (i) a representational point of view and (ii) a possibly inconsistent evidence state.

- **Observer-/context-indexing:** many Hyperseed predicates are implicitly of the form "*relative to observer O and context C*". Mathematically this becomes typed, indexed structure (e.g. relations valued in a quantale, enriched categories of contexts, etc.). This indexing is also a guardrail against category mistakes: without it, one is tempted to conflate statements about the world with statements about an agent's internal discrimination of the world, or to conflate stable properties with those that only hold under a particular conditioning regime. In the formalization, the same underlying entity may support multiple, incompatible partitions or similarity relations when viewed under different (O, C), and the theory aims to keep those variations explicit rather than hidden in prose.

  Remark 14. *Here "observer" and "context" should be read technically, not anthropomorphically: an observer is any system whose distinctions and updates we model, and a context is any conditioning structure that selects which distinctions and compositions are currently active (Hyperseed-Concept 86). One can think of O as fixing representational resources and update rules, while C fixes the slice of the world (or of the internal state) relative to which a judgment is made. Thus, a claim like "x and y are equivalent" is never purely absolute; it is an equivalence* relative to *which distinctions the observer can draw (Hyperseed-Concept* **??***, 98). From a modeling standpoint, this means that the formal objects in later sections should be read as living in families indexed by (O, C): for example, a "pattern" may be a pattern-for-O-in-C, and a "simplicity" measure may be a simplicity-relative-to-the-coding-scheme-available-to-O and the constraints activated by C. This does not weaken the theory; rather, it clarifies what kind of invariance would be meaningful. When we do obtain invariants (e.g. quantities or constructions insensitive to certain changes of context), that will be an explicit result rather than an implicit assumption.*

- **Paraconsistent indexing:** some Hyperseed judgments are intrinsically allowed to be both supported and opposed at the same time (e.g. value conflicts, ambiguous boundaries, "both random and predictable" limit constructions). Mathematically this becomes a non-explosive truth/evidence domain (the p-bit layer in Section 3). This indexing is meant to preserve information: it distinguishes "unknown" from "both-ways" and distinguishes "inconsistent evidence" from "lack of evidence." As the exposition progresses, this will permit us to combine multiple sources (subagents, sensors, heuristics, or evaluators) without first forcing agreement, while still supporting principled aggregation and comparison operations.

Remark 15. *Paraconsistency is not introduced here as a metaphysical indulgence but as a representational necessity: when evidence streams, subagents, or value sources disagree, we want to record the disagreement rather than force an artificial collapse into a single scalar certainty. This is particularly vivid for ethical and motivational predicates (Hyperseed-Concept 198, 197), but it also appears for boundary predicates such as self/other (Hyperseed-Concept 165) and for limit notions such as ineffability and unknowability (Hyperseed-Concept* **??***, 196). The formal strategy we adopt aligns with paraconsistent semantics in the spirit of multi-valued logics [23] and with later resonance-oriented applications [24]. Operationally, the point is that later definitions can be written so that they are monotone in evidence and robust under fusion: adding a new (possibly conflicting) source should refine the state of information rather than crash the logic. When this works well, it also clarifies which parts of Hyperseed are genuinely normative (depending on value inputs) and which parts are structural (depending only on the algebra of evidence combination). The* p-bit *layer is therefore both a technical tool and a conceptual separation principle: it lets us say, precisely, when a claim is "in tension" rather than merely "false."*

2.2 Layered view: the Hyperseed "semantic stack"

For navigation, it is helpful to group the ontology into a small number of layers. Table 1 is not meant to be exhaustive; it is a map of the main build-up route. In this section, "layer" should be understood as a *dependency stratum*: later terms are intended to presuppose (at least implicitly) earlier ones, so that definitions can be staged rather than mutually recursive. The goal is not to enforce a rigid hierarchy, but to provide an orienting spine that makes it easier to locate where a concept is *introduced*, what kinds of prior distinctions it assumes, and what kinds of constructions it subsequently supports. In particular, the layering is designed to align with the dependency DAG discussed in this section: edges should predominantly point "upward" (from prerequisites to derived notions), even if, in practice, some modeling workflows will traverse the layers in the opposite direction (starting from agency or values and then unpacking the primitives they rely on).

Layer	Core vocabulary (representative)	What it enables
Primitives	occasions of experience; difference/distinction; repetition/variety; non-duality; presentational immediacy; abstract/concrete; first/second/third/fourth	typed "raw materials" for observer-relative modeling
Order and becoming	after/before; proto-time; becoming; event/process calculi	history-sensitive structure, causal/pre-causal ordering
Effort and simplicity	effort; resistance/submission; opening/closing; simplicity; compositional simplicity; structural complexity	resource-sensitive compression and generalization
Patterns and structure	pattern; pattern intensity; property; emergence; blend; hierarchy/heterarchy; pattern web	reusable structure; compositional organization; multi-scale description
Dynamics and coupling	tendency to take/reverse habits; self-weaving webs; resonance/dissonance; morphic resonance/anti-resonance	stabilization, amplification/decay, cross-context pattern transmission
Mind and agency	mind; representation (icon/index/symbol); perception; prediction/attraction; cause; control; attention; self/other; consciousness; autonomy	closed-loop cognition; self-models; coherent action under constraints
Values, life, society, cosmos	emotion/compassion; values/goals; rationality/ethics; energy/genenergy; belief systems/science; societies/mindplex/global brain; reality-systems; eurycosm/multiverse/y-verse; wu-wei	motivation, culture, long-range structure of "reality" as system-relative

Table 1: A pragmatic layered view of Hyperseed. The full inventory is listed in Appendix C.

The table can also be read as a set of *design affordances*. Each row suggests a typical "unit of work" for formalization: first establish a minimal observational alphabet (primitives), then add directed structure for change (order/becoming), then introduce explicit boundedness constraints (effort/simplicity), then define reusable regularities (patterns/structure), then account for their stabilization and transfer (dynamics/coupling), then specify control-relevant internal organization (mind/agency), and finally situate agents within normative and collective contexts (values/life/society/cosmos). This makes it clearer which later claims are meant to be *model-relative* consequences of earlier commitments (e.g., a notion of "control" presupposing some notion of "before/after," and a notion of "ethics" presupposing agents capable of goal selection and trade-offs). Conversely, when a concept appears to "skip" layers in exposition, the intent is typically that the missing dependencies are implicit and can be expanded by following the DAG edges back down.

Remark 16. *The table should be read as a map of* constraints propagating upward. *The primitives (Hyperseed-Concept 124, 98, 121) supply the minimal types of "what can be talked about"; the order/becoming layer (Hyperseed-Concept 63, 52, 142, 62) supplies a way to speak about directed change; effort and simplicity (Hyperseed-Concept 100, 169) supply a way to treat cognition as resource-bounded; and so on. In particular, the transition from simplicity to pattern is meant to be sharp enough to support later formal definitions of emergence (Hyperseed-Concept* **??***) rather than leaving "pattern" as a merely aesthetic label [5]. A useful practical reading is that each layer introduces a new kind of* invariance claim *and therefore a new family of admissible abstractions. For example, once distinctions and repetitions are in place, the order/becoming layer constrains which sequences of occasions can be treated as coherent histories; once effort and simplicity are explicit, admissible abstractions are additionally constrained by resource budgets (what can be represented, learned, or inferred under bounded computation and attention). The patterns/structure layer then adds criteria for when compressed descriptions count as stable "things" (properties, blends, hierarchical modules) rather than ad hoc summaries; dynamics/coupling adds criteria for when such things persist, transmit, or synchronize across contexts (resonance, anti-resonance, habit formation and reversal); mind/agency adds criteria for when pattern webs close into self-referential loops capable of prediction and control; and the final layer adds criteria for how such loops are steered and coordinated by valuations, norms, and shared world-models. This upward constraint flow is also intended to reduce ambiguity in later sections: when a term such as "cause" or "goal" is used, it should be interpretable as a derived notion built from the earlier commitments about directed change, bounded effort, and pattern stability, rather than as an unanalyzed primitive. When these dependencies are respected, disagreements about higher-level notions can often be localized to specific upstream choices (e.g., what counts as a distinction, what counts as simplicity, or what kind of ordering is assumed), making the ontology easier to test, modify, and extend without collapsing into purely verbal disputes.*

2.3 Concept inventory by module

Appendix C contains a completeness checklist. Here we group the same vocabulary into modules that will become the main "subgraphs" of the dependency DAG.

Remark 17. *These modules are not claimed to be natural kinds. They are closer to what a working mathematician might call a "good set of coordinates": a choice that makes the subsequent constructions easier to state, even if other coordinate choices are possible. In later sections, some concepts will deliberately cut across module boundaries (for example,* information *and* uncertainty *constrain nearly everything; Hyperseed-Concept* **??***, 195).*

Module P: Phenomenological primitives.
Primitivest primitives; occasions of experience; difference; distinction; repetition; variety; non-duality; non-dual variety; first/second/third/fourth; number; quantity; grouping; presentational immediacy; abstract/concrete.

Module T: Order, time, and becoming.
after/before; the asymmetry constraint (e.g. $A < B$ implies not$(B < A)$); proto-time; becoming; event and process calculi.

Module E: Effort and simplicity.
effort; resistance/submission; opening/closing; simplicity; compositional simplicity; (generalized) Kolmogorov complexity (as an interpretive anchor); structural complexity; minimum representational effort.

Remark 18. *The mention of Kolmogorov complexity is meant as an* anchor*, not a reduction: it provides a familiar paradigm where "simple" means "short description" [16]. Hyperseed's effort-based simplicity (Hyperseed-Concept 100, 169) is broader: effort may represent energetic cost, attentional cost, time, or any other resource relevant to an observer. This is also where the notion of "weakness" enters later as the systematic encoding of collapsed distinctions (Hyperseed-Concept 202, 143) [2, 3].*

Module S: Patterns and combinational structure.
process; system; coherence; recognition process; equivalence relation; combination; inheritance; association; lifting from instances to groups; pattern; pattern intensity; property; specific entity; emergence; blend; combinatorial-categorical pattern; combination system; interpreted combination system; combinational dynamical causal model.

Module I: Information, truth, and limits of representation.
probability; entropy/information; uncertainty; ineffability; soggy predicates; logical/empirical truth; experiential truth; unknowability/infinity/infinitesimally (including "potentially infinite" / "potentially infinitesimal" conceptual roles).

Module D: Higher-order structure and dynamics.
hierarchy/systemic hierarchy; subpattern hierarchy; heterarchy; pattern web; tendency to take habits; tendency to reverse habits; self-weaving webs; autocatalytic sets (as a closure motif); resonance/dissonance; morphic resonance/anti-resonance; pattern flow networks; mind-world correspondence.

Remark 19. *This module is where Hyperseed's "network metaphysics" becomes mathematically demanding: once pattern webs allow loops (Hyperseed-Concept 132,* **??***), we must be careful to distinguish (a) harmless dynamical cycles from (b) forbidden definitional cycles. The subsequent use of resonance and morphic resonance (Hyperseed-Concept 159, 115) is intended to make "coupling across contexts" an operator with algebraic properties, not a metaphor [13].*

Module M: Mind and cognition.
mind; contexts and aspects; registration; sensory system; "X registers A"; perception; representation; icon; index; symbol; prediction and attraction; cause; extensional predictive attraction; control; control hierarchy; perceptual hierarchy (as needed); attention/attentional focus; varieties of knowledge; cognitive synergy; self/other; self-continuity; development; space.

Remark 20. *The appearance of "cognitive synergy" here is deliberate (Hyperseed-Concept 73). In the engineering literature on AGI, synergy names the phenomenon where multiple weak inference/control processes, each insufficient alone, combine into a more general competence [19]. In the present reconstruction, this will later be expressed in compositional terms: interactions between context-indexed processes that preserve enough structure to be nontrivially cumulative.*

Module V: Values, emotion, and ethics.
joy/woe; emotion; compassion; values/feelings/goals; reward; goals implicit/explicit; reward maximization/goal seeking; value paraconsistency; criteria for rational decision; rationality; pleasure/pain/open-ended intelligence; categorical imperative; rational ethical decision; evil; cultural morality; (plus auxiliary terms in Appendix C, e.g. humility/grandiosity/ambition/humbition).

Module L: Life and energy.

energy/genenergy; metabolism; reproduction (within species); alive/dead; lifeform (biological/synthetic/evolved); biological lifecycle strata (infant/young/mature/old/elderly).

Module K: Knowledge, belief systems, and science.

questions; answers; beliefs; belief system; axiom systems; question networks; knowledge; thinking; science; state-dependent science; open-ended intelligence/open-ended benefit (as community-level properties, when applicable).

Module A: Agency, society, tools, and embodiment.

intent; stimulate/inhibit; agent; autonomous agent; tasks/intellectuality/general intelligence/narrow intelligence (as assessment vocabulary); society; tribe; collective mind systems; mindplex; global brain; social roles (teacher/student/worker/colleague); communicative acts and systems; culture; tools; machines; computers and programs; engineered; physical realizations; physical reality/body; algebraically asymmetric physical reality.

Taken together, these terms fix the minimal interface between an individual cognitive process and the wider world it must act within. In particular, "intent" and "stimulate/inhibit" supply a compact language for goal-directedness and control: an agent is characterized not only by internal states, but by the kinds of interventions it can apply (stimulate) or withhold/suppress (inhibit) in itself or in its environment. The pair "agent / autonomous agent" is used to distinguish systems that merely participate in causal chains from systems that can maintain and revise policies (e.g., select actions under changing constraints) without being micromanaged by an external controller.

The assessment vocabulary "tasks/intellectuality/general intelligence/narrow intelligence" is listed here as a deliberately lightweight scaffold: it does not commit the paper to any single benchmark suite, but it enables later statements of the form "system X is more/less general than system Y relative to task family $\mathcal{T}$" without conflating capability with implementation. This also clarifies that "intellectuality" is treated as an evaluative label that can be made more precise (by specifying tasks, environments, or information constraints) rather than as a primitive substance.

The society terms are included because agency is rarely purely individual in practice: "tribe" and "society" point to social coordination problems, while "collective mind systems" is a neutral umbrella for cases where group-level dynamics exhibit memory, attention, and decision-making analogues. The role vocabulary (teacher/student/worker/colleague) is meant as a concrete handle on asymmetric interaction patterns: roles encode who is expected to provide feedback, who is expected to learn, who delegates, and who executes, and thus they support later formalization of learning channels and authority channels. Likewise, "communicative acts and systems" and "culture" serve as the medium through which norms, knowledge, and coordination strategies persist beyond any single individual, functioning as shared external state.

The "tools; machines; computers and programs" cluster isolates the engineered substrate through which agency is amplified and stabilized: tools are treated as persistently available transformations (often with standardized interfaces), and programs represent repeatable procedures whose behavior can be referenced, audited, and recomposed. "Engineered; physical realizations" indicates that the same abstract procedure can have multiple embodiments, and that the analysis will sometimes need to separate an algorithmic claim (what transformation is computed) from a physical claim (what constraints and costs arise in a particular realization).

Finally, "physical reality/body; algebraically asymmetric physical reality" flags that embodiment is not only a matter of being in the world, but of being in a world with directional constraints. "Algebraic asymmetry" is meant to capture the idea that the environment can impose non-reversible mappings (e.g., irreversible dissipation, one-way channels, or constraints that break naive symmetry assumptions), so that an agent's reachable states and control options form a structured set rather than an unconstrained space. This is relevant whenever the paper later compares what is possible "in principle" to what is possible under thermodynamic, causal, or communication constraints.

Remark 21. *The cluster "mindplex / global brain" is best read as a claim about* coherence at scale*: when communication, shared artifacts, and shared goals generate high mutual constraint, the collective begins to behave like a single cognitive system (Hyperseed-Concept 113,* **??***) [12]. This paper does not assume a single sociological mechanism; rather, it builds enough formal vocabulary to state what such coherence would mean in the same language used for individual minds.*

One practical implication of reading mindplex/global-brain as "coherence at scale" is that the relevant unit of analysis can shift with coupling strength: weakly coupled groups may be better modeled as interacting agents, while strongly coupled groups may be modeled as a single composite agent with internal substructure. This motivates keeping both individual-level and collective-level terms in the same inventory, since the paper will later need to state conditions under which the composite description is warranted (e.g., high-bandwidth communication, stable shared memory artifacts, or robust alignment of goal proxies) without presuming that those conditions always hold.

Module C: Communion, spirituality, aesthetics, cosmos.
intersubjective reality; intersubjective communion; spiritual and psychedelic communion; spirituality; entheogen; religion; aesthetics/art; archetypes; empirical reality/reality-systems; cosmos/eurycosm; near eurycosm; universe; multiverse; guidable multiverse; y-verse; anthropic principle; big bounce; wu-wei; wu-wei dynamics; fluid flow and optimal control.

This module groups vocabulary for (i) shared experiential structure, (ii) meaning-making and value formation, and (iii) large-scale cosmological hypothesis spaces that contextualize agency. "Intersubjective reality" indicates that some "realities" are maintained by shared interpretation, shared language, and shared practices, even when participants disagree on metaphysics; "intersubjective communion" then names the act or process of aligning experience and interpretation across persons. "Spiritual and psychedelic communion" is included because altered states and ritualized contexts can change the effective channel capacity and the salience landscape by which meaning and value are negotiated, and the framework aims to be able to talk about such shifts without either endorsing or dismissing any particular tradition.

The cluster "spirituality; entheogen; religion; aesthetics/art; archetypes" is not introduced as a separate domain from cognition, but as a set of commonly observed generators of shared symbols, shared narratives, and shared evaluative patterns. "Aesthetics/art" is included because aesthetic judgment can function as an implicit optimization signal (e.g., compressive preference for certain structures), and "archetypes" is treated as a shorthand for recurrent, culturally transmissible patterns that can organize both personal experience and collective behavior.

"Empirical reality/reality-systems" distinguishes (a) measurement-grounded constraint and (b) broader systems of practice and interpretation that embed those measurements into a usable world-model. The term "reality-systems" is intended to allow multiple coexisting model bundles (scientific, mythic, pragmatic, artistic) to be compared by their constraints, predictions, and coordination affordances, rather than being treated as mutually exclusive declarations. "Cosmos/eurycosm; near eurycosm" supplies a scale vocabulary: the eurycosm is the broadest context under discussion, while a near eurycosm is a restricted but still expansive cosmic neighborhood relevant to local agency, observation, or intervention.

"Universe; multiverse; guidable multiverse; y-verse" enumerates increasingly permissive hypothesis classes for what exists and what can be influenced. A "guidable multiverse" is listed to name a regime where selection or steering among branches/worlds is at least conceptually meaningful within the theory's causal structure, enabling discussions of strategy that range over cosmological-level degrees of freedom. The "y-verse" serves as a compact placeholder for a particular cosmological construction used elsewhere in the Hyperseed vocabulary, and is kept here to ensure that later references do not silently import assumptions about uniqueness of history or uniqueness of laws.

The "anthropic principle" and "big bounce" entries are included as examples of how observer-conditions and cosmological dynamics can constrain plausible world-models and thus constrain what "reasonable" priors look like for agents embedded in such worlds. They also function as named handles for arguments where the existence of observers (or cycles of expansion/contraction) changes what kinds of explanations are admissible.

Finally, "wu-wei; wu-wei dynamics; fluid flow and optimal control" marks a bridge between experiential/ethical vocabulary and technical control theory. "Wu-wei" is used as a label for policy regimes where effective action arises from minimal forcing and maximal exploitation of system dynamics; "wu-wei dynamics" then points to the idea that such regimes can be analyzed, at least in part, with the same mathematics used for flow and control. The mention of "fluid flow and optimal control" is meant to license later analogies and formal translations (e.g., between effortless action narratives and solutions to constrained optimization in dynamical systems) while keeping clear that the paper is not claiming a one-to-one identity between spiritual descriptions and differential-equation models.

2.4 Dependency DAG: definition and interpretation

We now define the intended meaning of the DAG used throughout the paper. In particular, we separate *definitional* dependence (what must be fixed in order to state a definition unambiguously) from other looser relations such as historical inspiration, pedagogical convenience, or empirical correlation. The goal is to make clear what kind of "depends on" is being asserted when we draw an arrow.

Definition 1 (Expository dependency DAG)**.** *Let $\mathcal{C}$ be the set of Hyperseed concepts (as listed in Appendix C). An* expository dependency DAG *is a directed acyclic graph $G = (\mathcal{C}, \to)$ such that for concepts $A, B \in \mathcal{C}$, an edge $A \to B$ means:*

> *"In this paper's formalization, the definition (or primary semantics) of B uses A as a primitive or as an already-defined construction."*

Here "uses" is meant in the strict sense relevant to formalization: writing down the core clauses that fix the meaning of B requires that the meaning of A has already been fixed (even if only up to *isomorphism or up to some declared equivalence notion). Equivalently, $A \to B$ asserts that A is among the prerequisites for stating what counts as an instance of B, what data B carries, or what laws B must satisfy, as formalized in this paper. If the original Hyperseed presentation treats A and B as mutually interdefinable, we may still orient one direction for exposition; such choices are explicitly recorded as "cuts". A cut is not a claim that one direction is* mathematically prior *in all possible reconstructions; it is a bookkeeping decision that pins down one acyclic presentation order for the purposes of this document.*

Remark 22. ***Notation and conventions.*** *Here $\mathcal{C}$ is literally a set whose elements are* concept names *(or, more precisely, the formal tokens by which we refer to concepts). The symbol "$\to$" is the edge relation of the graph G; it is* not *logical implication and should not be read as a claim that A entails B. "Directed acyclic" means that there is no sequence $A_0 \to A_1 \to \cdots \to A_n$ with $A_n = A_0$; so the DAG forbids definitional loops, even though later dynamical structures will happily contain feedback loops. In particular, acyclicity is a constraint on* presentational dependence*: it ensures that we can choose a topological ordering of $\mathcal{C}$ so that each concept is introduced only after its declared prerequisites. When we later speak informally of one concept "depending" on another, the intended meaning is always via this edge relation (or its transitive closure), not merely that the concepts tend to co-occur in narrative explanations.*

It is sometimes convenient to distinguish the edge relation $\to$ from its transitive closure $\to^*$. An edge $A \to B$ is a claim of direct *definitional use, while $A \to^* B$ expresses that A is an* indirect *prerequisite for B through some chain of intermediate concepts. The DAG representation deliberately does not insist that all indirect prerequisites be drawn as edges; doing so would add visual clutter without adding information, since those edges would be derivable from reachability in G.*

Remark 23. ***Intuition.*** *An edge $A \to B$ says: "to speak clearly about B, we first commit to a formal meaning for A." This is a modest claim, but it is surprisingly stabilizing: it turns a web of mutually suggestive ideas into a sequence of obligations. In philosophical terms, it is a way of keeping the freedom of a conceptual network while still making room for the stern virtues of definition and proof. One can also read the DAG as separating two questions: (i) what it is* useful *to mention when motivating a concept, versus (ii) what it is* necessary *to have already fixed in order to state the concept precisely. The dependency DAG only records (ii), even though our prose will often use (i) for intuition-building.*

Examples. *A typical edge is "Distinction $\to$ Equivalence Relation": we treat an equivalence relation as something induced by which pairs the observer does* not *distinguish (Hyperseed-Concept 98,* **??***). Another example is "Effort $\to$ Simplicity": once an observer-relative cost notion is fixed, simplicity can be defined as what costs less (Hyperseed-Concept 100, 169). At the module level, one may think of this DAG as a coarse "dependency tower" that orders which formal commitments are made first [8]. In both examples, the arrow is meant to be read as a constraint on the* form *of the definition: the clauses defining "Equivalence Relation" refer to "Distinction" (or to data structures already introduced to formalize distinction), and the clauses defining "Simplicity" quantify over or otherwise invoke the previously fixed cost/effort notion. Conversely, we do* not *mean that every informal discussion of effort must precede every discussion of simplicity; rather, we mean that the formal semantics of simplicity, as we pin it down, is parameterized by (or constructed from) the earlier effort notion.*

Usefulness. *The DAG is useful because it lets us locate disagreements. If two formalizations differ, it is often because they choose different incoming prerequisites for a concept, or because they place different "cuts" between mutually constraining notions. Recording cuts explicitly also prepares the ground for later tradeoff reasoning: sometimes one can take "route A" (define B from*

A) or "route B" (define A from B), and the two routes may not be equivalent under resource constraints [9]. In practice, this also means that the DAG can function as a checklist for hidden assumptions: when a definition of B appears to "reach backward" to an undeclared prerequisite A, we either revise the definition, add the missing edge, or acknowledge that we have made an implicit cut. Thus the DAG is simultaneously a representational artifact (a picture of dependence) and a consistency discipline (a way to prevent accidental circularity in the formal layer).

Remark 24. *A DAG is not the only reasonable representation: Hyperseed itself emphasizes heterarchy and feedback. The DAG is a* scaffold*: later sections (especially those on pattern webs, habits, and mind) reintroduce cycles as dynamical and/or higher-categorical structure, rather than as definitional circularity. One can think of this as a separation of levels: the DAG controls the order in which* meaning is fixed*, while later cyclic structures describe how, once meanings are fixed, the corresponding entities may interact, compose, and self-modify over time. In particular, permitting feedback in dynamics does not require permitting feedback in definitions; the former concerns trajectories and updates, whereas the latter concerns well-foundedness of semantic commitments.*

Remark 25. *One may view this as a gentle compromise between two temperaments. The first temperament wants everything to be founded on primitives; the second temperament suspects that primitives are often just temporarily frozen knots in a larger fabric of mutual dependence. The expository DAG admits the second suspicion while still satisfying the first temperament's demand: "show me where you started, and show me that you did not smuggle in what you later claim to derive." Put differently, we allow that many conceptual pairs can be made equivalent by adding enough structure (or by weakening the notion of equivalence), but we still insist on choosing and documenting a one-way street for the purpose of a linear exposition. This is especially important in a document that mixes formal definitions with interpretive commentary: the DAG is the device that keeps the interpretive layer from silently importing circular justifications into the formal layer.*

2.5 High-level DAG (module graph)

At the coarsest granularity, the build order used by this paper is:

```
(P) primitives
  -> (T) order/time/becoming
  -> (E) effort/simplicity
  -> (S) patterns/combination systems
  -> (D) webs/habits/resonance
  -> (M) mind/representation/control
  -> (A) agency/society/tools
  -> (C) reality-systems/cosmos/wu-wei

(I) information/truth/limits is a cross-cutting module:
  (P,T,E,S,D,M,V,A,C) -> (I) and (I) feeds back as constraints on all modules.

(V) values/emotion/ethics draws on:
  (P,T,E,S,D,M,I) -> (V), and then informs (M,A,C) via control and culture.

(L,K) life and knowledge/science sit between (M) and (A,C):
  (E,S,D,M,V) -> (L,K) -> (A,C).
```

Read the arrows as "uses as an input vocabulary" rather than as a claim that later modules are metaphysically prior: the intent is that each module introduces a handful of new definitions, operators, or invariants that become available to subsequent modules. In particular, the direction of the edges is chosen to support reconstruction: later modules should be expressible using the earlier ones with minimal back-references, so that proofs and toy implementations can proceed in a mostly one-way manner.

The labels are meant to be mnemonic anchors for a small number of recurrent themes. The primitives (P) are the minimal typed atoms and relations the rest of the paper is willing to assume. The order/time/becoming layer (T) introduces the infrastructure for sequencing, precedence, and change. Effort/simplicity (E) packages the bias toward compressive description and feasible action (so that "doing" and "describing" do not float free of resource constraints). Patterns/combination systems (S) then provide the combinators and closure principles needed to build reusable structures. Webs/habits/resonance (D) describe the way local patterns stabilize into networks, attractors, and learned regularities. Mind/representation/control (M) formalizes internal models, feedback, and policy-like constructs, after which agency/society/tools (A) treats multi-agent coordination and externalization into artifacts. Finally, reality-systems/cosmos/wu-wei (C) is where global "world"-level organization and the stance of non-forcing or alignment-with-dynamics can be stated using the preceding machinery.

The module graph is therefore not a claim that (say) society is "made of" mind in a reductionist sense; it is a claim about what the paper chooses to introduce first so that later constructions have a clear dependency footprint. This is also why the verbatim presentation resembles a build system: the goal is to make it easy for a reader (or an implementer) to locate which earlier notions are permitted as dependencies when a later notion is defined.

Remark 26. *The "feedback" from (I) back into all modules is not a violation of acyclicity because it is not a claim of definitional dependence in the strict sense; it is a claim of* constraint propagation*. Once one formalizes probability, entropy, uncertainty, or ineffability (Hyperseed-Concept 139,* **??***, 195,* **??***), one typically discovers that earlier definitions need to be indexed or weakened to remain coherent under limited representation. In other words, the mathematics of limits of representation is not merely another module; it is a set of lenses that refract the whole ontology.*

Concretely, this is the same phenomenon that occurs when a previously informal ontology is "typed": one may have introduced a clean notion of state, cause, or agent, and then later discover that any usable account must respect ambiguity, partial observability, finite code length, or statistical identification limits. The resulting revision is not that the earlier objects were ill-formed, but that their intended use requires additional side-conditions (e.g., measurability, identifiability, bounded description length, admissible inference rules). In this sense, (I) acts like a global coherence check: it does not supply new everyday entities, but it determines which formulations survive contact with compression, uncertainty, and representational finitude.

The placement of (V) similarly reflects a methodological choice. Values/emotion/ethics is downstream of (I) because any explicit treatment of preferences, norms, or affect that is meant to constrain control must confront uncertainty, aggregation, and the distinction between "what is true" and "what is endorsed." At the same time, (V) is upstream of key parts of (M) and (A): control without a value-like objective is underdetermined, and culture without norm-like stabilizers is structurally incomplete. The indicated influence of (V) on (M,A,C) should thus be read as the introduction of evaluative functionals that shape learning, feedback, and coordination, not as an attempt to reduce ethics to a single scalar.

The intermediate status of (L,K) is meant to capture that "life" and "knowledge/science" are simultaneously internal and external: they depend on representational and control notions (M), but they also generate the reliable regularities and instrumented practices that make large-scale agency and world-modeling possible. The edge $(E, S, D, M, V) \to (L, K)$ highlights that accounts of living systems and scientific inference typically require (i) resource-bounded optimization (E), (ii) compositional structure (S), (iii) networked stabilization and habit-formation (D), (iv) internal representation and feedback (M), and (v) evaluative constraints (V) such as survival, coherence, or epistemic norms. The subsequent $(L, K) \to (A, C)$ then reflects that collective agency and "cosmos"-level claims are best stated after one has a story about adaptive organization and disciplined knowledge production.

This orientation matches the intended mathematical reconstruction: Sections 3–5 build the formal substrate and an executable toy instance, and Sections 6–26 then walk the modules in roughly the above order. The ordering is not meant to be the only possible traversal; rather, it is a default path that minimizes forward references while keeping the reader's stack small. When later sections temporarily refer back to earlier modules, it is intended to be for reuse of established operators or for the kind of representational constraint updates described in the remark above, not for introducing new foundational primitives retroactively.

2.6 Key concept-level dependencies (selected adjacency list)

The module DAG is useful but too coarse to guide formalization choices. Below is a selected adjacency list for the most load-bearing concept dependencies. Each arrow indicates a likely definitional prerequisite in the systematic reconstruction. In particular, an arrow $A \to B$ should be read as: "to state B cleanly (and to make its intended invariances explicit), one typically needs a prior handle on A." This is weaker than logical implication and weaker than ontological priority; it is primarily a claim about what scaffolding is needed so that later definitions do not smuggle in unexamined structure.

Remark 27. *The adjacency list is intentionally phrased in informal English, because at this stage it is serving as a* planning document*. Later sections will replace many arrows by explicit definitions and theorems. Still, it is useful to read these lists as hypotheses about what must come first, and to notice where one might want alternative cuts. In practice, an "alternative cut" often amounts to changing which notions are taken as primitive (e.g. whether to treat effort or simplicity as basic), or to changing the ambient notion of "context" under which distinctions, groupings, and cost are evaluated. Where the list suggests a linear prerequisite chain, one should also watch for latent mutual dependence: some concepts may be most naturally characterized by a small package of interlocking definitions rather than a single strict ordering.*

Primitives to structure.

```
Occasions of experience
  -> (difference, presentational immediacy, abstract/concrete)

Difference
  -> distinction
  -> repetition, variety, non-duality, non-dual variety

Distinction
  -> grouping, equivalence relation (observer-relative)
  -> contexts/aspects (as "which distinctions are active")
  -> (proto-)entropy via distinction graphs (cross to Module I)
```

The intended reading here is that "occasions of experience" supply the minimal arena in which anything like comparison can occur; "difference" is then the first relational articulation within that arena, and "distinction" is difference stabilized into a usable form (e.g. something that can be applied repeatedly, carried across contexts, or used to define sameness-by-absence-of-separation). The parenthetical cluster "(difference, presentational immediacy, abstract/concrete)" is deliberately grouped because, in some reconstructions, one might treat these as co-emergent facets rather than as strictly sequential.

Remark 28. *Philosophically, this part of the graph is where "the given" is first permitted to articulate itself. A distinction (Hyperseed-Concept 98) is not merely a label; it is a commitment to treating some pair as different* within a context*. Grouping and equivalence then arise as the shadow cast by repeated non-distinctions: to say "these are the same" is to say "my active distinctions do not separate them" (Hyperseed-Concept* **??***,* **??***). The cross-edge to entropy anticipates later constructions where a distinction structure induces an information measure (Hyperseed-Concept* **??***), in the spirit of distinction-based accounts of information such as logical entropy [17]. Two technical cautions are implicit. First, the observer-relativity of equivalence is not meant to trivialize equivalence; rather, it highlights that an equivalence relation is indexed by a selected set of active distinctions (and, therefore, by the granularity at which the observer is operating). Second, the route from distinctions to entropy is not only "counting distinctions"; it also depends on what is taken to be the space of possible distinctions (or the space of distinguishable states) and on whether distinctions are weighted, probabilistic, or context-conditioned. These choices determine whether the induced information measure behaves more like a simple partition measure, a graph-based impurity, or a probability-weighted entropy analogue.*

Order, time, and process.

```
After/before (partial order; directional flow)
  -> proto-time
  -> becoming (process compatible with proto-time)
  -> event and process calculi (history-indexed predicates)
```

Here "after/before" is treated as an ordering primitive that can be applied wherever directed dependence is meaningful (causal, computational, inferential, or phenomenological). The phrase "partial order" matters: proto-time is allowed to have incomparable elements (e.g. independent subprocesses), which is essential if one later wants to accommodate concurrency, branching, or multi-scale organization without forcing an artificial total order.

Remark 29. *The asymmetry implicit in after/before (Hyperseed-Concept 52, 63) is not necessarily a claim about physical time; it is a way of encoding directed constraint. Proto-time (Hyperseed-Concept 142) is then the minimal structure needed to speak about "earlier" and "later" without yet committing to metric time. This is congenial to process-ontological perspectives (compare [15]) while remaining fully compatible with purely computational histories. One reason to keep this layer thin is that later formalisms (e.g. event calculi, process calculi, rewriting systems, or state-transition semantics) can impose additional structure as needed: discrete versus continuous time, branching versus linear histories, and explicit notions of simultaneity. By placing "becoming" after proto-time, the graph flags that becoming is not merely change, but change* tracked *along an ordering—a requirement that becomes important when defining persistence, novelty, and history-indexed predicates without circularity.*

Effort, simplicity, and pattern bootstrapping.

```
Effort (resource/cost, observer-relative)
  -> resistance/submission, opening/closing (effort gradients or regimes)
  -> simplicity (what costs less effort)
  -> minimum representational effort (principle)

Simplicity + combination (composition law)
  -> compositional simplicity
  -> pattern (representation-as-simpler)
  -> pattern intensity (quantitative degree of simplification)
```

This cluster is written to keep the reconstruction honest about where optimization enters. Treating effort as primitive allows one to talk about "cheaper" and "costlier" representations before committing to any particular currency (time, memory, description length, energy, attention, or risk), while still permitting later specialization. The "minimum representational effort" line should be read as a bridge principle: it does not claim that observers always achieve minima, but that there is explanatory pressure toward lower-effort representations when available.

Remark 30. *This is the hinge on which the formal reconstruction turns. If effort is primitive (Hyperseed-Concept 100), then simplicity becomes a derived notion, not an aesthetic preference (Hyperseed-Concept 169). The move from "simplicity + combination" to "pattern" is the point where structure becomes reusable: a pattern (Hyperseed-Concept 130) is, roughly, a way of representing many instances with less effort than enumerating them. This is closely aligned with the "weakness" viewpoint, where collapsed distinctions are not merely failures but also generalizations [3, 2]. The explicit mention of a "composition law" is meant to prevent ambiguity about how effort aggregates: does combining two representations add costs, take a maximum, introduce overhead, or allow shared substructure? Different choices yield different notions of compositional simplicity and, consequently, different notions of what counts as a "pattern." By treating pattern intensity as a quantitative degree of simplification, the graph anticipates later questions of scale: when does a small local gain in representational effort accumulate into a robust, system-level regularity, and when is it too marginal to matter?*

Patterns to properties, emergence, and blends.

```
Pattern intensity
  -> property attribution (patterns-as-properties)
  -> emergence (intensity not reducible to components)
  -> blend (compositional merge of pattern systems)

Combination systems / interpreted combination systems
  -> combinational dynamical causal models
  -> combinatorial-categorical patterns
```

The first block indicates a conceptual shift from "patterns as compressions" to "patterns as predicates we are willing to project." If a pattern robustly reduces effort across a family of instances, it becomes natural to reify it as a property attribution: we treat the pattern as something the instances *have*. The second block flags that once combination is formalized (syntactically and/or semantically), one can state more structured claims about dynamics and causality using the same underlying compositional machinery.

Remark 31. *Pattern intensity is meant to be the quantitative pivot: it allows one to say not merely that a pattern exists, but that it compresses (or coheres) more or less strongly (Hyperseed-Concept 82, 181). Once intensity exists, emergence becomes a testable claim: does the whole exhibit an intensity that cannot be accounted for by the intensities of the parts (Hyperseed-Concept* **??***)? These ideas connect directly to Hyperseed's broader account of pattern and hierarchical/heterarchical organization [5]. The dependency "pattern intensity $\to$ blend" is intended to guard against arbitrary mixing: without some notion of strength (or salience) of patterns, a "blend" risks being merely a disjunction or a bag-of-features. Intensity provides a handle for principled merge policies (e.g. prioritize high-intensity substructures, penalize incoherent overlaps, or preserve components that drive most of the simplification). Similarly, the route through interpreted combination systems emphasizes that "dynamical causal models" and "combinatorial-categorical patterns" are not separate add-ons: they are ways of making the same compositional substrate carry semantics (interpretation) and temporal dependence (dynamics).*

From patterns to webs and dynamics (habits/resonance).

```
Patterns
  -> subpattern hierarchy and systemic hierarchy
  -> heterarchy and pattern web (loops and multi-path dependence)

Pattern webs + proto-time
  -> pattern flow networks
  -> tendency to take habits / reverse habits (time-indexed reinforcement)

Habit dynamics + coupling across contexts
  -> morphic resonance / anti-resonance
  -> self-weaving webs (autocatalytic closure motif)
```

The intent of this final cluster is to mark where "pattern" stops being a static representational convenience and becomes an active participant in system evolution. A subpattern hierarchy suggests nested reuse (patterns built from patterns), whereas heterarchy and pattern webs allow mutual constraint and feedback (patterns supporting, inhibiting, or redefining one another in loops). Adding proto-time turns these webs into directed flow structures, so that one can speak about reinforcement, stabilization, and path-dependence without presupposing a particular physics.

Remark 32. *The step from "pattern web" to "pattern flow networks" is meant to introduce a graph-of-graphs viewpoint: nodes may themselves be patterns (or pattern systems), edges encode influence or transport of constraint, and temporal indexing (via proto-time) makes it meaningful to compare a web "now" to the same web "later." In that setting, a "habit" can be treated as a statistically or structurally stabilized transition tendency: repeated traversals of certain subwebs lower effective effort along those routes, which in turn increases their future likelihood, producing reinforcement. The explicit inclusion of "reverse habits" is a reminder that stabilization is not monotone: regimes can switch, gradients can invert, and previously reinforced pathways can be actively suppressed when contexts shift. Finally, "morphic resonance / anti-resonance" is placed downstream of coupling across contexts to emphasize that resonance is not magic correspondence; it is a claim about cross-context influence mediated by shared (or alignable) pattern structure. Anti-resonance, correspondingly, captures systematic interference: coupling that increases effort, destroys coherence, or forces incompatible distinctions to coexist. The "self-weaving webs" arrow indicates a* *closure motif: webs that, through their own habit dynamics, maintain and elaborate the very pattern infrastructure that enables further habit formation, yielding an autocatalytic style of organization.*

Remark 33. *The progression here is from static structure to time-sensitive reinforcement. Pattern webs (Hyperseed-Concept 132) allow the same local pattern to participate in multiple global organizations (heterarchy; Hyperseed-Concept* **??***). Adding proto-time makes reinforcement meaningful: habits are, mathematically, stable tendencies of update rules over histories (Hyperseed-Concept 189, 188). Morphic resonance is then a claim about how habit-strength can propagate across contexts without requiring literal identity of the underlying substrate (Hyperseed-Concept 115, 114) [13]. In other words, the dependency chain is not merely thematic: each step introduces an additional degree of freedom that the previous level cannot express cleanly. "Static structure" accounts for compositional organization, but cannot on its own distinguish a pattern that is merely present from a pattern that is* maintained *by repeated successful updating across episodes; proto-time supplies the ordering needed to define reinforcement as a property of trajectories rather than snapshots. Heterarchy matters here because reinforcement can stabilize multiple, partially incompatible global organizations simultaneously, so that "the same" local regularity can be reinforced in different roles depending on which context is active. On this reading, morphic resonance (and anti-resonance) is best interpreted as a constraint on cross-context generalization of such stabilized tendencies: what transfers is not a token pattern but a bias in the update dynamics that makes certain organizations easier (or harder) to reconstitute elsewhere.*

Mind, representation, control, and self.

```
Pattern web + contexts/aspects
  -> mind (as a system of interlocking representations and processes)

Registration/sensory system + contexts/aspects
  -> perception (registration causing representation updates)

Representation
  -> icon/index/symbol (structure-preservation constraints)
  -> prediction/attraction (probabilistic or inferential dependence)
  -> cause (attraction plus precedence plus simplicity bias)
  -> control and control hierarchy (action selection shaping future perception)

Attention/attentional focus
  -> cognitive synergy (interaction of multiple partial inference/control processes)

Self/other + self-continuity
  -> development (directed transformation of self-model patterns)
  -> consciousness/reflective consciousness (closure conditions on self-modeling)
  -> autonomy (degree of internally sourced causation/control)
```

Remark 34. *This list expresses a sober thesis: mind is not taken as a primitive substance, but as a certain kind of organized pattern web with context-sensitive update rules (Hyperseed-Concept 111, 132, 86). Representation then subdivides by semiotic constraint (icon/index/symbol; Hyperseed-Concept* **??***,* **??***, 184), while control and attention formalize the closed-loop character of cognition (Hyperseed-Concept 87, 60). The final cluster (self/other, consciousness, autonomy) names closure properties: the system not only predicts and acts, but also models itself as a locus of prediction* *and action (Hyperseed-Concept 165, 85, 119). A useful way to read the arrows is as "explanatory sufficiency" rather than strict logical implication: given a pattern web plus a disciplined notion of context/aspect, one can* construct *a notion of mind as the emergent regime in which representations and processes mutually constrain one another over time. Likewise, perception is not treated as a passive channel but as the special case where registration events are explicitly permitted to drive representation updates under contextual gating; this makes perception inherently fallible and revisable, rather than definitionally veridical. The icon/index/symbol subdivision then clarifies what is being preserved across updates (similarity structure, contiguity/trace, or convention-like mapping), which in turn constrains what kinds of prediction are cheap or robust. "Cause" appears here as an enriched notion of attraction: precedence supplies temporal direction, and a simplicity bias supplies a compressive preference that turns mere correlational pull into a causal-ascription heuristic within the system's inference machinery. Finally, the self/other and self-continuity cluster can be read as the point at which the representational/control loop becomes reflexive: development tracks systematic changes in the self-model, consciousness adds a closure requirement on how that self-model participates in updating, and autonomy measures the extent to which control signals are generated endogenously rather than merely relayed from external perturbations.*

Values, society, and cosmos.

```
Paraconsistent valuation (both-for and both-against)
  -> joy/woe, emotion, compassion
  -> values/feelings/goals, reward, rationality/ethics

Multiple minds + communication + shared artifacts
  -> society/tribe/culture, collective mind systems
  -> mindplex/global brain (high-coherence collectives)

Reality-systems (prediction-stabilized patterns)
  -> physical reality/body (special constrained reality-system)
  -> intersubjective reality (shared constraints)
  -> cosmos/eurycosm and (multi-, y-)verse constructions (observer- and signal-relative)
```

Remark 35. *The first arrow block emphasizes that valuation need not be a single number: it can be a structured, even conflicting evidence object (hence paraconsistency; Hyperseed-Concept 198) [23]. The second block emphasizes that collectives are not just sums of individuals; coherence can be a new mode of organization (Hyperseed-Concept 170, 91, 113). The third block makes explicit that "reality-system" is a technical phrase: it refers to those stabilized patterns that survive prediction and action loops, including intersubjective stabilization (Hyperseed-Concept 149,* **??***) and, at the widest scale, eurycosmic constructions (Hyperseed-Concept* **??***, 116) [18]. The inclusion of wu-wei (Hyperseed-Concept 206, 207) anticipates later discussion where "least-effort" dynamics are treated in a quantale-geometric style [21]. It is also important that paraconsistent valuation is presented upstream of emotion and ethics: on this dependency view, affective phenomena are not external add-ons to "rational" cognition, but are emergent summaries of multi-sided evaluative evidence that can legitimately contain tension (simultaneous approach/avoid, endorsement/repulsion) without forcing immediate collapse to a scalar utility. The bridge to reward and goals then becomes a question of how such structured valuations are operationalized into policy updates, including cases where different sub-processes endorse incompatible actions and attention/control must negotiate a workable compromise. For the social block, communication and shared artifacts are not merely channels for* *transmitting already-formed beliefs; they function as persistence mechanisms that stabilize representations across individuals and across time, thereby enabling collective memory and coordinated control policies that no isolated agent could maintain. The mindplex/global brain line can therefore be read as a further closure condition: when inter-agent coupling becomes sufficiently high-bandwidth and mutually predictive, the collective can exhibit its own attractors, norms, and self-maintaining dynamics. For the reality-system block, "prediction-stabilized" highlights that what counts as "real" in this framework is inseparable from the success of coupled prediction–action loops under constraints. The "physical reality/body" item is then not an ontological demotion but a special case in which constraints are unusually tight, regular, and widely shared, making certain pattern families exceptionally stable across observers and interventions. Intersubjective reality is explicitly listed to mark that many constraints are social (linguistic, institutional, technological) and hence partially negotiable, yet still objectively operative for agents embedded in them. Finally, the observer- and signal-relative phrasing for (multi-, y-)verse constructions is meant to keep the dependency honest: cosmological scope here is treated as an extrapolation of stabilization principles, not as a leap to unconstrained metaphysics; the later wu-wei discussion then adds a variational/geometric intuition for why some stabilized trajectories appear "effortless" relative to the agent's control costs.*

2.7 Mathematical load-bearing walls

The DAG above is large; only a few edges are truly load-bearing for the mathematical reconstruction. These are the edges that force the choice of formal core (Section 3) and that determine whether the rest of the ontology can be reduced cleanly. In practice, "load-bearing" here means: if one weakens or removes the edge, one typically loses either (i) compositionality (the ability to combine local descriptions into coherent global ones), (ii) gradedness (the ability to speak about degrees rather than only yes/no predicates), or (iii) robustness under partial inconsistency (the ability to reason without requiring total agreement across perspectives).

1. **Distinction → weakness/simplicity.** We need a compositional way to encode "which distinctions an observer fails to make" and how that composes. This is the primary motivation for quantale weakness.

   Remark 36. *The idea is that an observer's limitations can be treated as algebraic data: a structured record of which pairs are* not *separated by the observer's active distinctions (Hyperseed-Concept 98). Quantale weakness (Hyperseed-Concept 143) then aggregates these undistinguished pairs in a way that composes cleanly across contexts [3]. Philosophically, one may say: weakness is not merely error; it is the condition that makes generalization possible. A technical point worth making explicit is that the algebra is doing two jobs at once: it records indistinguishability data, and it supplies an internal notion of accumulation. When weakness is modeled in a quantale-like structure (complete lattice with a monoidal product), one can interpret joins as "taking the least upper bound of limitations" and the monoidal product as "combining limitations along a pipeline of observations." This is exactly the kind of compositional bookkeeping that later allows "simplicity" to be defined relative to what distinctions are even available to the observer in the first place.*

2. **Effort → observer-relative simplicity.** Hyperseed treats effort as primitive; simplicity is defined by effort cost. This commits the formalization to explicit resource indexing, not just abstract truth-valuation.

   Remark 37. *This is where the reconstruction refuses a common temptation: to identify simplicity with some absolute minimality. Instead, simplicity becomes relative to a system's costs* *and constraints (Hyperseed-Concept 100, 169). This is congenial both to computational realism and to the more philosophical point that "the same" world can be carved differently by different modes of access. Formally, the point of taking effort as primitive is that it provides a parameter against which many later notions can be measured: approximation quality, compressibility, action feasibility, and even which inferences are practically stable. In particular, if two representations have equal truth-conditions but different effort profiles, Hyperseed treats them as non-equivalent for an embodied agent; this is the step that prevents the framework from collapsing into purely extensional semantics.*

3. **Simplicity → patterns and pattern intensity.** Patterns are "representations as something simpler"; pattern intensity is the quantitative pivot that generates properties, emergence, and structure.

   Remark 38. *Pattern intensity is crucial because it turns "pattern" from a binary predicate into a graded quantity that can support inequalities, monotonicity, and stability claims (Hyperseed-Concept 130,* **??***) [5]. Without some intensity-like notion, emergence risks becoming merely verbal; with it, emergence can be articulated as a failure of additive decomposition, or as a fixed point phenomenon in dynamical settings. It is also the bridge from local comparisons ("this description is simpler than that one for this observer") to global structural claims ("these macroscopic regularities persist under perturbation"). Intensity gives a handle for statements of the form: under a given effort budget, a pattern remains identifiable (or predictive) across a family of contexts; this supports the later use of order-theoretic or enriched-categorical machinery, where morphisms can carry not only existence but strength.*

4. **Pattern webs → habits → morphic resonance.** To reach morphic resonance without handwaving, one needs (i) a dynamical reinforcement operator on webs, and (ii) a cross-context coupling notion that can transmit reinforcement without forcing consistency.

   Remark 39. *Here the demand for rigor is especially sharp: morphic resonance (Hyperseed-Concept 115) is only interesting if it is more than a poetic synonym for "things influence each other." The formal core must therefore supply operators that (a) update pattern webs over proto-time (habits; Hyperseed-Concept 189) and (b) couple distinct contexts in a way that can amplify or damp signals even under partial conflict [13, 24]. The load-bearing content is that "habit" must be representable as an* iterable *update rule on structured objects (pattern webs), rather than as an informal narrative of repetition. In other words, the formalism must make sense of the question "what is the cumulative effect of applying reinforcement n times?" and must allow comparison of the resulting webs (e.g., by a refinement order or graded similarity). Likewise, "resonance" must be a controlled interaction between contexts: strong enough to transfer reinforcement, but weak enough to avoid imposing a single global state that would erase the very contextuality the framework aims to preserve.*

5. **Value conflict → paraconsistent evaluation.** Ethics, motivation, and even stable agency require a semantics that can represent genuine conflict without collapsing everything into a single scalar utility and without explosive inference. This motivates p-bit-style paraconsistent valuation.

   Remark 40. *This is, in a sense, the ethical analogue of observer-relativity. Just as an observer may be unable to draw every distinction, an agent may be unable (or unwilling) to collapse every value into a total order (Hyperseed-Concept 197, 198). The formal core therefore treats conflict* *as first-class data, rather than as a bug to be eliminated by definition [23]. The mathematical pressure is that evaluation must remain compositional even when inputs disagree: combining reasons should not force immediate resolution, but it should still yield structured outputs that can guide action. A paraconsistent scheme can represent, for the same proposition or action, simultaneous support and opposition at varying strengths; this makes it possible to model ethical tradeoffs, motivational ambivalence, and multi-objective control without reducing everything to a single number that hides internal tensions.*

6. **Context and composition $\to$ enriched/categorical structure.** The ontology repeatedly composes processes, representations, and contexts. A quantale-enriched category (and in some places higher-categorical structure) is the natural container for these compositions.

   Remark 41. *The guiding thought is Russellian in spirit: to avoid confusion, one should make the types and modes of combination explicit. Categorical structure provides disciplined composition laws; quantale enrichment provides graded comparison and approximation. Together, they let us say not only that two contexts relate, but* to what degree *and in what compositional manner (Hyperseed-Concept 86, 141). Concretely, enrichment is what allows "maps between contexts" to carry nontrivial semantics: a hom-object can encode effort, approximation loss, weakness, or similarity, and composition can express how these quantities accumulate along a chain of translations. Where the ontology speaks about patterns-of-patterns, or transformations between transformation-schemes, higher-categorical structure becomes the disciplined way to avoid conflating levels (processes, meta-processes, and so on), while still permitting the "web" viewpoint in which multiple compositional routes can coexist and be compared.*

A final methodological note is that these edges are not merely a list of topics, but constraints on *what kinds of definitions are admissible*. For example, if weakness does not compose, then observer-relativity becomes inexpressible at scale; if effort does not index semantics, then "simplicity" becomes detached from agency; if conflict explodes inference, then any realistic value theory becomes trivial. The formal core is therefore selected less by aesthetic preference than by the requirement that these specific forms of composition, grading, and controlled inconsistency all coexist in one coherent mathematical envelope.

2.8 Where observer-relativity and paraconsistency enter

Two "non-classical" themes appear early and remain present throughout:

Observer-relativity. Distinctions, simplicity, probability, reality, and even "what counts as the same" are indexed by a system or context. Formally, this means we will not treat most predicates as absolute, but as living in a structure like "context C supports relation/predicate R with value v". One can read this as replacing a global truth-valuation $R(\cdot)$ with a family of context-indexed valuations $R_C(\cdot)$, or more generally with an evidential semantics in which C contributes both the available vocabulary (what can be expressed) and the operational constraints (what can be measured, computed, or distinguished). In particular, "indexed by a system or context" is meant literally: changing C is allowed to change not only numerical outputs (e.g. probabilities) but also which comparisons are meaningful at all (e.g. whether two states are distinguishable or whether a coarse-graining identifies them). This perspective also makes room for partiality: a context may return a value v that is not simply `true/false` but reflects limited resolution, missing resources, or an explicitly graded assessment.

A useful mental model is that C packages a viewpoint together with its interface: sensors, internal state, background theory, and cost constraints. Then the same underlying situation can induce different supported relations R in different contexts, not merely because of disagreement, but because the contexts genuinely implement different partitions of possibility space and therefore different notions of "sameness," "cause," or "relevance."

Remark 42. *The phrase "supports ... with value v" anticipates the algebra of graded evidence used later. The point is not merely that different observers disagree; it is that the ontology is built to record* how *they disagree, e.g. which distinctions are unavailable, which resources are scarce, or which contexts are operative (Hyperseed-Concept 98, 100, 86). In particular, the additional slot v is intended to store more than a Boolean; it can encode confidence, strength, cost-adjusted plausibility, or multi-component evidence, depending on the later choice of evidence domain. Thus, rather than saying "R is true," the framework aims to say something closer to "R is supported to degree v in context C," where the phrase "in context C" may itself include which measurements were admissible and which inferential moves were allowed.*

It is also important that observer-relativity is not an optional "interpretation layer" placed on top of an otherwise absolute theory. Instead, later constructions (e.g. combining aspects, projecting to coarser views, or comparing agents with different resources) will use the context-indexing as a primitive bookkeeping device: if two contexts cannot even express the same predicate in the same way, the formalism should make that mismatch explicit rather than silently identifying them.

Paraconsistency. Hyperseed allows (and sometimes requires) situations where evidence supports both a claim and its negation, or where boundaries are both present and absent depending on perspective. This shows up in at least: (i) conflicting evidence about equivalence/distinction, (ii) value conflicts in motivation and ethics, (iii) ambiguous self/other boundaries, and (iv) limit constructions where signals are "both random and predictable" (y-verse style motivation). The formal core therefore must support non-explosive reasoning with explicit conflict. Concretely, the target behavior is that from a contradiction $P \wedge \neg P$ one should *not* be able to infer arbitrary conclusions; instead, contradictions are treated as localized states of tension that can be carried, compared, and acted upon. A standard way to model this is to let the "evidence value" for a proposition contain separate components for support and refutation (so that both can be simultaneously nonzero), yielding the familiar four qualitative modes: supported-only, refuted-only, both (inconsistent), and neither (undetermined). In this reading, the phrase "supports both a claim and its negation" is not a rhetorical flourish but a structural allowance: the evidence algebra is expected to represent such pairs directly, rather than forcing an immediate collapse to classical inconsistency.

Paraconsistency also interacts with observer-relativity in two directions. First, conflicts can arise *across* contexts (different C give incompatible supported values for the same R), and the framework should be able to store and reason about those incompatibilities without erasing them. Second, conflicts can arise *within* a single context when the context itself aggregates multiple subsystems, time-slices, or heuristics that are each partially reliable; in that case the context-indexing does not remove contradiction, and paraconsistency is needed even before comparing observers.

Remark 43. *The intended stance is pragmatic: if a system is to reason and act under uncertainty and disagreement, it must be able to represent conflict without self-destruction. A paraconsistent evidence domain can encode "for" and "against" simultaneously and then permit later operators (attention, control, learning) to modulate which parts of the conflict matter in which contexts (Hyperseed-Concept 60, 87, 198) [23, 24]. This is also a way to keep "contradiction" distinct* *from "noise": the system may track that there are coherent reasons on both sides, and that resolving the conflict requires additional effort, new measurements, different abstractions, or a change in priorities rather than merely more samples. In the limit, classical reasoning can be recovered as a special case when the evidence domain happens to forbid simultaneous support and refutation (or when an operator projects inconsistent states down to a consistent subdomain), but the default theory keeps the richer state space available so that conflicts can be carried forward until some later stage makes them decision-relevant.*

2.9 How this DAG drives the rest of the paper

The remainder of the paper follows the DAG in three passes: the goal is that each pass tightens the link between informal motivation and formal commitments, while keeping the direction of dependence explicit. In particular, earlier material is intended to be sufficient to justify later constructions without silently importing extra structure, so that the reader can check (locally) what is doing the work at each step.

- Sections 3 and 4 instantiate the load-bearing walls as a minimal core. In practice, this means fixing the smallest set of primitives, typing/axiom schemes, and admissible inference moves that all downstream modules will reuse.
- Section 5 demonstrates that the core reaches nontrivial dynamics (including morphic resonance) in a finite universe. The point of placing this early is diagnostic: it serves as a concrete witness that the core is not merely consistent-by-design, but also expressive enough to generate structured behavior under explicit, fully checkable choices.
- Sections 6–26 systematically assign each Hyperseed concept (Appendix C) to a precise construction, definition, or reduction within the core. This is the "accounting" pass: wherever a term appears in the concept inventory, the reconstruction supplies an unambiguous formal handle (or a declared reduction) and makes clear which earlier nodes in the DAG it actually depends on.

Because the DAG is acyclic, this organization also enforces a reading discipline: if a later module seems to require a premise not yet introduced, that is a signal either that the dependency edge is missing from the diagram or that the module is in fact using additional assumptions that should be surfaced and labeled. Accordingly, forward references are meant to be informational rather than foundational: they may preview where a definition will be used, but the definition itself should only rely on what lies upstream.

Remark 44. *A useful way to read what follows is to treat the DAG as a promise: whenever a later section appeals to a concept A, the reader should be able to trace backwards along $\rightarrow$-edges to see what was already fixed, and therefore what is genuinely being assumed. If the reconstruction succeeds, this trace should feel like descending a well-built staircase rather than like falling through a trapdoor. Operationally, this means that apparent "intuitions" should be recoverable as consequences of earlier commitments, and that any genuinely new assumption should correspond to an explicit new node or edge rather than an unnoticed shift in meaning.*

Concept coverage in this section. This section explicitly inventories (by module) the full Hyperseed vocabulary and provides the master dependency DAG used to structure the formal reconstruction (including the load-bearing edges that determine the formal core). As a result, the reader can use this section as an index of where each term is anchored: the inventory locates the first point of formal responsibility for a concept, while the DAG clarifies which earlier notions must be in place for that anchoring to be legitimate.

3 Minimal formal core

Outline

- Specify the minimal "data types" (entities, contexts, valuations, relations) and the design requirements (observer-relativity, paraconsistency, compositionality).
- Define the `p-bit` truth-value domain and a small set of paraconsistent connectives and derived observables (support, opposition, conflict, indeterminacy).
- Define a commutative quantale V that can simultaneously serve as (i) an evidence domain and (ii) an aggregation domain for weakness and pattern measures.
- Define V-valued relations and their quantale-style composition, and interpret them as approximate correspondences.
- Define a V-enriched category (and/or quantaloid) of contexts/processes and the basic notion of approximate morphism used later for mind–world correspondence.
- Define resonance as an operator induced from `p-bit` evaluations (via a logic-to-complex embedding) and give the abstract form of resonance-driven propagation.

Summary and Hyperseed concepts covered

This section fixes a small algebraic/categorical substrate that will be used throughout the paper. The guiding idea is that Hyperseed's "soft" notions (distinction, simplicity, pattern, emergence, habit, resonance) are best treated as *graded* and often *paraconsistent*, and that they must compose cleanly across contexts [1].

Concretely, we build on: (i) `p-bit`-valued paraconsistent semantics for partial and conflicting evidence [23, 24]; (ii) a commutative quantale V for aggregating evidence, weakness, and intensities [3]; (iii) V-valued relations, modules, and V-enriched categories to express composition, approximation, and context translation [7]; and (iv) a resonance construction that turns paraconsistent evaluation structure into a coupling signal [24].

Hyperseed concepts covered.

- Distinction; indistinction/equivalence (observer-relative, graded). Hyperseed-Concept 98; Hyperseed-Concept **??**.
- Contexts/aspects; representation; approximate morphism / correspondence. Hyperseed-Concept 86; Hyperseed-Concept 157; Hyperseed-Concept 112.
- Effort-adjacent core proxies: weakness/simplicity as "failed distinctions" (full effort theory comes later). Hyperseed-Concept 202; Hyperseed-Concept 143; Hyperseed-Concept 169.
- Pattern and emergence (only the minimal scaffolding needed here; the main treatment is in Section 9). Hyperseed-Concept 130; Hyperseed-Concept **??**.
- Resonance/dissonance; the core coupling idea that later becomes morphic resonance/anti-resonance. Hyperseed-Concept 159; Hyperseed-Concept 97; Hyperseed-Concept 115; Hyperseed-Concept 114.

Purpose and "minimality" criterion. By "minimal formal core" we mean the smallest collection of mathematical primitives sufficient to (a) state the main constructions unambiguously, and (b) ensure that all later notions are *portable across contexts* via explicit composition laws. In particular, the formal layer here is not intended to be a full foundational reconstruction of Hyperseed; rather, it functions as a common interface between informal conceptual vocabulary and the later technical developments (patterns, emergence, translation, and resonance dynamics). A useful litmus test for whether a primitive belongs in this section is whether it is needed to define: (i) observer-relative evaluation, (ii) graded combination/propagation of evaluations, and (iii) approximate correspondence between structures.

Observer-relativity as an explicit parameter. The term "context" is treated as a first-class parameter rather than implicit background. Operationally, this means that any evaluation (truth, evidence, similarity, or correspondence) will be indexed by, or otherwise depend on, a context/aspect, so that the same entity may support different (even incompatible) attributions under different observational regimes. This explicit context dependence is what allows later constructions to represent translation, alignment, and weaving between viewpoints without collapsing all evaluations into a single globally consistent picture.

Why paraconsistency is structural rather than exceptional. Hyperseed-style modeling frequently involves partial evidence and mutually antagonistic constraints (e.g. an item that is simultaneously supported and opposed by different processes, or by the same process under different approximations). The point of introducing `p-bit` at the core is that "conflict" should be representable *without* forcing triviality: contradiction is recorded as a stable, graded state rather than an error condition. Accordingly, derived observables like support/opposition/conflict/indeterminacy are not merely diagnostic; they become quantitative signals that later participate in resonance, selection, and stabilization.

Compositionality as the non-negotiable design requirement. The repeated emphasis on relations, enriched categories, and quantale composition reflects a single requirement: evaluations must compose in a way that is associative and monotone (and hence usable for chaining approximations and propagating constraints). This is the formal analog of the informal claim that patterns and distinctions can be built out of simpler ones and transported through intermediate representational layers. In later sections, this compositionality is what permits multi-step mind–world correspondences (and inter-context translations) to be compared, aggregated, and iterated.

Interpreting the quantale V as a shared measurement substrate. The commutative quantale V is introduced to unify several graded notions that otherwise remain disconnected: strength of evidence, degree of weakness (as an effort-adjacent proxy), and pattern intensity or salience. The intent is that V provides both an ordering (to compare degrees) and a monoidal combination (to aggregate degrees across components, steps, or channels). Because the same algebraic structure supports both "evidence accumulation" and "cost/weakness aggregation," later definitions can express tradeoffs and co-variation (e.g. a correspondence that is strong but "expensive," or simple but weakly supported) within a single calculus.

V-valued relations as approximate correspondences. A V-valued relation may be read as assigning, to each candidate pair, a graded degree of correspondence rather than a Boolean yes/no match. Quantale-style composition then implements the idea that correspondences can be chained through intermediates, with the resulting degree determined by aggregating the degrees along the path and taking the appropriate supremum over alternatives. This recovers a standard intuition: an approximate match from A to C can be mediated by many different B-level representations, and the best available mediation determines the effective correspondence.

Enrichment and the "shape" of translation. The move from V-valued relations to V-enriched categories/quantaloids provides a language in which "processes" or "contexts" themselves can be organized compositionally. Enrichment is used here to avoid treating translation as a binary predicate; instead, morphisms carry degrees that can represent approximation quality, stability, or adequacy of representation. This becomes important when later sections compare alternative representational pipelines: two translations may exist between the same contexts but differ in graded adequacy, and those differences should themselves compose and propagate.

Resonance as an induced coupling signal. The resonance construction is included in the minimal core because it links logical evaluation to dynamical interaction: paraconsistent assessment is turned into a quantity that can drive propagation, reinforcement, or suppression. The mention of a logic-to-complex embedding indicates that resonance will be treated not only as magnitude but also as having a phase-like structure suitable for interference, alignment, and cancellation effects. Abstractly, resonance-driven propagation should be read as a schema: evaluations generate couplings; couplings modulate future evaluations; and the resulting feedback can stabilize patterns (resonance) or destabilize them (dissonance).

How the listed Hyperseed concepts attach to the formal layer. The items in the "Hyperseed concepts covered" list are meant to be grounded immediately by the above primitives: distinctions correspond to graded separations induced by valuations; equivalences are context-relative identifications supported by V-relations; weakness/simplicity are tracked by quantale aggregation over "failed distinctions"; patterns and emergence are prepared by having a compositional notion of correspondence; and resonance/dissonance are realized as operators acting on graded, possibly conflicting, evaluations. This anchoring is intentionally lightweight here, so that later sections can introduce richer versions (e.g. full effort theory and detailed pattern criteria) without changing the underlying compositional interface.

3.1 Design requirements and core data types

Hyperseed's informal presentation mixes phenomenology, ontology, and computation [1]. To make this mathematically tractable without destroying its intent, we treat the following features as *requirements* rather than optional add-ons:

1. **Observer-relativity.** Distinctions, simplicity, and uncertainty are indexed by a context/observer. Hyperseed-Concept 86.

2. **Paraconsistency.** Conflicting evidence ("both yes and no") must not entail triviality. Hyperseed-Concept 198.

3. **Gradation.** Most predicates (distinction, similarity, salience) are not crisp in realistic settings. Hyperseed-Concept 96; Hyperseed-Concept 195.

4. **Compositionality.** Combining processes or contexts should correspond to algebraic composition. Hyperseed-Concept 140; Hyperseed-Concept **??**.

5. **Approximation.** Many Hyperseed claims are about approximate morphisms (not exact isomorphisms). Hyperseed-Concept 112.

These requirements are intended to function together rather than independently. In particular, observer-relativity makes it unavoidable that distinct contexts can generate apparently incompatible verdicts about the same underlying situation, which motivates paraconsistency; gradation then refines this further by allowing "how incompatible" and "to what degree" to be part of the mathematical state rather than an informal afterthought. Compositionality ensures that once we admit multiple contexts and multiple processes, we can still build large models from smaller ones without losing interpretability, while approximation clarifies that the compositional laws we use should support robust *near-preservation* of structure (e.g., preservation up to tolerance, slack, or bounded distortion) rather than demanding brittle exactness.

Remark 45 (Why these requirements are not merely technical)**.** *Observer-relativity makes the mathematics mirror the epistemic situation: distinctions are not properties of the world in isolation, but of a world-as-grasped by some situated system. Paraconsistency acknowledges that real cognitive systems often carry simultaneous reasons for and against a claim; insisting on classical consistency would force premature collapse of lived ambiguity into brittle binaries. Gradation then supplies the missing continuum between "yes" and "no," allowing us to speak of weak, partial, and contested distinctions without erasing them.*

Compositionality and approximation are the two pillars that prevent this from being mere bookkeeping. Compositionality ensures that combining contexts or processes has a principled algebraic meaning, rather than being an ad hoc patchwork. Approximation recognizes that most correspondences in cognition and science are structural homologies, not perfect matches: a map can be useful precisely because it is good enough *while cheaper than exactness (a theme that will later connect to effort and simplicity; cf. Hyperseed-Concept 100 and Hyperseed-Concept 169).*

A further non-technical point is that these requirements jointly preserve a phenomenological reading: agents routinely operate with partially formed categories, revise them under pressure of evidence, and nevertheless act compositionally (they build larger plans from smaller habits) under approximate guidance (plans succeed when they are close enough). The formal core is therefore meant to support stable action under graded, context-indexed ambiguity*, rather than to eliminate ambiguity by stipulation.*

We therefore work with a minimal set of *core data types*:

Definition 2 (Universe of entities (local))**.** *A* local universe *is a set X whose elements are called* entities*. In applications, X may represent occasions of experience, perceived objects, internal representational states, or abstract pattern-tokens.*

Remark 46 (Intuition and examples for a local universe)**.** *This definition is deliberately modest: a "universe" here is not the cosmos but a chosen domain of discourse. One may think of it as the scope of what a particular model, observer, or subsystem is currently willing to count as distinct* things*. In Russell's sense, we begin with a type of objects, and only later attach predicates and relations; this postpones metaphysical commitments while keeping the mathematics clean.*

Examples: (1) In a toy perceptual model, X might be a finite set of perceived stimuli, say $\{a, b, c\}$. (2) In a cognitive architecture, X might be a set of internal memory items or attention tokens (Hyperseed-Concept **??***). The usefulness is that essentially all later structure (relations, valuations, composition) can be built on top of this minimal carrier set; we avoid prematurely committing to whether entities are "physical," "mental," or "abstract" (Hyperseed-Concept 136; Hyperseed-Concept 51; Hyperseed-Concept 83).*

It is also important that "local" allows X to be small, partial, or purpose-bound. For instance, an entity may be a coarse-grained token standing for a cluster of finer-grained sub-entities not presently tracked; conversely, what counts as a single entity in one modeling choice can be expanded into many entities in a refined choice. This flexibility is essential later when we talk about correspondence and approximation: a mapping between domains typically relates different *local universes (e.g., a perceptual token-space and a hypothesized external object-space), and the formalism should allow those universes to have different granularities while remaining comparable.*

Definition 3 (Contexts (observers/aspects))**.** *A* context *(or observer/aspect) C is a package of structure on a local universe X_C that includes:*

- *a* p-bit*-valued evaluation of propositions or relations (Section 3.2);*
- *a distinguished family of V-valued relations used to represent (in)distinction, similarity, and correspondence (Section 3.5);*
- *optional weights/saliences on entities (used by weakness and intensity functionals).*

Concretely, one may think of C as determining not only *which* entities are in play (via X_C), but also the admissible questions about them (via the chosen relations) and the permitted answer-values (via p-bit and V). Put differently: X_C supplies the "vocabulary" of entities, while the remaining components of the context supply a "semantics" that can tolerate conflict and degrees. This separation will later make it possible to speak precisely about translating information across contexts (e.g., carrying a graded similarity relation from one observer to another) and about composing contexts (e.g., forming joint standpoints that aggregate evidence with controlled loss).

Remark 47 (Contexts as perspectival packages)**.** *A context is not merely a "parameter"; it is an organized standpoint: it determines what counts as evidence, how evidence aggregates, and what sorts of comparisons can be composed. In Peircean terms [14], one may regard the context as providing the mediating habits (Thirdness) by which raw encounters (Secondness) are stabilized into usable generalities (Firstness). In Hyperseed's vocabulary, this is the formal shadow of* Contexts and Aspects *(Hyperseed-Concept 86).*

Example: Two contexts might share the same underlying set X of stimuli but disagree on which pairs are "the same for purpose P," because one context emphasizes color while another emphasizes shape. The point of packaging is practical: observer-relativity is not sprinkled across the theory as a warning label; it becomes explicit structure that can be translated, compared, and composed (later connecting to mind–world correspondence; Hyperseed-Concept 112, and to engineering concerns in cognitive systems [19]).

This packaging also clarifies what it means for two observers to "disagree." They need not disagree by assigning opposite classical truth-values; they may instead (i) assign incompatible paraconsistent values to the same proposition, (ii) agree on a proposition's evaluation but disagree on the induced similarities and distinctions, or (iii) differ in salience so that the same informational state leads to different downstream choices. Stated formally, contexts let us locate disagreement in a specific component (evaluation, relation-family, weighting) rather than treating it as an unanalyzable global mismatch.

The later ontology will add time, dynamics, effort, habit reinforcement, and self-reference on top of this; here we only build the minimal algebraic scaffolding.

3.2 Paraconsistent p-bit values

Definition 4 (p-bit domain)**.** *A* p-bit *truth value is a pair* $v = (v^+, v^-)$ *with* $v^+, v^- \in [0,1]$*, interpreted as degrees of* positive *and* negative *evidence. We write*

$$\mathbb{V} := [0,1]^2.$$

Remark 48 (Notation unpacking and philosophical motivation)**.** *The notation* $v = (v^+, v^-)$ *should be read literally as an* evidence record*: the superscripts* $+$ *and* $-$ *denote support-for and support-against, not "probability" and "one minus probability." The square* $[0,1]^2$ *means we allow any pair of real numbers between* 0 *and* 1*; thus* $\mathbb{V}$ *is the unit square, interpreted epistemically rather than geometrically. This choice parallels evidence-pair traditions in paraconsistent and bilattice-inspired semantics [23].*

Intuitively, paraconsistency enters because cognitive and scientific life routinely supplies mixed reasons. A system may have strong evidence for a claim in one subsystem and strong evidence against it in another, without immediately dissolving into incoherence. The p-bit *domain is a minimal way to encode this while remaining computationally cheap and algebraically tractable (and it aligns with later resonance constructions based on interference [24]).*

Remark 49 (Simple examples and why the domain is useful)**.** *Example 1:* $v = (1,0)$ *can be read as "maximally supported and not opposed," a classical truth-like corner. Example 2:* $v = (1,1)$ *is "both strongly supported and strongly opposed," representing genuine conflict rather than confusion. Example 3:* $v = (0,0)$ *represents lack of evidence either way (ignorance). Between these corners lie graded states such as* $(0.7, 0.2)$ *(mostly supported, weakly opposed).*

The utility is that we can carry conflicting or incomplete information forward through compositions and aggregations without forcing premature resolution. Later, when values and goals conflict (Hyperseed-Concept 198) or when boundaries between self and other are ambiguous (Hyperseed-Concept 165), this capacity becomes structurally necessary rather than merely convenient.

Remark 50 (Belnap corners as extremes)**.** *The four extreme points*

$$(1,0),\ (0,1),\ (1,1),\ (0,0)$$

correspond to the classical four-valued paraconsistent states: true, false, both, neither. The interior points represent graded mixtures.

Derived observables. From $v = (v^+, v^-)$ we will frequently use the following derived quantities:

$$\mathrm{supp}(v) := v^+, \qquad \mathrm{opp}(v) := v^-,$$

$$\mathrm{bias}(v) := v^+ - v^- \in [-1,1], \qquad \det(v) := \max(v^+, v^-) \in [0,1], \qquad \mathrm{conf}(v) := \min(v^+, v^-) \in [0,1].$$

Here $\mathrm{conf}(v)$ is a simple "contradiction/co-presence" score (both-sides present), while $1 - \det(v)$ is a simple "indeterminacy" score (neither-side strong).

Remark 51 (Why these observables are the right minimal statistics)**.** *The pair* (v^+, v^-) *contains two degrees of freedom; the derived quantities extract different "faces" of the same datum.* bias *tells us which way the evidence leans;* conf *tells us how much the evidence is* internally at war. det *measures whether there is any strong commitment (either pro or con), and* $1 - \det$ *measures a kind of uncertainty. These are not the only possible summaries, but they are monotone and inexpensive, and they harmonize with later constructions where we must compare many judgments quickly.*

A useful mental picture is to imagine a compass: bias *corresponds to east–west pull, while* conf *corresponds to a northward pull toward "both." This geometric metaphor will become literal once we embed* $\mathbb{V}$ *into* $\mathbb{C}$ *in Section 3.9.*

Definition 5 (Negation)**.** *Define the involution*

$$\neg(v^+, v^-) := (v^-, v^+).$$

Remark 52 (Intuition, example, and why involution matters)**.** *Negation swaps positive and negative evidence: what was counted as support is now counted as opposition and vice versa. For example, $\neg(1,0) = (0,1)$ and $\neg(0.8, 0.3) = (0.3, 0.8)$. This is an involution: applying it twice returns the original value, $\neg(\neg v) = v$.*

This operation is useful because it cleanly separates the representation of evidence from any particular choice of connectives. It also makes anti-resonance propagation (Definition 22) formally simple: one can propagate "the contrary" without inventing a new evidence calculus each time.

Definition 6 (Evidence-style conjunction and disjunction)**.** *Define*

$$v \wedge w := \big(\min(v^+, w^+),\ \max(v^-, w^-)\big), \qquad v \vee w := \big(\max(v^+, w^+),\ \min(v^-, w^-)\big).$$

Remark 53 (Intuition via constraints and two quick examples)**.** *The connective $v \wedge w$ behaves like an "and" for positive evidence and like an "or" for negative evidence: to support $A \wedge B$ you must support both (hence* min*), but to oppose $A \wedge B$ it suffices to oppose either (hence* max*). Dually, $v \vee w$ takes the easiest support (*max*) but the hardest opposition (*min*).*

Example: if $v = (0.9, 0.1)$ and $w = (0.4, 0.8)$ then

$$v \wedge w = (0.4, 0.8), \qquad v \vee w = (0.9, 0.1).$$

So the conjunction inherits the weaker support and the stronger opposition; the disjunction inherits the stronger support and the weaker opposition. This is useful because it respects the intuition that a single strong refutation can undermine a conjunction, while a single strong support can sustain a disjunction.

Remark 54 (Interpretation)**.** *Under these connectives, supporting $A \wedge B$ requires supporting both (hence* min *on positive evidence), while refuting $A \wedge B$ requires refuting either (hence* max *on negative evidence). Dually, supporting $A \vee B$ requires supporting either (*max*), while refuting $A \vee B$ requires refuting both (*min*). This is one standard "evidence pair" paraconsistent semantics; other monotone choices are possible.*

It may help to keep the intended reading explicit: a value $v = (v^+, v^-)$ records independent *degrees of positive and negative evidence, so v^+ and v^- need not sum to 1 and may simultaneously be large (a conflicted state), or simultaneously be small (an uninformed state). With that in mind, the $\wedge/\vee$ clauses above are just the order-theoretically simplest way to implement "need both" versus "need either" for support/refutation, using the lattice operations* min *and* max *on each evidence coordinate.*

In particular, if A is strongly supported but also strongly opposed, and similarly for B, then $A \wedge B$ remains strongly supported only insofar as both *supports remain high (hence the* min*), while it becomes strongly opposed as soon as* either *conjunct attracts strong opposition (hence the* max*). The dual intuition for $\vee$ is analogous: disjunction is easy to support (any disjunct suffices) but hard to refute (both must be refuted). These asymmetries are exactly what lets the semantics tolerate inconsistency without collapsing into triviality.*

Definition 7 (Implication (one convenient choice))**.** *Define implication by*

$$v \to w := (\neg v) \vee w.$$

Remark 55 (What this implication expresses and why we do not overcommit to it)**.** *The definition $v \to w := (\neg v) \vee w$ is the familiar material-implication pattern translated into the evidence-pair setting: "if v then w" is treated as "either not-v or w." For example, if $v = (1, 0)$ (strongly supported) and $w = (0, 1)$ (strongly opposed), then $v \to w$ becomes maximally conflicted, reflecting the idea that a supported antecedent with an opposed consequent is problematic.*

One should also read this connective operationally: increasing evidence against *v (i.e. increasing the negative coordinate of v, which becomes positive evidence for $\neg v$) makes $v \to w$ easier to support, while increasing evidence* for *w also makes $v \to w$ easier to support, since it is a disjunction. Conversely, to refute $v \to w$ one must refute* both *$\neg v$ and w, meaning (intuitively) one must have strong support for v together with strong opposition to w; this matches the classical idea that an implication fails precisely when the antecedent holds but the consequent does not, while still allowing the paraconsistent possibility that additional counterevidence coexists.*

We include implication mainly as a bridge to conventional logical reading. Much of the later theory leans more on monotone aggregation and composition (quantale joins/products and enriched-category inequalities) than on any particular internal logic. This restraint is intentional: Hyperseed aims to model cognition where inference is often heuristic, resource-bounded, and context-sensitive, so algebraic monotonicity often does more work than a single, universal implication connective [19, 20].

Accordingly, nothing in the sequel depends on material implication validating all familiar proof principles (e.g. unrestricted modus ponens under inconsistency), and alternative paraconsistent implications could be substituted if one wishes to enforce different inferential behavior. The point of Definition 7 is thus representational convenience: it supplies a recognizable "if–then" connective that interacts predictably with $\neg$ and $\vee$ in the evidence-pair algebra, without claiming to be the unique or cognitively privileged notion of implication.

For the toy model and much of the later ontology, we will rely more heavily on *monotone aggregation* (quantale joins and monoidal products) than on any particular choice of implication; the above is included mainly to provide a familiar logical vocabulary when needed.

3.3 Quantales as aggregation and composition domains

Definition 8 (Commutative quantale)**.** *A* commutative quantale *is a tuple $(V, \leq, \bigvee, \otimes, e)$ such that:*

1. *$(V, \leq)$ is a complete lattice with joins $\bigvee S$ for all $S \subseteq V$;*
2. *$(V, \otimes, e)$ is a commutative monoid;*
3. *$\otimes$ distributes over arbitrary joins:*

$$a \otimes \Big(\bigvee_i b_i\Big) = \bigvee_i (a \otimes b_i), \qquad \Big(\bigvee_i b_i\Big) \otimes a = \bigvee_i (b_i \otimes a).$$

Remark 56 (Basic consequences worth keeping in mind)**.** *Because $(V, \leq)$ is a complete lattice, it in particular has a bottom element $\bot := \bigvee \emptyset$ and a top element $\top := \bigvee V$, and it also has all meets $\bigwedge S$ (as joins in the opposite order). The distributivity axiom implies that, for each fixed $a \in V$, the map $(-) \mapsto a \otimes (-)$ preserves arbitrary joins; similarly $(-) \mapsto (-) \otimes a$ preserves arbitrary joins. In particular, $\otimes$ is monotone in each argument:*

$$b \leq c \implies a \otimes b \leq a \otimes c, \qquad b \leq c \implies b \otimes a \leq c \otimes a.$$

This monotonicity is the order-theoretic statement that "adding evidence cannot reduce a composed influence." It is the minimal property needed to make repeated update steps behave predictably when we later iterate propagation operators.

A useful special case of join-preservation is the interaction with $\perp$*:*

$$a \otimes \perp = a \otimes \left(\bigvee \emptyset\right) = \bigvee \emptyset = \perp, \qquad \perp \otimes a = \perp,$$

so $\perp$ *acts as an absorbing element for composition. Intuitively, "impossible/absent influence" remains impossible/absent under chaining.*

Remark 57 (Notation and intuition for quantales)**.** *The symbols are meant to be read in an order-theoretic way. The relation* $\leq$ *is an information/strength ordering;* $\bigvee$ *is the join (least upper bound), i.e. the operation of aggregating many pieces of evidence into the weakest upper bound that dominates them. The operation* $\otimes$ *is the monoidal product, interpreted as a form of sequential or conjunctive composition. The element* e *is the unit for* $\otimes$*.*

A quantale can be thought of as "logic with arithmetic": it allows you to accumulate *many influences (*$\bigvee$*) and also to* chain *influences (*$\otimes$*) in a way that interacts well with accumulation (distributivity). This is precisely what we need for Hyperseed's graded and compositional notions of distinction, weakness, and pattern propagation [3].*

The commutativity assumption is not strictly necessary in all quantale applications, but it matches the intended reading here where the combination of two influences is not sensitive to their left/right ordering at the level of scalar weights. Later, directionality will be represented in the relational structure (source/target of a link) rather than in the scalar itself, so a commutative $\otimes$ *keeps the scalar calculus simple while still supporting non-symmetric networks.*

Remark 58 (Simple examples and why quantales are useful here)**.** *Example 1: The Boolean quantale* $(\{0,1\}, \leq, \vee, \wedge, 1)$ *yields ordinary relational composition and crisp distinctions. Example 2: The unit interval with* $\bigvee = \max$ *and* $\otimes = \cdot$ *yields fuzzy relational composition. Our later choice* $V = [0,1]^2$ *is a paraconsistent generalization of this.*

To connect these examples to the way Hyperseed will use them: if one represents a pattern-propagation relation as a V*-valued adjacency matrix, then the "two-step influence" from* x *to* z *through intermediate nodes* y *is computed by composing along* y *using* $\otimes$ *and then aggregating over all* y *using* $\bigvee$*. In the Boolean case this recovers existential path composition; in the fuzzy case it recovers the standard max-product or sup-product style composition. The quantale axioms are exactly what ensures that this matrix-style multiplication is associative, so that multi-step propagation does not depend on arbitrary parenthesization.*

Quantales serve Hyperseed as a disciplined replacement for informal phrases like "combine these influences" or "propagate this pattern." They guarantee that iterative updates behave monotonically and that multi-step compositions can be reassociated without ambiguity (associativity of relational composition ultimately rests on the distributivity axiom). This becomes essential once we discuss resonance-driven propagation and habit reinforcement, where repeated composition is the rule rather than the exception (Hyperseed-Concept 189; Hyperseed-Concept 188).

The paraconsistent choice $V = [0,1]^2$ *can be read as tracking two graded channels (e.g. support and counter-support) simultaneously. In that setting,* $\leq$ *will typically be chosen so that moving "up" corresponds to having at least as much support and at least as much counter-support, and the join* $\bigvee$ *becomes a pointwise "take the strongest available components." What matters at this stage is that quantales give a single abstract interface: regardless of whether we are in a crisp, fuzzy, or paraconsistent regime, the same definitions of aggregation and chaining apply.*

Quantales are a natural "glue" structure for Hyperseed because they simultaneously support: (i) graded aggregation (joins); (ii) sequential or conjunctive composition (monoidal product); and (iii) order-theoretic monotonicity (needed for observer-relativity and refinement arguments).

Operationally, items (i)–(iii) are the minimum needed to speak about networks where many partial influences converge on a node (hence $\bigvee$), where influences can traverse multiple links (hence $\otimes$), and where strengthening local information cannot create a global weakening (hence monotonicity). This is why the quantale layer sits in the "minimal formal core": it pins down the algebraic laws that make later propagation operators well-defined, compositional, and stable under iteration.

3.4 A canonical p-bit quantale

Definition 9 (Canonical commutative p-bit quantale)**.** *Let $V := ([0,1]^2, \leq, \oplus, \otimes, e)$ where:*

- $(a^+, a^-) \leq (b^+, b^-)$ *iff* $a^+ \leq b^+$ *and* $a^- \leq b^-$ *(componentwise order),*
- $(a^+, a^-) \oplus (b^+, b^-) := (\max(a^+, b^+), \max(a^-, b^-))$ *(join),*
- $(a^+, a^-) \otimes (b^+, b^-) := (a^+b^+, a^-b^-)$ *(monoidal product),*
- $e := (1, 1)$ *(unit).*

Then V is a commutative quantale.

Remark 59 (Why this is a quantale (explicit properties))**.** *The statement that V is a commutative quantale unfolds into three routine facts: (i) $([0,1]^2, \leq)$ is a complete lattice; (ii) $(V, \otimes, e)$ is a commutative monoid; and (iii) $\otimes$ distributes over arbitrary joins in each argument.*

For (i), completeness is componentwise: given any family $\{(a_i^+, a_i^-)\}_{i \in I} \subseteq [0,1]^2$, its join is

$$\bigvee_{i \in I} (a_i^+, a_i^-) = \Big(\sup_{i \in I} a_i^+,\ \sup_{i \in I} a_i^-\Big),$$

and its meet is defined analogously with infima; these exist because $[0,1]$ is complete. For finite joins, this recovers $\oplus$ as the componentwise maximum.

For (ii), associativity and commutativity of $\otimes$ follow from associativity and commutativity of multiplication in $[0,1]$ applied componentwise, and $e = (1,1)$ is a two-sided unit since $a^\pm \cdot 1 = a^\pm$.

For (iii), fix (b^+, b^-) and a family $\{(a_i^+, a_i^-)\}_{i \in I}$. Then

$$\Big(\bigvee_{i \in I} (a_i^+, a_i^-)\Big) \otimes (b^+, b^-) = \Big((\sup_i a_i^+) b^+,\ (\sup_i a_i^-) b^-\Big) = \Big(\sup_i (a_i^+ b^+),\ \sup_i (a_i^- b^-)\Big) = \bigvee_{i \in I} \big((a_i^+, a_i^-) \otimes (b^+, b^-)\big),$$

using that multiplication by a fixed $b^\pm \in [0,1]$ preserves suprema in $[0,1]$ (it is monotone and Scott-continuous on the complete lattice $[0,1]$). The same argument applies in the other argument, hence $\otimes$ preserves arbitrary joins separately, as required for a quantale.

Remark 60 (How to read $\oplus$ and $\otimes$ in this specific quantale)**.** *The operation $\oplus$ takes componentwise maxima: it is an "evidence accumulation" operator. If one source gives evidence $(0.7, 0.2)$ and another gives $(0.5, 0.9)$, then the aggregate is $(0.7, 0.9)$: we keep the strongest support and the strongest opposition, because both may matter in a paraconsistent setting.*

This reading also highlights that $\oplus$ is idempotent and commutative: aggregating the same piece of evidence twice does not inflate it, and order of aggregation does not matter. Moreover, since $\oplus$ is the join induced by $\leq$, the inequality $(a^+, a^-) \leq (a^+, a^-) \oplus (b^+, b^-)$ expresses that aggregation is information-increasing in each coordinate.

The operation $\otimes$ multiplies components: it is a "co-occurrence" or "chaining" operator. If two independent stages each preserve positive evidence at rates a^+ and b^+, then the two-stage preservation is a^+b^+ (and similarly for negative evidence). This multiplicativity is computationally convenient and aligns with common probabilistic intuitions without reducing evidence-pairs to ordinary probabilities.

Algebraically, $\otimes$ is monotone in each argument with respect to $\leq$: if $(a^+, a^-) \leq (a'^+, a'^-)$ then $(a^+, a^-) \otimes (b^+, b^-) \leq (a'^+, a'^-) \otimes (b^+, b^-)$, because multiplication by $b^{\pm} \in [0,1]$ preserves order. Intuitively, strengthening either the positive or negative component cannot weaken the chained outcome.

Remark 61 (Bottom and top)**.** *The least element is $\bot = (0,0)$ and the greatest element is $\top = (1,1) = e$. Intuitively, $\bot$ represents "no evidence either way", while $\top$ represents "maximal evidence on both sides". This is acceptable (and sometimes desirable) in paraconsistent settings; if one wants $\top$ to mean "maximally true" instead, one may instead work with a different ordering (e.g. a truth order vs. a knowledge order). For the present paper, the componentwise order is treated as an* information aggregation order*.*

Concretely, with the information aggregation (knowledge) order, $(a^+, a^-) \leq (b^+, b^-)$ means that b contains at least as much supporting evidence and at least as much opposing evidence as a. Under this interpretation, increasing either coordinate represents adding information rather than resolving a truth-value; hence it is consistent for $\top$ to carry maximal values in both coordinates.

Remark 62 (A concrete example and why $e = (1,1)$ is not a paradox)**.** *It may look strange that the monoidal unit e carries* maximal *evidence in both components. But e is not intended to represent "the proposition that is perfectly true." It represents "no loss under composition": composing with e should not attenuate either positive or negative evidence. In that sense, e plays the role of a neutral element for information-flow, not a metaphysical truth.*

This choice is particularly appropriate when the lattice order is read as "having at least as much information" (knowledge order). Under that reading, $(1,1)$ is indeed the most informative point: it contains maximal positive and maximal negative evidence simultaneously. This echoes the bilattice tradition that separates truth-order from knowledge-order [23].

A small numerical check may help: for any (a^+, a^-) we have $(a^+, a^-) \otimes (1,1) = (a^+, a^-)$, whereas $(a^+, a^-) \oplus (1,1) = (1,1)$. Thus e is neutral for chaining ($\otimes$) but absorbing for aggregation ($\oplus$), exactly as one expects when $\oplus$ is a join operation and e happens to coincide with the top element in the chosen order.

Remark 63 (Residuals (optional but often useful))**.** *Many quantale-based constructions use the (right) residual $x \Rightarrow y := \bigvee\{z \mid x \otimes z \leq y\}$ when it exists; in a quantale it always exists by completeness. In the present $[0,1]^2$ instance, the residual is componentwise and can be written explicitly using the usual residuum of multiplication on $[0,1]$:*

$$(a^+, a^-) \Rightarrow (b^+, b^-) = \big(a^+ \Rightarrow_\times b^+,\ a^- \Rightarrow_\times b^-\big), \qquad a \Rightarrow_\times b := \begin{cases} 1, & a = 0, \\ \min\{1,\ b/a\}, & a > 0. \end{cases}$$

This observation is not required for the basic development, but it clarifies that the canonical choice supports implication-like operations (as adjoints to chaining) without leaving the p-bit *domain.*

Remark 64 (Other choices)**.** *The specific operations above are not mandatory. Any commutative quantale compatible with the intended monotonicities can be substituted. The canonical choice is used because it is simple, computable, and supports the toy model in Section 5.*

For example, one could replace componentwise multiplication by a different t-norm (and componentwise maximum by the corresponding join if one changes the underlying order), or keep the componentwise order but use an alternative monoidal product reflecting a different notion of sequential combination. The key constraints are that $\otimes$ be associative, commutative, monotone, and distribute over joins, so that the general quantale calculus remains available.

3.5 V-valued relations and quantale composition

Definition 10 (V-valued relations)**.** *Given a set X, a V-*valued relation *on X is a map*

$$R : X \times X \to V.$$

More generally, a V-valued relation from X to Y is a map $R : X \times Y \to V$.

Remark 65 (Basic special cases and why "relations" is the right word)**.** *When $V = \mathbf{2} = \{\bot, \top\}$ with $\oplus = \vee$ and $\otimes = \wedge$, a V-valued relation $R : X \times Y \to V$ is exactly an ordinary (crisp) relation: $R(x, y) = \top$ means "related" and $R(x, y) = \bot$ means "not related." When $V = [0, 1]$ with $\oplus = \sup$ and $\otimes$ a t-norm, one recovers standard fuzzy relations. The present setting keeps the same relational syntax $R(x, y)$ but allows richer evidence types, so that the same formalism can express classical, fuzzy, and paraconsistent/bi-graded correspondences as instances.*

Remark 66 (Intuition: relations as graded, possibly conflicting correspondences)**.** *A classical relation says only whether (x, y) is related (yes/no). A V-valued relation assigns to each pair (x, y) a value in V encoding graded evidence. When $V = [0, 1]^2$, this means we can simultaneously record degrees of "x matches y" and "x does not match y," without forcing a collapse. This directly supports Hyperseed's graded distinction/indistinction (Hyperseed-Concept 98).*

Example: If X is a set of perceived objects and Y is a set of internal symbols, then $R(x, y) = (0.8, 0.1)$ might mean the system mostly endorses interpreting object x as symbol y, with mild counterevidence. In a conflicting case, $R(x, y) = (0.8, 0.8)$ records a genuine ambiguity: strong reasons to map and strong reasons not to map. Such relations are a natural substrate for representation and correspondence (Hyperseed-Concept 157; Hyperseed-Concept 112) as discussed in cognitive-systems settings [19].

Remark 67 (Terminology: evidence values live in a poset, not necessarily numbers)**.** *It is important that V is used only through its order and its two operations. Even when one writes pairs such as $(0.8, 0.1)$, the formal reading is: $R(x, y)$ is an element of an ordered structure in which one can (i) combine pieces of evidence along a path using $\otimes$, and (ii) aggregate alternative paths using $\oplus$ (a join). Thus the same definitions apply when V is non-numeric (e.g. logical truth values, cost semirings, or other complete lattices equipped with a compatible "multiplication").*

Definition 11 (Quantale "matrix" composition)**.** *Given $R : X \times Y \to V$ and $S : Y \times Z \to V$, define their composite*

$$(S \circ R)(x, z) := \bigoplus_{y \in Y} R(x, y) \otimes S(y, z).$$

When V is complete and $\otimes$ distributes over joins, this composition is associative.

Remark 68 (Well-definedness for infinite Y and why completeness matters)**.** *For finite Y, the expression $\bigoplus_{y \in Y}$ is just a finite join. For general (possibly infinite) Y, the definition requires that arbitrary joins exist in V so that $\bigoplus_{y \in Y}(\cdots)$ is meaningful. This is exactly the "completeness" condition in the quantale assumption, and it is the reason quantales (rather than merely monoids or semirings) are the natural ambient algebra for relation-like composition over arbitrary sets.*

Remark 69 (Notation unpacking and a small example)**.** *The symbol $\bigoplus_{y\in Y}$ denotes the join (supremum) over all intermediates y. It plays the role of "there exists a good intermediary" but in a graded way: we aggregate the evidence contributed by each path $x \to y \to z$ using $\otimes$, and then take the best/most informative aggregate using $\oplus$.*

Example (finite Y): if $Y = \{y_1, y_2\}$ then

$$(S \circ R)(x,z) = \big(R(x,y_1) \otimes S(y_1,z)\big) \ \oplus \ \big(R(x,y_2) \otimes S(y_2,z)\big).$$

This is literally matrix multiplication with $(+,\cdot)$ replaced by $(\oplus,\otimes)$. The usefulness is that it gives a principled notion of chaining approximate correspondences, essential for modeling multi-step representation pipelines (e.g. perception $\to$ internal model $\to$ action), and it will later support pattern-web propagation rules (Hyperseed-Concept 132).

Remark 70 (Associativity: what "$\otimes$ distributes over joins" buys you)**.** *The associativity claim can be seen by expanding both sides pointwise. Given $R : X \times Y \to V$, $S : Y \times Z \to V$, and $T : Z \times W \to V$, one has*

$$\big(T \circ (S \circ R)\big)(x,w) = \bigoplus_{z\in Z}\Big(\bigoplus_{y\in Y} R(x,y) \otimes S(y,z)\Big) \otimes T(z,w),$$

and distributivity of $\otimes$ over joins allows one to rewrite this as

$$\bigoplus_{z\in Z}\bigoplus_{y\in Y} R(x,y) \otimes S(y,z) \otimes T(z,w).$$

Similarly,

$$\big((T \circ S) \circ R\big)(x,w) = \bigoplus_{y\in Y} R(x,y) \otimes \Big(\bigoplus_{z\in Z} S(y,z) \otimes T(z,w)\Big),$$

which also becomes

$$\bigoplus_{y\in Y}\bigoplus_{z\in Z} R(x,y) \otimes S(y,z) \otimes T(z,w).$$

Since joins are associative/commutative up to the ambient order (and $\otimes$ is associative), these two expressions coincide. Thus the "matrix" composition is not merely suggestive: it is genuinely functorial under the standard quantale axioms.

Remark 71 (Interpretation as approximate correspondence)**.** *A V-relation $R : X \times Y \to V$ can be read as a graded, possibly inconsistent correspondence: $R(x,y)$ is the amount of evidence that x in X "matches" y in Y (or is "the same" for some purpose), with both positive and negative components allowed. Composition then corresponds to chaining correspondences through an intermediate representation.*

Remark 72 (Reading $\oplus$ as aggregation of alternatives rather than averaging)**.** *The join $\oplus$ should be read as an order-theoretic "best supported" (or "most informative") combination of alternatives, not as an arithmetic average. In particular, if one alternative path yields strictly stronger evidence than another, the join simply retains the stronger one. This is one reason quantale composition is well-suited to propagation of constraints or supports in a pattern web: multiple routes can contribute, but the algebra specifies precisely how they compete or reinforce.*

Definition 12 (Identity V-relation)**.** *For a set X, define $\mathrm{id}_X : X \times X \to V$ by*

$$\mathrm{id}_X(x,y) := \begin{cases} e & \text{if } x = y, \\ \bot & \text{if } x \neq y. \end{cases}$$

Remark 73 (Why this is the correct identity and what $\perp$ does)**.** *The identity relation is meant to say: an element matches itself with full compositional strength, and matches distinct elements with none. Here $\perp$ is the least element of V (in the* p-bit *quantale, $\perp = (0,0)$), so it contributes no evidence under joins and attenuates completely under products.*

A quick check in the finite case confirms the intuition: composing any $R : X \times Y \to V$ with id_X *on the left leaves R unchanged because only the $x = y$ term contributes nontrivially. This identity is essential because it lets us treat V-relations as morphisms in a bona fide category (so that associativity and identity laws hold), which in turn is what makes later compositional arguments about contexts and translations well-typed rather than metaphorical.*

Remark 74 (Left and right unit laws pointwise)**.** *It is useful to keep in mind the explicit pointwise verification. For $R : X \times Y \to V$ and $x \in X$, $y \in Y$,*

$$(R \circ \mathrm{id}_X)(x,y) = \bigoplus_{x' \in X} \mathrm{id}_X(x,x') \otimes R(x',y) = e \otimes R(x,y) \;\oplus\; \bigoplus_{x' \neq x} \perp \otimes R(x',y) = R(x,y),$$

using $\perp \otimes v = \perp$ and $\perp \oplus v = v$. Similarly $\mathrm{id}_Y \circ R = R$. *These computations are routine but conceptually important: they show that* id_X *acts exactly like the diagonal matrix with e on the diagonal and $\perp$ elsewhere, matching the matrix analogy from Definition 11.*

With these definitions, sets and V-relations form a category (indeed, a standard quantaloid construction when one varies X).

3.6 V-enriched categories and approximate morphisms

Hyperseed frequently talks as if there are "morphisms" between internal and external pattern structures, but these morphisms are rarely exact. Quantale enrichment provides a uniform language for this [7].

A useful way to think about the role of the quantale $(V, \leq, \otimes, e)$ is that it supplies a *scale of comparison* (the order $\leq$) together with a *compositional aggregator* (the monoidal product $\otimes$) and a *baseline unit* (the element e). In many applications V is not merely a set of "weights": it is chosen so that arbitrary joins $\bigvee$ exist and $\otimes$ distributes over them, ensuring that "taking the best available evidence" and "composing evidence" interact coherently. Although we assume commutativity here for simplicity, many of the intended readings (e.g. asymmetric translation effort) can be modeled in noncommutative quantales as well; the thin axioms below are written so that the directional nature of $\mathcal{C}(A,B)$ is retained regardless.

Definition 13 (V-enriched category (thin form))**.** *Let $(V, \leq, \otimes, e)$ be a commutative quantale. A* V-enriched category $\mathcal{C}$ *consists of:*

- *a class of objects* $\mathrm{Ob}(\mathcal{C})$*;*
- *for each $A, B \in \mathrm{Ob}(\mathcal{C})$, a hom-value $\mathcal{C}(A,B) \in V$;*

such that for all A, B, C:

$$e \leq \mathcal{C}(A,A), \qquad \mathcal{C}(A,B) \otimes \mathcal{C}(B,C) \leq \mathcal{C}(A,C).$$

Remark 75 (Canonical choices of V)**.** *Different choices of quantale recover familiar "approximate" semantics. If $V = \mathbf{2} = \{\perp \leq \top\}$ with $\otimes = \wedge$ and $e = \top$, then a thin V-category is exactly a preorder: $\mathcal{C}(A,B) = \top$ means "A entails/reaches B" and the composition axiom is transitivity. If*

$V = [0,1]$ with $\leq$ the usual order, $e = 1$, and $\otimes$ a t-norm (often multiplication), then $\mathcal{C}(A, B)$ can be read as a graded confidence/support. If one instead wishes to model cost *or* distance*, a standard choice is the Lawvere quantale $V = ([0,\infty], \geq, +, 0)$ (note the reversed order), in which case the same inequality becomes the triangle inequality for extended pseudo-metrics: going via B cannot be cheaper than going directly. These examples underline that the "same" formalism can encode either support-like or cost-like readings by a systematic choice of order and tensor.*

Remark 76 (What "thin form" means and how to picture it)**.** *In an ordinary category, $\mathcal{C}(A, B)$ is a* set *of morphisms. In the thin enriched form used here, we collapse that set to a single graded value: $\mathcal{C}(A, B) \in V$ measures "how well A leads to B" (as support, feasibility, similarity, etc.). This is closer to a preorder than to a category with many arrows, but it is often exactly what is needed for resource-sensitive modeling: we care about* degree of accessibility *more than about enumerating all witnesses.*

Example: objects could be contexts, models, or descriptions; then $\mathcal{C}(A, B)$ might encode the degree to which B can be obtained from A by a translation or refinement step. The axioms then say: each object can reach itself at least as well as the unit e, and going from A to B and then B to C cannot yield better support than a direct A to C value (a quantitative triangle-like law). This is a convenient formal home for Hyperseed's many "approximate correspondence" claims (Hyperseed-Concept 112).

Equivalently, one can read a thin V-category as a V-valued preorder*: it records, for every ordered pair (A, B), a single "strength" of the statement "A is at most as informative as B" (or "A can be transformed into B") in a way that is reflexive and transitive in the enriched sense. This perspective is often helpful when translating informal monotonicity claims into lemmas, because one can appeal directly to enriched reflexivity/transitivity rather than to the existence of explicit witnessing arrows.*

Remark 77 (How to read the axioms)**.** *These axioms say: identity evidence is maximal (or at least not worse than e), and chaining two correspondences yields a correspondence that is (weakly) no stronger than the direct one. The direction of the inequalities depends on whether one models "cost" (where smaller is better) or "support" (where larger is better). Here we model graded support, so composition multiplies support and is bounded above by direct support.*

It is often useful to keep two derived intuitions in mind. First, the enriched composition law is a submultiplicativity *constraint: whatever proxy for "evidence" $\mathcal{C}(A, B)$ represents, indirect evidence obtained by composing steps cannot systematically dominate direct evidence. Second, the axiom is robust under coarse-graining: if one later refines the modeling to track multiple pathways explicitly, taking a join/supremum over pathways typically yields a thin hom-value that still satisfies the same inequality because $\otimes$ distributes over joins in a quantale.*

Definition 14 (V-functor (thin form))**.** *A* V-functor *$F : \mathcal{C} \to \mathcal{D}$ between V-enriched categories is a function on objects such that*

$$\mathcal{C}(A, B) \leq \mathcal{D}(F(A), F(B))$$

for all objects A, B.

Remark 78 (Intuition: structure preservation up to monotone improvement)**.** *A V-functor sends each object in $\mathcal{C}$ to an object in $\mathcal{D}$ and guarantees that any accessibility/support present in $\mathcal{C}$ is* not *lost under translation. In other words, if A supports reaching B to degree $\mathcal{C}(A, B)$, then $F(A)$ supports reaching $F(B)$ at least as strongly in $\mathcal{D}$.*

Example: $\mathcal{C}$ might be a category of world-states and $\mathcal{D}$ a category of internal representations. Then F models a representational mapping that does not reduce the system's ability to track certain *transitions. This is one rigorous way to capture "approximate morphism" talk in cognitive modeling [19], while retaining the flexibility that F need not be invertible or information-preserving in the classical sense.*

In practice, many mappings of interest are not strictly structure-preserving but are lax *or* approximate *in the sense that they preserve lower bounds on support rather than exact values. The thin V-functor inequality is exactly such a laxness condition: it asks only that the image correspondence in $\mathcal{D}$ be* at least as permissive *(in the $\leq$-order sense) as the original correspondence. This matches the modeling stance in which internal representations may "fill in" or "smooth over" distinctions present in the world while still enabling reliable downstream composition of inferences.*

Why enrichment is enough for "approximate morphisms." In later sections we will represent many Hyperseed correspondences as either: (i) V-functors (structure-preserving maps), or (ii) V-relations/modules (structure-preserving correspondences that need not be functional). Both are stable under composition and admit quantitative comparison.

Concretely, "admit quantitative comparison" can be read pointwise: given two candidate correspondences of the same type, one can often define an ordering by saying that one is no worse than the other exactly when it assigns everywhere-greater (support-like) hom-values (or everywhere-lower costs, in the dual convention). This makes it possible to phrase optimization or "best available translation" problems entirely inside the enrichment order, without prematurely committing to a particular algorithmic realization.

Remark 79 (Why this suffices for a large portion of Hyperseed's needs)**.** *One might worry that a "thin" enriched category cannot express all the nuance of internal representations, which often involve many distinct mechanisms. But much of Hyperseed's ontology, at least at the scaffold level, asks questions of the form: "to what degree does structure A constrain or entail structure B?" For this, a single graded hom-value is often the right abstraction: it forgets implementation details while preserving compositional inequality laws, which are the main invariants needed to prove monotonicity and stability results later.*

This choice is also methodologically Russellian: replace metaphysical speculation with a calculus of relations whose algebraic laws are explicit. When more expressivity is required (multiple arrows, higher morphisms, transformations between transformations), the enriched perspective remains compatible with refinement rather than needing replacement.

A further pragmatic benefit is that thin enrichment cleanly separates two concerns that are often conflated in informal discussions: (a) the existence *of a pathway from A to B, and (b) the* quality *or* reliability *of that pathway. In a thin V-category the former is encoded by whether $\mathcal{C}(A, B)$ is above a chosen threshold, while the latter is encoded by its precise value; proofs can then be parameterized by the threshold without changing the underlying formal statements.*

Remark 80 (Optional higher-categorical extension)**.** *Nothing in this section requires higher categories. However, some Hyperseed themes (e.g. perspective shifts, equivalence up to reparameterization, and self-reference) are naturally expressed using groupoids and $(\infty, 1)$-categorical equivalence. Where needed later, one may treat "entities" as objects of an $(\infty, 1)$-groupoid and treat observer translations as higher morphisms. The present section provides the 1-categorical "spine" on which that extension can be built.*

Even in the presence of higher structure, thin enrichment remains useful as a decategorified "shadow": one can map a higher groupoid of transformations to a V-valued accessibility relation by assigning to each pair (A, B) an aggregate strength of all higher paths from A to B (e.g. a supremum over witnesses, a probability, or a robust similarity score). Thus the enriched spine is not merely a preliminary simplification but also a stable interface between qualitative and quantitative layers.

3.7 Quantale weakness as "failed distinctions"

We now formalize the simplest quantitative proxy for Hyperseed's simplicity/generalization idea: an observer is "simpler" (or more general) when it collapses more distinctions [3, 2]. Hyperseed-Concept 202; Hyperseed-Concept 143; Hyperseed-Concept 169.

The key move in this subsection is to represent "what the observer does not (or chooses not to) discriminate" as a relation on X, and then to aggregate the "importance" of the collapsed pairs using the ambient quantale structure. This keeps the formal core small while still allowing different downstream readings (perceptual limitations, abstraction, compression, or deliberate coarse-graining).

Definition 15 (Salience/importance weights)**.** *Let X be a set and let $\mu : X \to V$ be a weight map. Intuitively, $\mu(x)$ encodes how much the observer cares about distinguishing x (or how much "mass" x has for aggregation).*

Remark 81 (Intuition and examples for μ)**.** *The weight map μ is a formal admission that not all entities matter equally. Two observers may agree on which pairs are indistinct yet differ on the consequences because one treats certain entities as salient and others as negligible. This aligns with Hyperseed's emphasis on attention and salience (Hyperseed-Concept 60).*

Example 1: In a perception task, $\mu(x)$ might reflect how often x occurs or how costly it is to misclassify it. Example 2: In an internal cognitive model, $\mu(x)$ might encode how emotionally charged or goal-relevant an item is, which will later connect to values and emotion (Hyperseed-Concept **??***; Hyperseed-Concept* **??***). The usefulness is that weakness and pattern measures become sensitive not only to* how many *distinctions are lost, but to* which *ones.*

Operationally, μ is the hook by which context enters the otherwise combinatorial object $H \subseteq X \times X$: changing attention, goals, or risk tolerance can be modeled simply by changing μ, without changing X itself. In particular, assigning $\mu(x) = \bot$ (or the least element of V) can be read as declaring x negligible for the present analysis, since such elements will not contribute to weakness after multiplication by $\otimes$ and aggregation by $\bigoplus$.

Definition 16 (Crisp failed-distinction set)**.** *A* failed-distinction set *is a subset $H \subseteq X \times X$ whose elements are the pairs an observer treats as indistinguishable (in a given context and for a given purpose).*

Remark 82 (Intuition: a formal shadow of "cannot tell apart")**.** *A failed-distinction set H records where the observer's discriminative power collapses: $(u, v) \in H$ means that, for the relevant purpose, u and v are treated as the same. If one were modeling classical equivalence, one might demand reflexivity, symmetry, and transitivity. Here we do* not *impose those axioms: in cognitive reality, indistinction can be asymmetric or context-fragmented, and transitivity can fail under noise or shifting attention (Hyperseed-Concept* **??***; Hyperseed-Concept 195).*

Example: If X consists of similar visual stimuli, H may contain (u, v) when the system confuses u for v. The usefulness of keeping H separate from a fully axiomatized equivalence relation is that it allows us to measure weakness and then later study what closure operations (e.g. compositional propagation) do to H as a form of emergence (Hyperseed-Concept **??***).*

Note also that H is allowed to include or exclude diagonal pairs (u, u). If $(u, u) \in H$ is permitted, it can be interpreted as "self-collapse" in the sense that the observer does not maintain a stable distinction of u from itself across time or internal state (e.g. due to temporal aliasing); if it is excluded, then weakness is driven purely by cross-entity confusions. The formalism itself does not force either convention; one can choose the modeling stance appropriate to the domain.

Definition 17 (Weakness of a failed-distinction set)**.** *Given (X, μ) and $H \subseteq X \times X$, define the* weakness *of H by*

$$w(H) := \bigoplus_{(u,v)\in H} \mu(u) \otimes \mu(v).$$

Remark 83 (Notation unpacking, intuition, and a tiny example)**.** *The symbol $\bigoplus$ denotes the join/supremum in the quantale V (in the canonical* p-bit *quantale, this is componentwise* max*). The product $\otimes$ is the quantale monoidal product (in the canonical case, componentwise multiplication). Thus each indistinct pair contributes a combined weight $\mu(u) \otimes \mu(v)$, and $w(H)$ aggregates all such contributions.*

Example (canonical p-bit *quantale): if $\mu(u) = (0.9, 0.9)$ and $\mu(v) = (0.5, 0.5)$ then $\mu(u) \otimes \mu(v) = (0.45, 0.45)$. If H contains several pairs, then $w(H)$ keeps the maximum positive component and maximum negative component among the pair-weights. This is a minimal but robust way to say: "weakness is at least as large as the most significant collapsed distinction." The definition is useful because it creates a monotone scalar-like measure (in V) that can be compared across observers/contexts and will later interface with pattern intensity and effort tradeoffs [3].*

A useful basic property, immediate from the definition and the order structure of V, is monotonicity in H: if $H \subseteq H'$ then every join-summand for H is also present for H', hence $w(H) \leq w(H')$. In words, declaring additional pairs as indistinct cannot reduce weakness. Likewise, if $\mu \leq \mu'$ pointwise (meaning $\mu(x) \leq \mu'(x)$ for all x), then $w_{\mu}(H) \leq w_{\mu'}(H)$, expressing that increasing salience can only increase (or preserve) measured weakness.

When V has a top element $\top$ and $\otimes$ is order-preserving, one can also read $w(H) \leq \bigoplus_{(u,v)\in H} \top = \top$ as a trivial upper bound, and $w(\varnothing) = \bot$ as the base case: an observer that collapses no tracked distinctions (in the current context) has minimal weakness.

Remark 84 (Fuzzy failed distinctions)**.** *One can generalize H from a crisp set to a V-valued relation $H : X \times X \to V$ and define*

$$w(H) := \bigoplus_{(u,v)\in X\times X} H(u, v) \otimes \mu(u) \otimes \mu(v),$$

which reduces to Definition 17 when H is $\{e, \bot\}$-valued. The crisp form is sufficient for the sanity theorem in Section 4 and for minimal exposition.

In this fuzzy reading, $H(u, v)$ can be interpreted as a graded degree of indistinguishability or confusion: $\bot$ means "fully distinguished" and larger values mean "more collapsed." The algebraic form then says that weakness is obtained by combining (via $\otimes$) three factors: how much the observer fails to distinguish the pair, and how salient each endpoint is. The crisp case corresponds to the indicator-like choice

$$H(u, v) = \begin{cases} e & (u, v) \in H, \\ \bot & (u, v) \notin H, \end{cases}$$

so that only the designated indistinct pairs contribute to the join.

Remark 85 (Why weakness formalizes "simplicity" rather than merely "error")**.** *It is tempting to read H as a set of mistakes, but in Hyperseed the collapse of distinctions is not always a failure; it is often a strategy of generalization. A system with limited resources may deliberately treat many cases as "the same" to gain compression and transfer. The weakness functional captures this tradeoff by measuring the extent of such collapse, without presuming it is bad. In later sections, effort and description-length considerations will supply the missing normative layer, connecting to algorithmic compression intuitions [16].*

This is also why the definition is phrased purely in terms of indistinction and salience, rather than in terms of an externally provided "ground truth": the same H may be advantageous or disastrous depending on which downstream tasks are prioritized (encoded, here, primarily through μ and later through explicit utility/effort structure).

Interpretive link to Hyperseed simplicity. Hyperseed treats simplicity as observer-relative and grounded in the distinctions an observer can afford to make. The weakness $w(H)$ is a direct algebraic instantiation: larger failed-distinction sets (or heavier collapsed pairs) produce larger weakness. Later, effort and description length will provide additional structure on top of this.

Because $w(H)$ lives in the same quantale V used elsewhere in the minimal formal core, it can be compared, combined, or bounded using the same operations as other quantities (e.g. pattern intensities). This is one reason to prefer a quantale-valued measure rather than a single real number: the ordering and aggregation structure needed for later composition is already present at the type level.

3.8 Interpretation map: from Hyperseed talk to core objects

The formal core is intended to be a "dictionary" rather than a full metaphysics [1]. In particular, the role of the mapping below is to make each piece of Hyperseed vocabulary point to a *typed* mathematical placeholder with a clear domain of definition (e.g. elements, relations, functionals) and with explicit rules for how it composes with the rest of the framework. This helps keep later constructions invariant under changes of philosophical reading: one may reinterpret the words, but the algebra of the surrogates stays fixed. A convenient minimal mapping is:

- **Entity / occasion token** $\rightsquigarrow$ element $x \in X_C$ in a context C. Hyperseed-Concept 124. Here X_C is not assumed to be a set of mind-independent "things"; it is simply the carrier of whatever items are *available to be related* inside the chosen standpoint C, so its intended meaning is operational rather than metaphysical.

- **Context / aspect / observer** $\rightsquigarrow$ package C with X_C and V-relations and valuations. Hyperseed-Concept 86. Concretely, C functions as the minimal bookkeeping device that fixes (i) what counts as an admissible token, (ii) what graded comparisons or constraints between tokens can be stated, and (iii) which valuation scheme interprets those graded statements in the chosen evidence structure V.

- **Distinction / indistinction** $\rightsquigarrow$ a designated V-relation $R_C : X_C \times X_C \to V$ (read as evidence-for/evidence-against "same for purpose P"), plus thresholded crisp projections if needed. Hyperseed-Concept 98; Hyperseed-Concept **??**. The point is that "distinguishability" is represented as *graded* rather than all-or-nothing: $R_C(x, y)$ records how strongly C supports treating x and y as the same (or as different, depending on the chosen polarity) relative to a purpose parameter P that may be implicit in C's choice of relation. When later arguments require a classical equivalence relation, one can recover it by selecting a threshold in V and projecting R_C to a crisp predicate, thereby making explicit exactly where discretization enters.

- **Simplicity / generalization** $\rightsquigarrow$ weakness $w(H)$ of an induced failed-distinction relation H. Hyperseed-Concept 169; Hyperseed-Concept 202; Hyperseed-Concept 143. Intuitively, H summarizes where a proposed distinction does *not* hold (or holds only weakly), and the functional $w(H)$ turns that summary into a scalar-like comparison value inside the ambient order of V (or an associated preorder). Reading "simplicity" as "ability to ignore differences without breaking too much," greater weakness corresponds to more aggressive generalization: the formalism makes that tradeoff measurable so that later optimization principles can compare different candidate abstractions.

- **Approximate morphism / correspondence** $\rightsquigarrow$ a V-relation (module) or V-functor between enriched structures. Hyperseed-Concept 112. This treats "correspondence" as something that may be many-to-many and degree-valued rather than a strict function: a module captures soft matching between carriers, while a V-functor captures structure preservation at the enriched level (so that similarity, entailment, or reachability relations are transported coherently). The choice between them is therefore not merely technical: it encodes whether the intended alignment is functional, relational, or compositional.

- **Pattern support** $\rightsquigarrow$ a constraint family on V-relations (or a subobject in an enriched category), ranked by weakness/intensity (developed later). Hyperseed-Concept 130; Hyperseed-Concept 132. In this dictionary, a "pattern" is not a primitive shape but a *condition* that admissible relations (or admissible objects) satisfy; support is then the degree to which the condition is met under the valuation scheme. The weakness/intensity ranking is included so that "pattern is present" becomes a comparative statement (which patterns are stronger, more stable, or more informative) rather than a binary label.

- **Resonance / coupling** $\rightsquigarrow$ a functional of paraconsistent valuations (Section 3.9) used to modulate cross-context propagation operators. Hyperseed-Concept 159; Hyperseed-Concept 115. The intent is that resonance is not itself another relation on X_C, but a higher-level aggregator acting on valuations (which may contain inconsistent or incomplete evidence) and returning a control parameter that gates how strongly information, constraints, or alignments are allowed to flow between contexts. Framed this way, "coupling" becomes something that can be tuned, composed, and compared, rather than a purely qualitative metaphor.

Remark 86 (Why a dictionary is philosophically honest)**.** *Hyperseed's ambition is ontological, but a mathematical reconstruction can remain neutral about ultimate metaphysics while still being precise about* inference rules *and* composition laws. *The dictionary approach acknowledges, in a Whiteheadian spirit [15], that much of what we call "reality" in practice is a stabilized network of relations and transformations between standpoints. What matters for theoremhood is not whether a term is metaphysically primitive, but whether its formal surrogate behaves coherently under the operations the theory demands.*

This mapping is also a safeguard: when later sections speak in richer language (pattern, habit, resonance, mindplex), we can always ask, "what is the corresponding object here, and what operations does it support?" The core thus acts as a semantic spine that keeps the later conceptual elaborations from drifting into purely metaphorical territory.

A further virtue is methodological: disagreements about interpretation can be localized. If two readings of "context" lead to the same algebraic interface (carriers, V-relations, valuations, and their induced operators), then the subsequent theorems apply to both; if they lead to different interfaces, the point of divergence is made explicit and can be analyzed as a change of axioms rather than as a purely verbal dispute.

This dictionary will be refined repeatedly in the systematic reconstruction part of the paper (Part II). In particular, later sections will add explicit assumptions on V (e.g. whether it is a quantale, bilattice, or other ordered algebra), clarify how valuations interact with composition of V-relations, and specify which additional structure on contexts is required to make cross-context propagation and comparison theorems well-posed.

3.9 Resonance derived from paraconsistency

Hyperseed uses "resonance" as a primitive-seeming word for coherent coupling. Hyperseed-Concept 159. To make it mathematically explicit while keeping the paraconsistent structure visible, we embed p-bit values into the complex plane [24]. This also sets the stage for later discussion of morphic resonance (Hyperseed-Concept 115) and related speculative inspirations [13].

Definition 18 (Logic-to-complex map)**.** *Define* $\sigma_C : \mathbb{V} \to \mathbb{C}$ *by*

$$\sigma_C(v^+, v^-) := (v^+ - v^-) \ + \ i\big((v^+ + v^-) - 1\big).$$

Remark 87 (Notation unpacking and intuition)**.** *Here* $\mathbb{C}$ *is the complex plane, and* i *is the imaginary unit. The map* σ_C *takes an evidence-pair* (v^+, v^-) *and produces a complex number whose real part is the evidence bias* $v^+ - v^-$ *and whose imaginary part is the total evidence* $(v^+ + v^-)$ *recentered so that* $v^+ + v^- = 1$ *maps to imaginary part* 0*.*

Intuitively, this is a way of turning paraconsistent structure into a phase-like *object: different kinds of certainty and conflict point in different directions. Once evidence lives in* $\mathbb{C}$*, we can use the geometry of angles and inner products to speak of alignment, opposition, and interference—concepts that mirror the phenomenology of resonance more closely than scalar similarities do.*

Remark 88 (Geometric meaning)**.** *The real part is the bias toward positive vs negative evidence. The imaginary part measures over- vs under-determination relative to the midpoint* $v^+ + v^- = 1$*:*

- $(1, 0) \mapsto 1 + 0i$ *("true" axis),*
- $(0, 1) \mapsto -1 + 0i$ *("false" axis),*
- $(1, 1) \mapsto 0 + 1i$ *("both" axis),*
- $(0, 0) \mapsto 0 - 1i$ *("neither" axis).*

Thus the four Belnap corners become the four cardinal directions in $\mathbb{C}$*.*

Remark 89 (Two simple examples and why complex geometry helps)**.** *Example 1:* $(0.9, 0.1)$ *maps to* $0.8 + i(0.0)$*, strongly positive and determinate. Example 2:* $(0.9, 0.9)$ *maps to* $0 + i(0.8)$*, indicating maximal conflict without bias. In the plane, these points are orthogonal directions: a bias-driven certainty is geometrically distinct from a conflict-driven certainty.*

This matters because many cognitive couplings are sensitive to kind *of certainty, not just amount. Two contexts can both be "highly committed" while one is committed via consensus and the other via internal contradiction; the embedding keeps these apart so that resonance can distinguish alignment from mere magnitude.*

Definition 19 (Local resonance kernel)**.** *For* $v, w \in \mathbb{V}$ *with* $\sigma_C(v) \neq 0$ *and* $\sigma_C(w) \neq 0$*, define the normalized alignment*

$$\mathrm{align}(v, w) := \frac{\Re\big(\sigma_C(v)\overline{\sigma_C(w)}\big)}{|\sigma_C(v)|\,|\sigma_C(w)|} \in [-1, 1].$$

If either $\sigma_C(v) = 0$ *or* $\sigma_C(w) = 0$*, set* $\mathrm{align}(v, w) := 0$*.*

Remark 90 (Notation unpacking: $\Re$, $\overline{(\cdot)}$, and $|\cdot|$)**.** *The symbol* $\Re(\cdot)$ *denotes the real part of a complex number. The bar* $\overline{z}$ *denotes complex conjugation, which reflects* z *across the real axis. The absolute value* $|z|$ *denotes the complex modulus (Euclidean norm). Thus* $\Re(\sigma_C(v)\overline{\sigma_C(w)})$ *is the* *standard real inner product on* $\mathbb{R}^2$ *written in complex notation, and the denominator normalizes by lengths to yield a cosine similarity.*

So $\mathrm{align}(v,w)$ *is literally the cosine of the angle between the two embedded evidence vectors. In geometric language: resonance is alignment of directions; anti-resonance is pointing in opposite directions; orthogonality is non-coupling.*

Remark 91 (Reading align)**.** $\mathrm{align}(v,w) = 1$ *indicates perfect alignment in the complex embedding (maximal "resonance"),* $\mathrm{align}(v,w) = -1$ *indicates perfect opposition (maximal "anti-resonance"), and values near* 0 *indicate weak coupling or orthogonality (e.g. true vs both).*

Remark 92 (Why define alignment locally before aggregating)**.** *Resonance in practice is rarely a single comparison; it is an emergent property of many coupled judgments across a network (Hyperseed-Concept 131; Hyperseed-Concept 132). The local kernel* $\mathrm{align}(v,w)$ *gives the primitive comparison from which larger interference measures can be built. By keeping the primitive symmetric and normalized, we avoid arbitrary scale artifacts when later summing many terms.*

In the paraconsistent resonance perspective [24], such kernels are the atoms of a broader interference calculus: coherent coupling corresponds to constructive interference of many phase-like contributions.

Many resonance phenomena involve aggregation over many coupled evaluations. The following interference functional is one simple way to obtain a scalar coupling score that increases under coherent alignment.

Definition 20 (Interference-based resonance for a family)**.** *Let* $z_1, \dots, z_n \in \mathbb{C}^d$ *and weights* $\alpha_1, \dots, \alpha_n \in \mathbb{R}_{\geq 0}$*. Define*

$$z_{\mathrm{tot}} := \sum_{k=1}^{n} \alpha_k z_k, \qquad I := \|z_{\mathrm{tot}}\|^2 - \sum_{k=1}^{n} \|\alpha_k z_k\|^2.$$

A bounded resonance score may be obtained by normalizing I *(e.g. by* $\sum_k \|\alpha_k z_k\|^2$ *when nonzero) and applying any monotone squashing map into* $[0,1]$.

Remark 93 (Intuition: constructive vs. destructive interference)**.** *The quantity* $\|z_{\mathrm{tot}}\|^2$ *measures the squared magnitude of the vector sum, while* $\sum_k \|\alpha_k z_k\|^2$ *measures the sum of squared magnitudes if there were no cross-terms. Their difference* I *is exactly the contribution of pairwise cross-terms: it is positive when vectors tend to align (constructive interference) and negative when they tend to cancel (destructive interference).*

More explicitly (for the usual inner product on $\mathbb{C}^d$*), expanding the square gives*

$$\left\|\sum_k \alpha_k z_k\right\|^2 = \sum_k \|\alpha_k z_k\|^2 \; + \; \sum_{i \neq j} \Re\big(\langle \alpha_i z_i, \alpha_j z_j \rangle\big),$$

so I *aggregates the (real parts of the) pairwise alignments* $\langle z_i, z_j \rangle$ *after scaling by* α_i, α_j*. In particular,* I *is sensitive not just to magnitudes but to relative directions/phases, which is exactly what one wants from a numerical proxy for "resonance" versus "anti-resonance."*

Example (scalar case $d = 1$*): if* $z_1 = z_2 = 1$ *and* $\alpha_1 = \alpha_2 = 1$*, then* $z_{\mathrm{tot}} = 2$ *so* $I = 4 - (1+1) = 2 > 0$*. If* $z_1 = 1$ *and* $z_2 = -1$*, then* $z_{\mathrm{tot}} = 0$ *so* $I = 0 - (1+1) = -2 < 0$*. This makes* I *a natural numerical surrogate for resonance/anti-resonance at the aggregate level.*

In intermediate situations I *can be close to* 0 *even when individual terms are strong, meaning that the aggregate is "balanced" by competing contributions; this is the quantitative sense in which interference captures the difference between mere presence of strong components and their ability to jointly amplify a shared direction.*

Remark 94 (Why we allow $z_k \in \mathbb{C}^d$)**.** *The extra dimension d allows us to embed multiple aspects of evaluation simultaneously—for example, multiple propositions, multiple relational edges, or multiple features of a pattern. This is a small but important generalization: resonance in rich systems is seldom one-dimensional. The formalism here is kept minimal, but it anticipates later constructions where patterns and contexts are multi-aspect objects (Hyperseed-Concept 86; Hyperseed-Concept 79).*

Allowing $\mathbb{C}$ (rather than restricting to $\mathbb{R}$) is useful even if one ultimately interprets relation-strengths as real-valued: complex phases provide a compact way to encode contextual "orientation" or timing/ordering effects, so that two strong components can either reinforce (similar phase) or suppress (opposite phase) without changing their magnitudes. In particular, the same magnitude data $\|z_k\|$ can yield different aggregate behavior depending on relative phases, which mirrors the idea that the same local evidence can support different global outcomes depending on context alignment.

Resonance as a driver of propagation. To connect resonance to later morphic-resonance dynamics, we introduce the abstract form of a resonance-driven update rule.

The point of isolating an abstract operator at this stage is that it factors "what is being propagated" (the V-relation) from "how propagation composes" (the quantale algebra), so later sections can swap in different concrete semantics for V without changing the propagation skeleton.

Definition 21 (Resonance-driven propagation operator (abstract form))**.** *Let $R_1, R_2 : X \times X \to V$ be V-relations in two contexts (or two subsystems). Let $K \in V$ be a coupling strength. Define*

$$\mathsf{Res}_K(R_1 \to R_2)(x,y) := R_2(x,y) \;\oplus\; \big(K \otimes R_1(x,y)\big).$$

Remark 95 (Intuition and a minimal example of an update)**.** *This update says: the new relation-value in context 2 is the old value, plus (in the quantale join sense) a contribution from context 1 scaled by coupling strength K. In the canonical* p-bit *quantale, $\oplus$ is componentwise* max*, so this means the update can only increase evidence components: resonance propagation accumulates rather than overwrites.*

Conceptually, K plays the role of a gain or transmissibility parameter: when K is low, even strong structure in R_1 has limited influence on R_2; when K is high, R_2 rapidly inherits (in the join sense) the strongest components present in R_1. Because the update is pointwise in (x,y), this is the minimal "local" propagation law; later dynamics can make K depend on (x,y) or on higher-order pattern statistics.

Example: if $R_2(x,y) = (0.2, 0.1)$, $K = (0.5, 0.5)$, and $R_1(x,y) = (0.9, 0.8)$, then

$$K \otimes R_1(x,y) = (0.45, 0.4),$$

so $\mathsf{Res}_K(R_1 \to R_2)(x,y) = (\max(0.2, 0.45), \max(0.1, 0.4)) = (0.45, 0.4)$*. This captures the intuition that strongly resonant structure in one context can "pull" another context toward similar evaluations, without requiring them to become consistent or to erase prior opposition (Hyperseed-Concept 159; Hyperseed-Concept 86).*

Note also that the form $R_2 \oplus (\cdots)$ makes the prior state of context 2 explicit: propagation is not a replacement map $R_2 \mapsto K \otimes R_1$, but a cumulative enrichment map. This is the algebraic analogue of treating contexts as memory-bearing substrates rather than as ephemeral registers.

Remark 96 (Why this is the right minimal form)**.** *The operator* Res_K *is:*

- *monotone in R_1, R_2, and K;*
- *explicitly paraconsistent: it can increase positive evidence without erasing negative evidence (and vice versa);*

- *compositional: repeated application composes via the quantale product.*

Section 5 instantiates this operator numerically and shows how it reaches a "morphic resonance" style update.

The compositionality point can be read operationally as a semigroup law for propagation strength: applying Res_{K_1} *and then* Res_{K_2} *yields an effect equivalent to a single step whose effective contribution from* R_1 *is scaled by a combination of* K_1 *and* K_2 *as dictated by* $\otimes$ *and* $\oplus$ *(with the precise normal form depending on distributivity properties available in the chosen* V*). This is one reason to phrase the update at the quantale level: the algebra already knows how to combine influences.*

Remark 97 (Why monotonicity is a feature, not a limitation)**.** *One might object that real learning sometimes decreases beliefs. That is correct; but the monotone operator here is intentionally the minimal* propagation *primitive. Decrease and revision will later enter via additional dynamics: decay, inhibition, competition between patterns, and anti-resonance mechanisms. In other words, we first isolate a clean "transmission" law and then layer conflict-resolution and forgetting on top, which is closer to how dynamical systems are often built in cognitive modeling [19].*

Technically, monotonicity is also what makes iterated updates well-behaved: one can form increasing chains $R_2 \preceq \mathsf{Res}_K(R_1 \to R_2) \preceq \mathsf{Res}_K(R_1 \to \mathsf{Res}_K(R_1 \to R_2)) \preceq \cdots$ *and then study their convergence or fixed points using standard order-theoretic tools when* V *supports them. This is helpful later when "habit" is modeled as a stabilized relation-value under repeated exposure.*

Definition 22 (Anti-resonance propagation (minimal choice))**.** *Define the anti-resonance operator by propagating negated evidence:*

$$\mathsf{AntiRes}_K(R_1 \to R_2)(x,y) := R_2(x,y) \ \oplus \ \big(K \otimes (\neg R_1(x,y))\big).$$

Remark 98 (Intuition: transmitting the contrary and modeling habit reversal)**.** *Anti-resonance propagation uses the same algebra as resonance but flips the incoming evidence via* $\neg$*. If* $R_1(x,y)$ *strongly supports a match, then* $\neg R_1(x,y)$ *strongly supports a mismatch, and vice versa. The resulting update tends to induce opposition or reversal in the target relation-values.*

Because $\neg$ *is applied before the same* $\otimes$*-scaling and* $\oplus$*-accumulation, this operator is not a different propagation mechanism but a different* polarity *of what is being transmitted. In paraconsistent settings (such as* $\mathsf{p\text{-}bit}$*), this is crucial: transmitting the contrary does not require removing the original support already present in* R_2*, so the target context can legitimately accumulate mixed evidence and thereby represent tension, ambiguity, or internal conflict rather than being forced into a prematurely consistent state.*

This gives a minimal formal hook for Hyperseed's idea that some couplings do not reinforce but rather destabilize or invert habits (Hyperseed-Concept 188; Hyperseed-Concept 114). The operator is intentionally simple; later sections can refine it by making K *depend on interference scores, context similarity, or resource constraints.*

In particular, one can anticipate variants where K *is large precisely when the interference indicator* I *is strongly negative (net cancellation), so that anti-resonant channels become more active when signals are out of phase; the present definition isolates the algebraic core needed for such couplings without committing to a specific functional dependence.*

Remark 99 (Toward "morphic" resonance)**.** *In Hyperseed terms, morphic resonance will arise when resonance-driven propagation interacts with (i) repeated exposure over proto-time, (ii) reinforcement/decay (habit-taking and habit-reversal operators), and (iii) a pattern web structure that makes some relation-values self-supporting. Those dynamical ingredients are added in Sections 5 and 12.*

From the perspective of the present minimal core, the key transition to "morphic" behavior is the emergence of feedback loops: once propagated relation-values in one context begin to act as sources for further propagation (possibly back into the original context, or into overlapping subcontexts), the system can amplify particular relational regularities and thereby exhibit the characteristic persistence associated with habits. The same feedback architecture can also sustain stable paraconsistent states (simultaneous support and opposition), which is one reason the update primitives above are designed to be compatible with non-classical evidence aggregation from the outset.

4 Core sanity theorems

Outline

- Prove monotonicity properties that justify interpreting $w(H)$ as "weakness."
- Prove basic boundedness/consistency properties for pattern intensity and resonance.
- State minimal categorical coherence properties needed later (functoriality, enrichment laws).

Summary and Hyperseed concepts covered

These theorems are intentionally simple. They exist to ensure that the chosen core definitions behave in the expected direction: more collapsed distinctions means greater weakness, and resonance behaves monotonically under coherent aggregation.

Hyperseed concepts covered.

- Distinction; equivalence; simplicity/weakness; pattern intensity (as a later derived quantity). (Hyperseed-Concepts 98, **??**, 169, 202, 143.)
- Resonance/dissonance (as interference monotonicity). (Hyperseed-Concepts 159, 97.)

Standing notation. Fix a commutative quantale $(V, \leq, \oplus, \otimes, e)$ and a set of entities X. Let $\mu : X \to V$ be an object-valuation. For a relation $H \subseteq X \times X$ interpreted as the set of *undistinguished pairs*, recall the (quantale) weakness functional

$$w(H) \;=\; \bigoplus_{(u,v)\in H} \mu(u) \otimes \mu(v).$$

(Here $\oplus$ is the quantale join/supremum.)

Remark 100. *A brief decoding of the symbols may help fix the intended reading. A* commutative quantale *is, in particular, a complete lattice $(V, \leq)$ equipped with a commutative, associative "multiplication" $\otimes$ with unit e, such that $\otimes$ distributes over arbitrary joins $\oplus$. Thus $\oplus$ should be read as a supremum (a generalized "maximum"), while $\otimes$ is the operation used to aggregate two pieces of graded evidence or intensity. This is precisely the algebraic setting in which one can speak coherently about combining local contributions and then taking their overall "best possible" aggregate; it is also the basic technical vehicle for quantale-style weakness in the sense of [3] (see Hyperseed-Concept 143).*

The set X is the local universe of entities (occasion-tokens, perceived items, or internal states), and $\mu : X \to V$ assigns each entity a weight/importance in the evidence domain V. The relation

$H \subseteq X \times X$ collects pairs that an observer/context fails to distinguish (Hyperseed-Concept 98). Then $w(H)$ takes every undistinguished pair (u, v), scores it by the combined weight $\mu(u) \otimes \mu(v)$, and aggregates all these scores via the join $\oplus$. Philosophically, this is a very Russellian move: one takes an apparently qualitative notion ("weakness" as failure-to-separate) and pins it to a monotone functional that can be reasoned about with lattice algebra, while leaving ample room for the phenomenological interpretation (Hyperseed-Concepts 202, 169).

It is also worth noting what information is, and is not, being retained. The functional $w(H)$ depends only on the set *of undistinguished pairs, not on any additional structure (e.g. transitivity, symmetry, or a metric-like notion of "how hard" a pair is to distinguish). Later sections may impose additional axioms on H (for instance, taking H to be an equivalence relation, or the kernel of an observation map), but the present sanity checks deliberately avoid such commitments: they isolate the order-theoretic behavior that should hold for* any *coarsening of distinctions.*

Finally, the commutativity of $\otimes$ ensures that $\mu(u) \otimes \mu(v)$ does not depend on the ordering of the pair. This matches the intended semantics when H is thought of as an undirected indistinction; if one later studies directed or asymmetric indistinction (e.g. attentionally one-way confusions), then one can still use the same formula, but should be explicit about whether H is closed under swapping coordinates.

Theorem 1 (Weakness is monotone under adding undistinguished pairs)**.** *Let $H, K \subseteq X \times X$ with $H \subseteq K$. Then $w(H) \leq w(K)$.*

Remark 101. *Intuitively, this theorem says: if you collapse* more *distinctions (i.e. you declare more pairs to be "undistinguished"), then you cannot become* less *weak. This is exactly the direction one expects if weakness is meant to proxy simplicity-as-coarsening: a coarser partition of experience (more identifications, fewer discriminations) carries less articulated structure, hence represents a stronger "failure to distinguish" (Hyperseed-Concepts 98, 202; see also [2, 3] for related motivations).*

This monotonicity is also a sanity check for later constructions. When patterns are modeled as constraints that reduce the space of distinctions in a controlled way (Hyperseed-Concepts 130, **??***), we will repeatedly compare "baseline" and "pattern-induced" indistinction relations. The present theorem guarantees that these comparisons can be made in the order-theoretic language of V without logical surprises.*

One can also read the result contrapositively: if some intervention (a new measurement, a refined conceptual scheme, an additional sensor) strictly decreases the computed weakness value, then it must have eliminated *at least one undistinguished pair of nontrivial weight. Thus w behaves like a coarse "certificate" that refinement has occurred, even when one does not track which distinctions were recovered.*

Proof. Since $H \subseteq K$, every term $\mu(u) \otimes \mu(v)$ included in the join for $w(H)$ also appears in the join for $w(K)$. Because $\oplus$ is a join (supremum) and hence monotone in each argument, adding more terms cannot decrease the result. ☐

Remark 102. Proof sketch. *The strategy is to reduce everything to the elementary fact that a supremum cannot go down when you enlarge the set you take the supremum over. Here the set being "enlarged" is the collection of pair-scores $\mu(u) \otimes \mu(v)$ indexed by $(u, v) \in H$ versus $(u, v) \in K$.*

Spelled out in lattice-theoretic terms, define two indexed families in V:

$$A = \{\mu(u) \otimes \mu(v) \mid (u, v) \in H\}, \qquad B = \{\mu(u) \otimes \mu(v) \mid (u, v) \in K\}.$$

Then $H \subseteq K$ implies $A \subseteq B$, and $w(H) = \bigoplus A$, $w(K) = \bigoplus B$. Since $\bigoplus$ is the least upper bound, $\bigoplus A \leq \bigoplus B$ follows from $A \subseteq B$ alone, with no need for any further algebraic properties of $\otimes$

beyond well-typedness. In particular, commutativity of $\otimes$ is conceptually natural but not used by this specific monotonicity argument.

This is one reason quantales are a convenient ambient structure: they provide (i) enough completeness so that arbitrary joins exist, and (ii) an order in which "more evidence aggregated" is reflected as "larger value." Even in the degenerate case $H = \varnothing$, the same reasoning applies: $\bigoplus_{(u,v)\in\varnothing}(\cdots)$ is the join of the empty subset of V, hence equals the bottom element of the lattice (often denoted $\perp$), so monotonicity includes the base case $\perp = w(\varnothing) \leq w(K)$ for all K.

A useful mental model is the Boolean quantale $V = \{0,1\}$ with $\oplus = \vee$ and $\otimes = \wedge$. If $\mu(x) = 1$ for all x, then $w(H) = 1$ iff H is nonempty, and the theorem becomes the trivial statement that if $H \subseteq K$ and H is nonempty then K is nonempty. More informative is the fuzzy/probabilistic-like setting $V = [0,1]$ with $\oplus = \max$ and (for instance) $\otimes = \cdot$; then $w(H)$ returns the maximum pairwise combined salience among the undistinguished pairs, so adding more undistinguished pairs can only maintain or increase that maximum.

In later applications, one often considers $K = H \cup H'$ where H' is the new set of collapsed distinctions introduced by an additional pattern or aggregation step. The theorem then reads $w(H) \leq w(H \cup H')$, making explicit that pattern-driven coarsening can be tracked purely by order comparison in V.

Proposition 1 (Weakness is monotone in each argument under unions)**.** *For any $H, K \subseteq X \times X$ one has*

$$w(H) \leq w(H \cup K) \qquad \text{and} \qquad w(K) \leq w(H \cup K).$$

Proof. Both inclusions $H \subseteq H \cup K$ and $K \subseteq H \cup K$ hold, so the claim follows immediately from Theorem 1. □

Remark 103. *This simple corollary is often the operational form of monotonicity: "adding an additional source of indistinction" is mathematically modeled by taking a union of relations. In contexts where multiple pattern constraints contribute independently to collapse of distinctions, the inequality above ensures that combining constraints by union can only increase (or leave unchanged) the overall weakness score.*

If one later introduces a directed *family of relations $(H_i)_{i\in I}$ with $H_i \subseteq H_j$ for $i \leq j$ (successive coarsenings), then repeated application yields a chain*

$$w(H_i) \leq w(H_j) \quad (i \leq j),$$

so the weakness values themselves form an increasing net in the complete lattice V. This observation is frequently used implicitly when taking limits of refinement/coarsening procedures, or when

The key step is not computational but conceptual: interpreting $w(H)$ literally as a join over a family makes monotonicity immediate. In particular, if $w(H) = \bigvee\{\,\phi(e) \mid e \in H\,\}$ for some assignment ϕ into V, then enlarging H simply enlarges the index set of the join, and completeness of the lattice ensures that taking the join over a larger family cannot decrease the value. One may visualize H as a set of edges in a graph on X (edges mark "undistinguished" pairs). Adding edges increases the pool of candidate weights, and a join/supremum can only stay the same or increase. Equivalently, $H \subseteq H'$ implies every upper bound of $\{\phi(e) \mid e \in H'\}$ is also an upper bound of $\{\phi(e) \mid e \in H\}$, so the least such upper bound (the supremum) satisfies $w(H) \leq w(H')$. This is exactly the sense in which "monotonicity is baked into the definition": no further algebraic identities are required beyond the order-theoretic behavior of joins.

Definition 23 (One possible pattern-intensity functional (placeholder))**.** ***[TODO: Replace with the final definition used in the paper.]*** *A* pattern intensity *functional is a map* $\mathrm{Int} : \mathcal{P} \to V$

from a space of candidate patterns $\mathcal{P}$ to the quantale V that increases when a pattern yields a more compressive (weaker/simpler) description of data relative to a baseline. Concretely, the intended reading is that V plays the role of a graded evidence/score domain: larger elements represent "more intensity" (however that is instantiated later), and the order $\leq$ is the sole structure used to compare intensities across patterns. The definition does not require $\mathcal{P}$ to carry additional structure (such as a lattice order), but later uses typically equip $\mathcal{P}$ with a refinement preorder so that monotonicity statements become meaningful.

Remark 104. *This definition is deliberately schematic: it identifies what a pattern-intensity* must do *(be a graded score in V) without committing to a single formula. Intuitively, $\mathcal{P}$ is the space of "possible regularities" one might impose on data (Hyperseed-Concept 130), and $\mathrm{Int}(P)$ measures how much* structural economy *the pattern P buys you compared to not using it (Hyperseed-Concepts 169, 82). In particular, "baseline" is meant to capture whatever reference situation corresponds to "no pattern" (or a default pattern family), so that intensity can be interpreted as a relative rather than absolute score. In compression language, one imagines that a stronger pattern allows a shorter description; in the weakness language, one imagines that a stronger pattern organizes indistinction in a way that can be exploited for prediction or representation (cf. the pattern/emergence viewpoint in [5]). The quantale viewpoint is that whatever concrete coding length or predictive advantage is used, it is ultimately funneled into an ordered structure where joins, tensors, and monotone maps preserve the comparisons one cares about.*

A simple toy example (consistent with later sections) is: let P specify that certain pairs in $X \times X$ must be treated as indistinct (or, conversely, must be distinguished), inducing a relation H_P of undistinguished pairs. Then $\mathrm{Int}(P)$ can be a monotone function of $w(H_P)$ relative to some baseline H_{base}. For instance, one may take $F(a,b) = b$ (pure weakness-as-intensity), or $F(a,b) = a \otimes b$ (combining baseline and pattern weakness multiplicatively/tensorially), or $F(a,b) = b \oplus a$ (a join-style aggregation); the theorem below is formulated to cover such choices as long as monotonicity is preserved. The point of keeping the definition abstract here is methodological: the later theory wants theorems that depend only on quantale-algebraic monotonicity, not on the idiosyncrasies of one specific intensity formula. In particular, by avoiding a fixed numeric encoding at this stage, one can later change the enrichment base V (e.g. to Boolean truth values, costs, probabilities, or degrees of evidence) without having to redo the monotonicity proofs from scratch.

Theorem 2 (Pattern intensity is bounded and respects refinement)**.** *Assume the intensity functional* Int *is defined in the form*

$$\mathrm{Int}(P) \;=\; F\big(w(H_{\mathrm{base}}),\, w(H_P)\big)$$

for some map $F : V \times V \to V$ that is monotone in each argument and is constructed using only the quantale operations $\oplus, \otimes$ and the order $\leq$. Then:

1. *(*Boundedness*) $\mathrm{Int}(P)$ lies between the least and greatest elements of V. Equivalently, writing $\perp$ and $\top$ for the bottom and top of the underlying complete lattice, one has $\perp \leq \mathrm{Int}(P) \leq \top$ for every $P \in \mathcal{P}$.*

2. *(*Refinement monotonicity*) If P refines Q in the sense that $H_P \subseteq H_Q$ (i.e. P leaves weakly fewer pairs undistinguished than Q), then $\mathrm{Int}(P) \leq \mathrm{Int}(Q)$. In words: moving to a finer pattern (fewer declared indistinguishabilities) cannot increase the weakness-based ingredient, so any monotone intensity aggregator cannot increase either.*

Remark 105. *In plain language, this theorem is saying two unsurprising but indispensable things. First, the intensity score never "escapes" the universe of discourse: it is always some element of the* *evidence lattice V, hence automatically confined between bottom and top. This is not a deep estimate but a type discipline: once the codomain is V and V is a complete lattice, every term built from V-operations has a well-defined place in the global order. Second, the ordering of patterns by* refinement *is respected by the intensity score: when one pattern P is "sharper" than another Q (it collapses fewer distinctions, i.e. it declares fewer pairs undistinguished), then the corresponding weakness-based ingredient $w(H_P)$ is smaller, and this order propagates through any monotone aggregator F. Note that the subset condition $H_P \subseteq H_Q$ is oriented so that refinement corresponds to* removing *edges from the "undistinguished graph": fewer edges means more distinctions are enforced.*

This connects directly back to Theorem 1: refinement monotonicity is not a new phenomenon but a consequence of the same lattice-theoretic discipline. In later sections, this is what allows one to treat "pattern selection" as a legitimate optimization or comparison problem, rather than as a collection of metaphors (Hyperseed-Concepts 130, **??***, 169; compare [5]). In particular, once refinement induces an order on patterns, one can speak coherently about maximizing intensity, computing Pareto frontiers under multiple scores, or proving existence of optima using completeness properties (when they apply), all without leaving the order-enriched setting.*

Proof. Because V is a complete lattice, it has a least element (bottom) and a greatest element (top). Any expression built from $\oplus$ and $\otimes$ on elements of V evaluates to an element of V, hence is automatically bounded between bottom and top. More explicitly, for any $v \in V$ one has $\perp \leq v \leq \top$ by definition of $\perp$ and $\top$, and therefore the same holds for $v = \mathrm{Int}(P)$ regardless of how F is parenthesized or composed, provided its values lie in V.

For refinement monotonicity: if $H_P \subseteq H_Q$, then by Theorem 1 we have $w(H_P) \leq w(H_Q)$. Monotonicity of F in its second argument (and the fact that $w(H_{\mathrm{base}})$ is fixed across P, Q) yields $\mathrm{Int}(P) \leq \mathrm{Int}(Q)$. If one also varies the baseline across comparisons, then monotonicity in the first argument would be needed as well; the present statement isolates the typical situation where the baseline is held constant and only the pattern-induced relation changes. □

Remark 106. Proof sketch. *The proof separates into two independent observations. Boundedness is immediate once one remembers that V is a complete lattice: there is simply nowhere else for* $\mathrm{Int}(P)$ *to land. Refinement monotonicity is a one-line reduction: $H_P \subseteq H_Q$ implies $w(H_P) \leq w(H_Q)$ by Theorem 1, and monotonicity of F propagates the inequality to* Int. *In many concrete instantiations, F will be built as a composition of monotone primitives (e.g. $F(a, b) = (a \otimes b) \oplus a$), and the statement "constructed using only $\oplus, \otimes$ and $\leq$" is precisely what guarantees monotonicity is preserved under such compositions.*

The key step is the use of structural monotonicity *rather than any specific numeric property. This is a recurring theme of the reconstruction: rather than rely on special arithmetic facts, we aim to work in the generality of order, join, and tensor, so that the same argument can later be transported to other enrichment bases via change-of-quantale results (cf. Proposition 2 below). One can also read this as a robustness claim: as long as the semantics of "combining evidence" is expressed by monotone quantale operations, refinement comparisons of patterns will behave predictably across models.*

Definition 24 (Interference-based resonance and dissonance (sanity model))**.** *Let I be a finite index set and let $a = (a_i)_{i \in I}$ be a finite family of complex-valued contributions $a_i \in \mathbb{C}$. Define the* resonance *and* dissonance *by*

$$\mathrm{Res}(a) \;=\; \left| \sum_{i \in I} a_i \right|, \qquad \mathrm{Dis}(a) \;=\; \sum_{i \in I} |a_i| \;-\; \mathrm{Res}(a).$$

Intuitively, $\mathrm{Res}(a)$ *measures coherent constructive interference, while* $\mathrm{Dis}(a)$ *measures the destructive-interference gap relative to perfect alignment.*

Remark 107. *A few immediate sanity checks are worth keeping in view. Because* $|\sum_i a_i| \le \sum_i |a_i|$ *by the triangle inequality,* $\mathrm{Dis}(a) \ge 0$ *always, so dissonance is a* nonnegative defect term *measuring the strictness of that inequality. At the extremes, if* $|I| = 1$ *then* $\mathrm{Res}(a) = |a_i|$ *and* $\mathrm{Dis}(a) = 0$, *while if* $\sum_i a_i = 0$ *then* $\mathrm{Res}(a) = 0$ *and* $\mathrm{Dis}(a) = \sum_i |a_i|$ *(complete cancellation). Both* Res *and* Dis *are also permutation-invariant in* I *(they depend only on the multiset of contributions), reflecting that the model is agnostic to any ordering of "inputs."*

It is also useful to note the scaling behavior: for any $c \in \mathbb{C}$ *one has*

$$\mathrm{Res}\big((ca_i)_i\big) = |c|\,\mathrm{Res}(a), \qquad \mathrm{Dis}\big((ca_i)_i\big) = |c|\,\mathrm{Dis}(a),$$

so the model separates a global strength factor $|c|$ *from the internal alignment structure of the phases.*

Remark 108. *Here the notation is meant to be read with the ordinary geometry of the complex plane in mind. The family* $a = (a_i)_{i\in I}$ *is a collection of "phasors" (vectors) in* $\mathbb{C}$, $|z|$ *denotes the complex modulus, and* $\sum_{i\in I} a_i$ *is their vector sum. Thus* $\mathrm{Res}(a)$ *is the length of the resultant vector, while* $\sum_i |a_i|$ *is the sum of the lengths. The quantity* $\mathrm{Dis}(a)$ *is exactly the shortfall between these two, i.e. how much cancellation occurs because the* a_i *point in different directions.*

In particular, $\mathrm{Dis}(a)$ *can be viewed as a quantitative proxy for "phase dispersion": holding the magnitudes* $|a_i|$ *fixed, any increase in disagreement among arguments* $\arg(a_i)$ *tends to reduce* $|\sum_i a_i|$ *and thereby increases* $\mathrm{Dis}(a)$*. For two contributions* $a_1, a_2 \neq 0$ *with relative angle* $\varphi = \arg(a_2) - \arg(a_1)$, *one has the explicit formula*

$$\mathrm{Res}(a) = \sqrt{|a_1|^2 + |a_2|^2 + 2|a_1||a_2|\cos\varphi}, \qquad \mathrm{Dis}(a) = |a_1| + |a_2| - \mathrm{Res}(a),$$

so dissonance increases monotonically as $\cos\varphi$ *decreases (i.e. as the vectors rotate away from one another toward opposition).*

This interference model is intentionally modest: it supplies a mathematically sharp proxy for the phenomenological language of resonance/dissonance (Hyperseed-Concepts 159, 97) without yet importing the full paraconsistent-to-complex embedding discussed elsewhere in the document. It is also aligned with the broader theme that "coherence" is a kind of constructive alignment and that "conflict" is measured by cancellation; related developments coupling paraconsistent structure to resonance-style propagation appear in [24].

Theorem 3 (Resonance is invariant under global phase and increases under coherent alignment)**.** *Let* $a = (a_i)_{i\in I}$ *be as in Definition 24.*

1. *(*Uniform phase rotation invariance*) For any real* θ,

$$\mathrm{Res}\big((e^{i\theta}a_i)_{i\in I}\big) \;=\; \mathrm{Res}(a), \qquad \mathrm{Dis}\big((e^{i\theta}a_i)_{i\in I}\big) \;=\; \mathrm{Dis}(a).$$

2. *(*Coherent-alignment monotonicity*) For any real* θ, *define the aligned family* $a^{(\theta)} = (|a_i|e^{i\theta})_{i\in I}$*. Then*

$$\mathrm{Res}(a) \;\le\; \mathrm{Res}\big(a^{(\theta)}\big) \;=\; \sum_{i\in I} |a_i|, \qquad 0 \;\le\; \mathrm{Dis}\big(a^{(\theta)}\big) \;\le\; \mathrm{Dis}(a).$$

   Moreover, $\mathrm{Res}(a) = \sum_i |a_i|$ *iff all nonzero* a_i *share a common phase.*

Remark 109. *A useful way to read the statement is that* Res *depends only on* relative *phases and magnitudes. Part (1) says that there is no distinguished "absolute reference direction" in the complex plane: rotating the entire configuration rigidly cannot affect either the resultant length or the cancellation defect. Part (2) identifies an extremal configuration at fixed magnitudes: among all families with the same* $|a_i|$*, the maximum possible resultant is achieved exactly by placing every vector on the same ray (common phase), and the dissonance is then forced to vanish.*

The inequalities also clarify an interpretive asymmetry: alignment can only help resonance (never hurt it), while misalignment can only increase dissonance (never decrease it), as long as magnitudes are held fixed. In later applications, this gives a clean monotonicity principle: any mechanism that reduces relative phase disagreement (or, more abstractly, reduces mutual contradiction among contributing terms) must move the model in the direction of larger Res *and smaller* Dis.

Remark 110. *This theorem formalizes two pieces of intuition that often remain implicit when one speaks of "resonance." First, resonance is not about absolute phase but about* relative *phase: rotating every contribution by the same angle changes nothing. Second, resonance is maximized when all contributions are aligned, in which case the resultant amplitude equals the sum of the individual amplitudes and dissonance vanishes.*

The result is important mainly because it validates a particular direction of explanation used later: if a coupling mechanism tends to align phases (or, more abstractly, tends to bring separate evaluative contributions into mutual agreement), then resonance increases and dissonance decreases. This is precisely the sort of monotone behavior one wants when resonance is used as a driver for cross-context pattern propagation (Hyperseed-Concepts 131, 159, 168) rather than as a merely poetic label.

Proof. (1) We have

$$\mathrm{Res}\big((e^{i\theta}a_i)_i\big) = \left|\sum_i e^{i\theta}a_i\right| = \left|e^{i\theta}\sum_i a_i\right| = \left|\sum_i a_i\right| = \mathrm{Res}(a).$$

Also $|e^{i\theta}a_i| = |a_i|$, so the sum of magnitudes is unchanged, hence Dis is unchanged as well. Equivalently, multiplying by $e^{i\theta}$ is an isometry of $\mathbb{C} \cong \mathbb{R}^2$, so it preserves all Euclidean lengths appearing in the definitions.

(2) By the triangle inequality,

$$\left|\sum_i a_i\right| \;\le\; \sum_i |a_i|.$$

But $\sum_i |a_i|e^{i\theta} = e^{i\theta}\sum_i |a_i|$, whose magnitude is exactly $\sum_i |a_i|$. Thus $\mathrm{Res}(a) \le \mathrm{Res}(a^{(\theta)}) = \sum_i |a_i|$. Since $\mathrm{Dis}(a) = \sum_i |a_i| - \mathrm{Res}(a)$, increasing Res (with the same $\sum_i |a_i|$) decreases Dis, and $\mathrm{Dis}(a^{(\theta)}) = 0$. One can also read this as: at fixed magnitudes, the maximal possible resultant is achieved by placing every term so that its contribution to the projection along the common direction is positive and maximal.

Equality in the triangle inequality holds iff all nonzero summands have the same argument, i.e. the a_i are all nonnegative real multiples of a common $e^{i\theta}$. □

Remark 111. Proof sketch. *Part (1) uses the fact that multiplying a complex number by* $e^{i\theta}$ *rotates it without changing its length, and that absolute value is invariant under such rotations. Part (2) is essentially the triangle inequality: the magnitude of a sum cannot exceed the sum of magnitudes, with equality exactly when all vectors point the same way.*

The key step is recognizing that "alignment" can be expressed by replacing each a_i with a vector of the same length but common phase. Geometrically, one may picture the a_i as arrows in the plane; the resonant case is when the arrows lie on top of each other, so their endpoint-to-endpoint addition is maximal, and the dissonant case is when they partially cancel. In this sense, $\mathrm{Dis}(a)$ *is not an additional primitive but a bookkeeping device that records precisely "how far" the configuration is from saturating the triangle inequality, which is why it behaves well under the sanity checks above (nonnegativity, vanishing in the fully aligned case, and maximality under total cancellation).*

Proposition 2 (Minimal categorical coherence for weakness: join-homomorphism and change of base)**.** *With $w(H) = \bigoplus_{(u,v)\in H} \mu(u) \otimes \mu(v)$ as above (where $\bigoplus$ denotes the* arbitrary *join in the complete lattice V, so the definition makes sense for finite or infinite H):*

1. *(*Complete join preservation*) For any family of relations $\{H_j\}_{j\in J}$,*

$$w\left(\bigcup_{j\in J} H_j\right) \;=\; \bigoplus_{j\in J} w(H_j), \qquad w(\emptyset) = \bot_V,$$

   where $\bot_V$ is the least element of the lattice V. In particular, overlaps among the H_j do not affect the result: if a given pair (u, v) appears in more than one H_j, it contributes the same element $\mu(u) \otimes \mu(v)$ multiple times, but because $\bigoplus$ is a join (hence idempotent), repeated contributions do not change the supremum.

2. *(*Functoriality under quantale homomorphisms*) If $\phi : V \to W$ is a (commutative) quantale homomorphism (preserving $\oplus, \otimes, e$), and if $\mu_W := \phi \circ \mu : X \to W$, then for every $H \subseteq X \times X$,*

$$\phi\big(w_V(H)\big) \;=\; w_W(H),$$

   i.e. computing weakness commutes with change of enrichment base. Equivalently, the assignment $H \mapsto w(H)$ is natural with respect to strict change-of-base maps ϕ that preserve the operations used in the definition of w (joins and tensor), so that the same relational evidence is merely re-expressed *in W rather than altered.*

Remark 112. *This proposition is the small categorical spine hidden inside an apparently elementary functional. Item (1) says that w behaves like a homomorphism from unions of relations to joins in V: the weakness of "either H_1 or H_2 or $\cdots$" is the join of their weaknesses. This is exactly what one wants if weakness is to be compatible with compositional constructions that build complex indistinction relations by taking unions (for example, when forming closures or aggregating evidence across subcontexts). Stated in slightly more algebraic terms, (1) says that $w : \mathcal{P}(X \times X) \to V$ is a* complete join-semilattice morphism *when $\mathcal{P}(X \times X)$ is ordered by inclusion and equipped with joins given by unions: it preserves arbitrary joins and therefore is automatically monotone (if $H \subseteq K$ then $w(H) \leq w(K)$), which matches the intuition that adding more indistinguishability pairs cannot decrease the overall weakness.*

Item (2) is a "change of base" principle: if one maps the quantale V into another quantale W in a structure-preserving way (via ϕ), then one can compute weakness either before or after applying ϕ and get the same answer. This is the order-enriched analogue of functoriality, and it is what allows later sections to shift between different evidence domains (e.g. probability-like versus possibilistic-like) while keeping the formal meaning of weakness stable (cf. the quantale-oriented development in [3]). Concretely, the point is that $w(H)$ is built from μ using only two constructors: taking tensor-products $\mu(u) \otimes \mu(v)$ and then taking their join; a quantale homomorphism preserves exactly these constructors, so it cannot "see" any difference between "compute-then-map" and "map-then-compute."

Proof. (1) Expand definitions and use that $\oplus$ is the join in V:

$$w\left(\bigcup_j H_j\right) = \bigoplus_{(u,v)\in\cup_j H_j} \mu(u)\otimes\mu(v) = \bigoplus_j \bigoplus_{(u,v)\in H_j} \mu(u)\otimes\mu(v) = \bigoplus_j w(H_j).$$

Also, the empty join is $\perp_V$, so $w(\emptyset) = \perp_V$. A slightly more explicit way to read the middle equality is that taking the join over the set $\bigcup_j H_j$ is the same as taking the join over the disjoint union of indexing data $\{(j,(u,v)) \mid (u,v)\in H_j\}$ and then observing that repetitions do not matter for suprema: if the same pair (u,v) is indexed multiple times, its contribution is duplicated but the join remains unchanged.

(2) Using preservation of joins and tensor by ϕ:

$$\phi\big(w_V(H)\big) = \phi\left(\bigoplus_{(u,v)\in H} \mu(u)\otimes\mu(v)\right) = \bigoplus_{(u,v)\in H} \phi(\mu(u)\otimes\mu(v)) = \bigoplus_{(u,v)\in H} \phi(\mu(u))\otimes\phi(\mu(v)) = w_W(H).$$

Here the second equality is exactly the "arbitrary-join preservation" part of being a quantale homomorphism, while the third equality is multiplicativity with respect to $\otimes$; together they ensure that ϕ commutes with the syntactic formation of w from μ. In particular, no special finiteness assumptions on H are needed: the argument applies uniformly to infinite joins because quantales are, by definition, complete join-semilattices with $\otimes$ distributing over arbitrary joins, and ϕ is assumed to respect this structure. ☐

Remark 113. Proof sketch. *For (1), the proof strategy is to "flatten" the indexing: taking the join over a union of sets is the same as taking a join over each set and then joining those results. This is the lattice-theoretic content of complete additivity with respect to unions. For (2), the strategy is to push ϕ through the defining expression for w using the fact that a quantale homomorphism preserves the operations used to build that expression. One can also view both statements as "no-surprises" coherence conditions: w is assembled from universal constructions (joins) and monoidal structure (tensor), so it must respect the canonical ways of rearranging those constructions.*

The crucial steps are exactly where the quantale axioms enter: preservation of arbitrary joins (to move ϕ past $\bigoplus$) and preservation of tensor (to rewrite $\phi(\mu(u)\otimes\mu(v))$ as $\phi(\mu(u))\otimes\phi(\mu(v))$). Visually, one can think of (2) as asserting that "measuring weakness" is invariant under a consistent change of measuring instrument: applying a monotone, structure-respecting regraduation of the evidence scale does not alter the computed weakness, aside from expressing it in the new units. For example, if V encodes evidence in one scale (say, additive costs) and W encodes it in another (say, a normalized or clipped cost domain), then a homomorphism ϕ that preserves the relevant joins and combinations ensures that the computed weakness is transported faithfully; what changes is only the codomain in which the resulting bound is reported.

5 Toy model: finite universe, p-bit quantale, and morphic resonance demo

Outline

- Fix a small finite universe X and two contexts C_1, C_2.
- Represent each context's "indistinction judgments" by a V-valued relation $R_i : X \times X \to V$.

- Compute weakness from R_i (as an "importance-weighted failure to distinguish").
- Represent patterns as finite constraint-sets on pairs in X, and define pattern support.
- Demonstrate "emergence" via quantale-compositional closure (transitive-like propagation of indistinction).
- Define morphic resonance and anti-resonance as cross-context coupling updates on relations.
- Add a tiny resonance score demo using the paraconsistent logic $\to$ complex mapping and interference.

Summary and Hyperseed concepts covered

This section instantiates the formal core of Section 3 in the smallest nontrivial setting. It provides an explicit computational picture of: (i) what it means to (fail to) make distinctions in a context, (ii) how simplicity/weakness aggregates, (iii) how a "pattern" can be a constraint that is supported to varying degrees, (iv) how pattern structure can *emerge* from composition/closure, and (v) how resonance can transmit pattern support across contexts, producing morphic resonance (and how anti-resonance can transmit opposition, producing habit reversal).

Hyperseed concepts covered.

- Distinction; equivalence relation; contexts/aspects.
- Weakness/simplicity; compositional simplicity; pattern; emergence.
- Resonance/dissonance; morphic resonance/anti-resonance; habits (as iterated updates).

Remark 114. *The point of this section is not to claim a faithful model of cognition or physics, but to give a* fully explicit *microcosm in which the core algebraic moves can be seen with one glance and checked with a calculator. In the language of Hyperseed's initial presentation [1], we are building a tiny "reality-system" where observer-relativity (Hyperseed-Concept 86), graded distinction (Hyperseed-Concept 98), weakness (Hyperseed-Concept 202), pattern (Hyperseed-Concept 130), and emergence (Hyperseed-Concept* **??***) appear as simple operations on a finite table.*

In particular, the "finite universe" assumption means that every object of interest can be concretely enumerated. Thus, once X is fixed, each context C_i can be treated as providing a complete *judgment table* $\big(R_i(x, y)\big)_{x,y\in X}$, i.e. a matrix whose entries live in a chosen truth-value/weight structure V. One should read $R_i(x, y)$ as: "*in context C_i, to what degree are x and y not distinguished?*" Depending on the choice of V, this degree may be probabilistic, fuzzy, possibilistic, or (as in this section) paraconsistent in the sense of allowing simultaneous support for and against indistinction.

The role of the p-bit quantale is to make three operations simultaneously available and computationally transparent: (i) an order $\leq$ expressing when one indistinction-value is *at most as strong* as another, (ii) a join (typically written $\vee$) expressing aggregation of evidence ("taking the better supported indistinction"), and (iii) a monoidal product (often written $\otimes$) that will be used to *compose* relations. Concretely, composition will take the familiar relational form

$$(R \circ S)(x, z) \;=\; \bigvee_{y\in X} \big(R(x, y) \otimes S(y, z)\big),$$

so that indistinction can propagate along intermediate y's; this is the precise sense in which a "transitive-like" closure can be computed and inspected entry-by-entry.

The weakness calculation is included here to make the informal phrase "failure to distinguish" operational. Because X is finite, weakness can be written as an explicit sum (or other finite aggregation) over pairs (x, y), with optional weights expressing that some confusions matter more than others in a given task or setting. In this way, weakness becomes a *scalar summary* extracted from a full table R_i, while still being sensitive to where (which pairs) the indistinction is concentrated. This also makes it clear how one can speak of "simplicity" as a property of a context: a context is "simple" (not because its world is objectively simple, but) because its distinction-table is coarse or permissive in a way that reduces discriminative burden.

Patterns enter in the most concrete possible way: as finite collections of constraints on pairs in X that a context may or may not support. A pattern can be read as a small "theory" about which objects should be treated as indistinct (or, depending on the constraint language chosen later in the section, which should be treated as distinct). Because R_i is graded, pattern satisfaction is graded as well: a pattern is not merely true/false in a context, but has a *support value* that can be computed by combining the relevant table entries with the operations of V. This gives an explicit bridge between the algebra (quantale-valued relations) and the intuitive notion of a recurring regularity (a pattern supported by the context's own judgments).

The point of demonstrating emergence via closure is that even when the pattern constraints are initially "local" (i.e. mention only a few pairs), compositional propagation can generate additional, *derived* indistinction facts. In the finite setting, this is visible as new nontrivial entries appearing (or strengthening) in the closure of R_i under $\circ$ (and, if taken, reflexive and/or symmetric completion), thereby turning an initially sparse set of judgments into a richer structure. This is the toy-model analogue of an "emergent pattern": not stipulated as a primitive constraint, but produced by the algebraic dynamics of the representational apparatus.

Finally, morphic resonance and anti-resonance are introduced here as explicit *cross-context update rules*. The guiding idea is that a context C_1 can influence a context C_2 by pushing R_2 toward (resonance) or away from (anti-resonance) the indistinction-structure present in R_1. Because everything is finite, such coupling can be written as an explicit formula (e.g. an update of the form $R_2 \leftarrow f(R_2, R_1)$ applied entrywise or via composition), iterated a few times, and numerically inspected. Interpreting repeated updates as "habit" formation is then not a metaphor but a literal iteration of a map on the space of V-valued relation tables.

The final bullet in the outline connects this to the paraconsistent logic aspect of p-bit by showing how a resonance (or interference) score can be computed even when evidence is inconsistent. Mapping the paraconsistent implication $\rightarrow$ into complex numbers is used in the demo as a compact way to encode phase-like reinforcement versus cancellation: agreement can add constructively, while certain mismatches can subtract, producing an explicit toy example of how "dissonance" can be more than mere absence of support. The purpose is not physical analogy per se, but a minimal, checkable instance where opposition is not collapsed into zero and can therefore drive anti-resonant change rather than being ignored.

5.1 Finite universe and two contexts

Let $X := \{a, b, c\}$. We consider two contexts C_1 and C_2 (think: two agents, or two spatial locations, or two subsystems) that each maintain a p-bit-valued relation

$$R_i : X \times X \to V, \qquad i \in \{1, 2\},$$

where $V = [0,1]^2$ is the p-bit quantale from Section 3.4. Concretely, each R_i can be pictured as a 3×3 table (a weighted adjacency matrix) whose entries are pairs in $[0,1]^2$. Keeping X finite makes it possible to compute closure, composition, and cross-context comparison explicitly and transparently: every "global" quantity is obtained by finitely many $\oplus$-aggregations of finitely many $\otimes$-products.

Remark 115 (Notation unpacking)**.** *Here $X \times X$ is the set of ordered pairs of entities, so $R_i(x,y) \in V$ is a* graded *statement about the pair (x,y) as judged in context C_i. The symbol $V = [0,1]^2$ means each value has two coordinates, typically written $R_i(x,y) = (R_i^+(x,y), R_i^-(x,y))$. The order on V is the componentwise order (so larger means "more evidence" in that channel), and the toy computations later implicitly use the standard* p-bit *quantale operations: $\oplus$ as componentwise maximum and $\otimes$ as componentwise multiplication, with unit $e = (1,1)$. This is the minimal paraconsistent evidence calculus needed for the rest of the examples. In particular, the choice of $\oplus = \max$ means that when multiple independent "routes" (or justifications) support a claim, the aggregated evidence keeps the strongest available support in each coordinate rather than averaging it away, while $\otimes = \cdot$ models attenuation along multi-step chains (products of confidences). The componentwise order makes the induced lattice structure transparent: $u \leq v$ iff $u^+ \leq v^+$ and $u^- \leq v^-$, so a value can increase in one channel without forcing any change in the other.*

Remark 116 (Two contexts as two ways of cutting the world)**.** *A context is, philosophically, a stance: a way an observer (or subsystem) decides what differences matter. Mathematically we encode that stance by a relation-valued table. This operationalizes observer-relativity: the same pair (x,y) can be judged "nearly identical" in C_1 and "clearly distinct" in C_2 without contradiction at the meta-level. This is one of the core motivations for paraconsistent semantics in the Hyperseed program (Hyperseed-Concept 86, 98). One can also view C_i as fixing a measurement protocol: which features are compared, what counts as noise, and which correlations are trusted. On this reading, changing contexts corresponds to changing the observational interface rather than changing the underlying set X.*

Remark 117 (Interpretation of $R_i(x,y)$)**.** *We interpret $R_i(x,y) = (R_i^+(x,y), R_i^-(x,y))$ as two-channel evidence about the proposition "x and y should be treated as the same (undistinguished) in context C_i":*

- *$R_i^+(x,y)$ is positive evidence supporting indistinction ($x \sim y$),*
- *$R_i^-(x,y)$ is negative evidence opposing indistinction (supporting distinction).*

Paraconsistency means both channels may be simultaneously high. It is useful to emphasize that this is not merely "probability of sameness" plus "probability of difference"; the two coordinates are not required to sum to 1 (and generally should not), because they represent potentially independent evidential sources. Thus $(1,1)$ represents maximal support and *maximal opposition, i.e. a fully conflicted or overdetermined state, whereas $(0,0)$ represents lack of information (neither support nor opposition). This separation is what allows later constructions to treat agreement and conflict as distinct, simultaneously trackable resources.*

Remark 118 (A simple concrete reading)**.** *If $R_i(x,y) = (0.9, 0.1)$ then context C_i has strong support for collapsing x and y and little opposition. If $R_i(x,y) = (0.9, 0.8)$ then C_i is in a conflicted state: it has strong reasons to identify and strong reasons to separate. And if $R_i(x,y) = (0.1, 0.8)$ then C_i is largely opposed to identifying x and y. This two-axis geometry is precisely what later allows "resonance" and "dissonance" to be treated as interference-like phenomena (Hyperseed-Concept*

159, 97). Geometrically, one can think of $R_i(x, y)$ as a point in the unit square, with qualitatively different regions: a "consensus-identify" region near $(1, 0)$, a "consensus-separate" region near $(0, 1)$, a "conflict" region near $(1, 1)$, and an "uninformative" region near $(0, 0)$. Later, when we compare contexts or compose relations along paths, these regions behave differently under $\oplus$ and $\otimes$, which is exactly what makes the toy model nontrivial even though the underlying set X is tiny.

For convenience we assume symmetry $R_i(x, y) = R_i(y, x)$ and set diagonal entries to the quantale unit $e = (1, 1)$ so that diagonal paths do not attenuate relation-composition (this is an algebraic convenience for the closure demo below). Equivalently, each R_i may be regarded as an undirected V-weighted graph with a designated self-loop of weight e at every node. This convention is especially convenient when we later form powers or closures of R_i: it ensures that length-k paths can always be extended to length $k + 1$ without changing their value by inserting a self-loop, so comparisons across path lengths are not artifacts of path padding.

Remark 119 (Why symmetry and why $R_i(x, x) = e$?)**.** *Symmetry is not logically necessary, but it matches the intended reading "x and y are (un)distinguished" as an (approximate) equivalence-like judgment (Hyperseed-Concept* **??***). Setting $R_i(x, x) = e = (1, 1)$ is likewise a modeling decision: it ensures that when we later compose relations, a path that "stays at x" contributes neutrally rather than shrinking values. In graph terms, we are giving each node a self-loop of maximal strength so that closure emphasizes multi-step connections between* distinct *nodes. Technically, this is the enriched-graph analogue of putting* 1 *on the diagonal of an adjacency matrix so that "no move" is always an available step. With $\otimes$ as multiplication, a diagonal value strictly below* 1 *would systematically damp all multi-step compositions, making it harder to interpret whether a decrease came from genuinely weak links between distinct nodes or merely from repeated diagonal attenuation. Note also that symmetry and reflexive diagonals together do* not *force transitivity: the later closure computation is precisely the mechanism that constructs the least transitive (or path-complete) strengthening consistent with the chosen $\oplus/\otimes$ aggregation.*

5.2 From relations to weakness: "failed distinctions"

Section 3.7 defined weakness for a crisp set $H \subseteq X \times X$ of undistinguished pairs. For the toy model it is useful to use the standard V-enriched generalization. In particular, passing from crisp H to a V-valued relation R lets us represent not only *whether* two items are treated as indistinct, but also *to what degree* that indistinction holds in each channel of the quantale, and then aggregate these degrees in a quantale-native way.

Remark 120. *Conceptually, weakness is meant to quantify "how much important structure is being collapsed": how costly it is, relative to what matters, to treat too many things as indistinct. In the Hyperseed literature this idea is developed as a quantale-native aggregation principle (Hyperseed-Concept 143; see also [3, 2]). Here we simply instantiate that principle on a finite set. One can view the weakness functional as a deliberately coarse proxy for "information lost under a compression": it does not attempt to reconstruct which distinctions were lost, but returns a single severity score that can be compared across candidate relations R.*

Definition 25 (Weakness of a V-valued relation)**.** *Fix an importance valuation $\mu : X \to V$. For a V-valued relation $R : X \times X \to V$, define*

$$w(R) \;:=\; \bigoplus_{(u,v) \in X \times X} \mu(u) \otimes R(u, v) \otimes \mu(v) \;\; \in V.$$

Remark 121. *The type of this definition is worth making explicit: since $\mu(u), R(u, v), \mu(v) \in V$ and $\otimes$ is the quantale product, each term $\mu(u) \otimes R(u, v) \otimes \mu(v)$ is again an element of V, and the (possibly large) family of such terms is then aggregated by the quantale join $\bigoplus$. Because X is finite in the toy model, the join is a finite join; in an infinite setting one would typically require the appropriate completeness so that the join exists.*

Remark 122 (Intuition)**.** *The expression for $w(R)$ is the same idea as the crisp case, but with two refinements. First, the relation $R(u, v)$ is graded, so "being undistinguished" is a matter of degree. Second, the valuation μ weights entities by importance, so collapsing a with something may count more than collapsing c with something. The quantale join $\bigoplus$ then aggregates all these weighted collapses into a single global score. In this toy quantale, the aggregation is a bottleneck (a max), so weakness is driven by the most severe important collapse; other quantales would yield sum-like or softmin-like notions of weakness. Equivalently, one can think of $w(R)$ as a "worst-case after weighting" criterion: among all pairs (u, v), it selects the pair whose weighted indistinction is most damaging, with the notion of "most damaging" determined by the join on V.*

Remark 123. *In many relational settings one may want to exclude diagonal pairs (u, u) from the aggregation, since an object being "undistinguished from itself" is not a failure of distinction. Here the definition sums over all of $X \times X$ for notational uniformity; in the worked toy instances one typically takes $R(u, u)$ to be the least element $(0, 0)$ (or otherwise fixed by convention) so that diagonal terms do not affect $w(R)$. If instead one sets $R(u, u) = e$, then the diagonal contributes the baseline importance $\mu(u) \otimes e \otimes \mu(u)$ and one should interpret the resulting weakness as including self-collapse as a fixed offset.*

Remark 124 (A tiny example)**.** *If $\mu(x) = (1, 1)$ for all x and R has only one substantial off-diagonal entry, say $R(a, b) = (0.9, 0.2)$ and all other off-diagonal entries are $(0, 0)$, then*

$$w(R) = (0.9, 0.2)$$

(up to symmetry/duplication conventions in the join). So in the bottleneck semantics, the global weakness simply mirrors the worst undistinguished edge. When multiple edges are present, $w(R)^+$ becomes the largest product-weighted positive indistinction, as noted below. In this example, if one also had $R(b, a) = (0.9, 0.2)$, the join would still return the same value, illustrating that duplicating the same worst edge does not change a max-type aggregator; by contrast, in an additive quantale, doubling could change the score and symmetry conventions would matter more.

Remark 125. *If $H \subseteq X \times X$ is crisp, embed it as a V-valued relation $\mathbf{1}_H$ via $\mathbf{1}_H(u, v) = e$ if $(u, v) \in H$ and $\mathbf{1}_H(u, v) = (0, 0)$ otherwise. Then $w(\mathbf{1}_H) = \bigoplus_{(u,v)\in H} \mu(u) \otimes \mu(v)$, recovering the earlier definition. This embedding is the standard "characteristic relation" construction: elements of H are assigned the multiplicative unit e so that the only contribution of such a pair is through the endpoint weights $\mu(u)$ and $\mu(v)$, while pairs not in H are assigned the least element so that they contribute nothing under $\otimes$ and $\bigoplus$.*

Definition 26 (A concrete importance valuation)**.** *In the worked example below we use*

$$\mu(a) = (1, 1), \qquad \mu(b) = (0.8, 1), \qquad \mu(c) = (0.6, 1).$$

Thus the positive channel weights importance (how costly it is to collapse distinctions involving an item), while the negative channel is left unweighted for simplicity. Note that these values impose an explicit ranking of "stakes": collapsing distinctions involving a is treated as most consequential, then b, then c, at least in the positive coordinate that drives the bottleneck score.

Remark 126 (Why weight only the positive channel here?)**.** *This is purely for pedagogical transparency. In many applications one would also want to weight negative evidence: e.g. "distinguishing a from b is more important than distinguishing c from b." The present choice keeps the numeric algebra minimal: the negative coordinate of $w(R)$ will be dominated by whatever negative evidence is largest, independent of μ. Nothing essential hinges on this choice; it merely fixes one explicit convention for the toy. Concretely, with $\mu(\cdot)^- = 1$ in this section, the negative coordinate behaves like an unweighted bottleneck over $R(u,v)^-$ (up to the way $\otimes$ combines negatives in the chosen quantale), so that the only place where "importance" visibly enters is the positive-coordinate term $\mu(u)^+\mu(v)^+R(u,v)^+$.*

Remark 127 (Reading $w(R)$ in this toy)**.** *With the quantale operations from Section 3.4, the first coordinate of $w(R)$ is*

$$w(R)^+ = \max_{u,v} \ \mu(u)^+\mu(v)^+R(u,v)^+,$$

i.e. a bottleneck-style "largest important collapsed link" score. This matches a minimax/bottleneck notion of simplicity: the strongest (most important) collapsed distinction dominates. Other aggregators (e.g. additive) are possible, but we keep the quantale-native choice here. For completeness, the second coordinate $w(R)^-$ is computed analogously using the $\otimes$-combination rule for the negative coordinate and the join $\bigoplus$ on that coordinate (which, for p-bit*, is again max-like); in the present toy convention $\mu(\cdot)^- = 1$, so the negative contribution is driven directly by the largest negative component appearing among the $\mu(u) \otimes R(u,v) \otimes \mu(v)$ terms.*

Remark 128. *The form $\mu(u)^+\mu(v)^+R(u,v)^+$ also makes it clear why $w(R)^+$ can be read as a "failed distinction" score rather than merely a raw strength score: even if $R(u,v)^+$ is moderately large, the weakness only becomes large when the endpoints are themselves important in the positive channel. Thus, collapsing two low-importance entities can remain cheap even if the relation strongly identifies them, while a weaker identification between high-importance entities can still dominate the global bottleneck.*

Remark 129 (Connection to "simplicity as failed distinction")**.** *It is easy to hear "simplicity" as a virtue and "failure to distinguish" as a vice. Hyperseed treats them as two faces of a single structural phenomenon: compression always forgets distinctions, and the question is* which *ones and at* what cost*. The quantale-functional $w(R)$ is precisely a knob for that trade: it quantifies the degree and importance of collapsed distinctions in a context (Hyperseed-Concept 169, 202). In particular, when used alongside a competing objective (e.g. a fit-to-data or coherence score), $w(R)$ provides the "simplicity pressure" by penalizing relations that identify too much of what the valuation μ declares significant.*

5.3 Patterns as finite constraints and pattern support

In this toy setting, a "pattern" will be a finite set of pair-constraints that should be jointly supported. This choice builds in two simplifying assumptions that are useful later: (i) patterns are *finitely checkable* objects (one can compute their support by a finite aggregation), and (ii) the only structure inside a pattern is *which pairs are demanded to cohere.* Nothing in this subsection requires that the constraints be consistent in the classical sense; instead, consistency becomes an emergent, graded property of the support values.

Definition 27 (Pattern as a constraint-set on pairs)**.** *A* pattern *is a finite set*

$$P \ \subseteq \ X \times X$$

(typically symmetric and excluding the diagonal) interpreted as a conjunction of constraints "for all $(u, v) \in P$, treat u and v as (approximately) undistinguished."

Remark 130 (Conventions: symmetry, diagonal, and multiplicity)**.** *Formally, nothing breaks if P includes ordered pairs or diagonal pairs; these are conventions chosen to keep the toy notion aligned with the intended reading. Symmetry corresponds to treating "u matches v" as interchangeable with "v matches u," and excluding (u, u) avoids constraints that are tautological in most similarity-like contexts. Because P is a* set*, not a multiset, repeating the same constraint does not artificially increase its influence; if one wanted repeated evidence, that would be modeled in R (as stronger support) or by a different pattern formalism.*

Remark 131 (Intuition and relation to the general notion of pattern)**.** *In a large theory, a "pattern" is often something like a model, a regularity, or a compression ([5, 16]). Here we take the smallest possible fragment of that idea: a pattern is just a finite list of pairwise identifications that are supposed to hold together. This is deliberately austere: it makes patternhood into a constraint satisfaction problem, and the only subtlety is that satisfaction is graded and paraconsistent. One can regard P as specifying a tiny "hypothesis" about which distinctions the system is willing to ignore (at least locally), and the role of R is to provide context-dependent evidence for and against each such local identification.*

Remark 132 (Simple examples)**.** *With $X = \{a, b, c\}$, the set $P = \{(a, b)\}$ is the pattern "a is identified with b." The set $P = \{(a, b), (b, c)\}$ is the pattern "$a \sim b$ and $b \sim c$." If one additionally includes (a, c) then P is a triangle/cluster constraint. In later sections, such constraint-sets will be replaced by richer pattern objects, but the logical spine is the same: a pattern is something that asks multiple local judgments to cohere (Hyperseed-Concept 130). It is worth noting that, at this toy level, $P = \{(a, b), (b, c)\}$ does* not *itself enforce transitivity; it merely requests two local identifications. Whether "a and c should also cohere" is a further constraint, represented by adding (a, c) explicitly (or by a separate closure principle introduced later, if desired).*

Definition 28 (Pattern support)**.** *Given a context relation R and a pattern P, define the (conjunctive) pattern support*

$$S_R(P) \;:=\; \bigotimes_{(u,v)\in P} R(u, v) \;\in V.$$

In particular,

$$S_R(P)^+ = \prod_{(u,v)\in P} R(u, v)^+, \qquad S_R(P)^- = \prod_{(u,v)\in P} R(u, v)^-.$$

Remark 133 (Empty pattern and the unit of conjunction)**.** *Since $\bigotimes$ is a multiplicative "big conjunction," the empty pattern $P = \varnothing$ evaluates to the multiplicative unit:*

$$S_R(\varnothing) = 1_V.$$

This matches the logical convention that an empty conjunction is trivially satisfied. In the two-channel setting, this should be read as "the empty set of demands contributes no constraint at all," rather than as a substantive claim about the world; nontrivial content only appears once at least one pair-constraint is included.

Remark 134 (Notation unpacking)**.** *The symbol $\bigotimes$ is the quantale analogue of a big conjunction: we multiply the evidence-values for each required pair. Because our $\otimes$ is componentwise multiplication, $S_R(P)^+$ is literally the product of the positive supports for each constraint, and similarly for*

$S_R(P)^-$. *Thus the more constraints you ask for, the harder it becomes to keep the support high—an algebraic reflection of the simple thought that conjunction is stricter than a single predicate. Equivalently, each additional constraint* (u, v) *acts as a multiplicative "gate" that can only decrease (or, in the best case, preserve) the overall degree whenever* $R(u, v)^{\pm} \leq 1$ *in the ambient scale.*

Remark 135 (Monotonicity in the pattern argument)**.** *Because* $\otimes$ *is monotone in each argument, enlarging a pattern can only make it harder to satisfy: if* $P \subseteq Q$*, then (componentwise in the* V*-order)*

$$S_R(Q) \;\leq\; S_R(P).$$

Concretely, $S_R(Q)^+$ *is* $S_R(P)^+$ *multiplied by the additional positive factors required by* $Q \setminus P$*, and likewise for the negative channel. This is the toy analogue of the general principle that adding conjuncts strengthens a theory.*

Remark 136 (A concrete computation)**.** *For intuition, suppose* $P = \{(a, b), (b, c)\}$ *and (in some context)* $R(a, b) = (0.9, 0.2)$ *and* $R(b, c) = (0.6, 0.8)$*. Then*

$$S_R(P) = (0.9 \cdot 0.6,\ 0.2 \cdot 0.8) = (0.54,\ 0.16).$$

In this example, the pattern is moderately supported (0.54*) and only weakly opposed (*0.16*), even though one constituent pair has high opposition in isolation; the multiplicative aggregation makes the overall opposition sensitive to* joint *opposition across all constraints rather than to a single contested link. This "jointness" is exactly the behavior expected of a conjunction-like operator.*

Remark 137 (Paraconsistent reading of $S_R(P)$)**.** *When* $S_R(P) = (s^+, s^-)$*, the pattern is:*

- *supported to degree* s^+*,*
- *opposed to degree* s^-*,*
- *and may be simultaneously both (if both are high).*

This is exactly why the two-channel semantics is useful: the theory can represent "the pattern is strongly present and strongly resisted" without collapsing into triviality. That tension is one of the seeds from which later notions of dissonance, reversal, and habit dynamics grow (Hyperseed-Concept 159, 97). In particular, a high s^+ *indicates that each demanded identification is locally well-supported, while a high* s^- *indicates that each demanded identification is also locally well-opposed; these can coexist without forcing an all-or-nothing verdict.*

Remark 138 (Why conjunctive aggregation is the right toy default)**.** $S_R(P)$ *is a deliberately minimal "all-of" aggregator (a toy conjunction). More elaborate pattern measures used later in the full paper (pattern intensity, emergence criteria, etc.) can be layered on top of this. For Section 5, the goal is simply to have a compact, checkable notion of "this pattern is supported / opposed / contradictory." The multiplicative form is especially convenient because it makes the dependence on individual constraints explicit and local: every pair in* P *contributes a visible factor, so changes in* R *(or edits to* P*) have transparent effects on the aggregate.*

5.4 Emergence via compositional closure

A key Hyperseed intuition is that patterns can emerge from composition rather than being explicitly present. In the relation-quantale, this is exactly what composition and closure do: if $R(a, b)$ and $R(b, c)$ are strong, then $R(a, c)$ becomes strong in the closure even if it started weak. In other words, the "emergent" link $a \to c$ is not stipulated as a primitive datum; it is forced by the algebra of chaining. This is the graded analogue of how (crisp) transitive closure turns a set of edges into all reachable edges, except that here reachability is replaced by a quantale-valued notion of support for a connection.

Remark 139. *This is a precise algebraic analogue of the informal slogan "structure implies more structure": a system that treats a as (approximately) the same as b, and b as the same as c, is under pressure to treat a as the same as c. In classical logic that pressure is transitivity of equivalence. In a graded setting the same pressure becomes a closure operator built from $\oplus$ and $\otimes$. This is one minimal formal doorway into Hyperseed's notion of emergence (Hyperseed-Concept* **??**; *see also [5] for broader discussion). One can also read this as a disciplined way of converting* local *judgments (pairwise links) into* global *judgments (consistency across chains) while remaining inside the same algebraic universe V. When V is the* p-bit *quantale used in this toy model, the same mechanism propagates not only "positive support" but also any built-in notion of "opposition" or "incompatibility" that $\otimes$ and $\oplus$ encode.*

Definition 29 (Quantale composition of V-valued relations)**.** *For V-valued relations $R, S : X \times X \to V$, define*

$$(R \circ S)(x, z) \;:=\; \bigoplus_{y \in X} R(x, y) \otimes S(y, z).$$

Remark 140 (What this composition means)**.** *The variable y plays the role of an intermediate "bridge" entity. For each bridge y, the quantity $R(x, y) \otimes S(y, z)$ measures how strongly x connects to z by going through y. Then the join $\bigoplus_{y \in X}$ takes the best such bridge in the quantale order. Because $\oplus$ is a max in this toy, composition chooses the strongest multi-step path. This is the same algebra that underlies weighted path problems in idempotent semirings, but here it is interpreted as propagation of indistinction judgments. Equivalently, if one thinks of R and S as $|X| \times |X|$ matrices with entries in V, then $\circ$ is the usual "matrix product" but with $(+, \times)$ replaced by $(\oplus, \otimes)$; the bridge index y is exactly the summed-over index. This perspective is often useful for concrete computations in the finite-universe toy setting, since repeated composition becomes iterated (quantale-)matrix multiplication.*

Definition 30 (Transitive-like closure)**.** *Define $R^{(1)} := R$ and $R^{(n+1)} := R^{(n)} \circ R$. Define the closure*

$$\mathrm{Cl}(R) \;:=\; \bigoplus_{n \geq 1} R^{(n)}.$$

Remark 141 (Intuition: closure as "all finite chains")**.** *The power $R^{(n)}(x, z)$ measures evidence for connecting x to z by a chain of n edges. Taking $\bigoplus_{n \geq 1}$ then means: allow* any *finite chain length, and keep whichever chain provides the strongest support (and strongest opposition) for the resulting link. In a finite universe, $\mathrm{Cl}(R)$ can often be computed by iterating composition until no entry improves. Note that the definition starts at $n \geq 1$, so it is a "transitive-like" closure rather than a reflexive-transitive closure: we do not automatically force a maximal self-link $R(x, x)$ via an $n = 0$ identity step. If one wanted the reflexive-transitive variant, one would typically adjoin the identity relation I (with $I(x, x) = \top$ and $I(x, z) = \bot$ for $x \neq z$ in the V-order) and take $\bigoplus_{n \geq 0} R^{(n)}$; the present choice isolates what is generated purely by chaining the given evidence in R.*

Remark 142 (Finite stabilization in the toy universe)**.** *Because X is finite and $\oplus$ is idempotent in this setting, the ascending sequence*

$$R^{(1)} \;\leq\; R^{(1)} \oplus R^{(2)} \;\leq\; \cdots \;\leq\; \bigoplus_{k=1}^{N} R^{(k)} \;\leq\; \cdots$$

often stabilizes after finitely many steps when computed entrywise: beyond some length, longer chains do not improve any value. Operationally, this is why one can implement $\mathrm{Cl}(R)$ *by repeated composition and pointwise* $\oplus$*-accumulation until a fixed point is reached, mirroring classical algorithms for transitive closure (e.g. Floyd–Warshall) but with the boolean semiring replaced by* $(V, \oplus, \otimes)$*. The theorem below identifies the mathematical reason that this fixed point is the "right" one: it is exactly the least self-composition-stable extension above* R*.*

Theorem 4 (Closure is transitive and is the least transitive extension above R)**.** *Let* $R : X \times X \to V$*. Then:*

1. *(*Extensive*)* $R \leq \mathrm{Cl}(R)$*.*

2. *(*Transitive*)* $\mathrm{Cl}(R) \circ \mathrm{Cl}(R) \leq \mathrm{Cl}(R)$*.*

3. *(*Least*) If* T *is any relation with* $R \leq T$ *and* $T \circ T \leq T$*, then* $\mathrm{Cl}(R) \leq T$*.*

Remark 143 (What the theorem is saying, in plain language)**.** *The theorem asserts that* $\mathrm{Cl}(R)$ *behaves exactly as a closure should. First, it does not forget what you started with: every direct judgment in R remains present (possibly strengthened). Second, once you have closed, composing closed relations does not generate anything genuinely new: the closure is stable under composition, which is the graded analogue of transitivity. Third, it is the* smallest *such stable extension: any other relation* T *that contains* R *and is closed under self-composition must also contain* $\mathrm{Cl}(R)$*. In particular, statement (2) says that after closure, every composite chain-of-chains can be "flattened" back into a single finite chain already accounted for in* $\mathrm{Cl}(R)$*, so no additional emergent links remain hidden behind further iteration.*

Remark 144 (Why it matters here)**.** *This result is a sanity check that the toy "emergence" mechanism is not ad hoc. If we claim that emergent pattern structure arises from iterating compositional implications, then* $\mathrm{Cl}(R)$ *is the canonical object that embodies "everything implied by finite compositional chaining." In later categorical language,* Cl *is a standard closure operator induced by enrichment. So this theorem connects the concrete numeric demo back to the abstract compositionality requirement in Section 3. It also clarifies the sense in which emergence here is* conservative*:* $\mathrm{Cl}(R)$ *can add new strong links, but it does so only when they are justified by existing links and the fixed rules* $(\oplus, \otimes)$*, i.e. by the chosen notion of compositional propagation encoded in the quantale.*

Proof. (1) The join defining $\mathrm{Cl}(R)$ includes $R^{(1)} = R$, hence $R \leq \mathrm{Cl}(R)$.

(2) Using distributivity of $\circ$ over joins (true in the relation quantale) and associativity of $\circ$:

$$\mathrm{Cl}(R) \circ \mathrm{Cl}(R) = \left(\bigoplus_{m \geq 1} R^{(m)} \right) \circ \left(\bigoplus_{n \geq 1} R^{(n)} \right) = \bigoplus_{m,n \geq 1} \left(R^{(m)} \circ R^{(n)} \right).$$

Here distributivity can be read entrywise: for each (x, z), the definition of $\circ$ and the fact that $\otimes$ distributes over $\oplus$ allow one to pull joins outside and regroup them into a single (possibly larger) join over pairs (m, n). But $R^{(m)} \circ R^{(n)} = R^{(m+n)}$ by associativity of composition, so

$$\mathrm{Cl}(R) \circ \mathrm{Cl}(R) = \bigoplus_{m,n \geq 1} R^{(m+n)} \leq \bigoplus_{k \geq 1} R^{(k)} = \mathrm{Cl}(R).$$

The final inequality holds because every index of the form $k = m + n$ with $m, n \geq 1$ satisfies $k \geq 2$, and the join over all $k \geq 1$ dominates the join over the subset $k \geq 2$ in the quantale order.

(3) If $R \le T$ and $T \circ T \le T$, then by induction $R^{(n)} \le T$ for all n. Taking joins yields $\mathrm{Cl}(R) = \bigoplus_{n \ge 1} R^{(n)} \le T$. Concretely, the induction step uses monotonicity of $\circ$: if $R^{(n)} \le T$, then

$$R^{(n+1)} \;=\; R^{(n)} \circ R \;\le\; T \circ T \;\le\; T,$$

where $R \le T$ is used in the middle inequality. □

Proof sketch. The strategy is to recognize $\mathrm{Cl}(R)$ as the join of all finite compositional powers of R. Extensiveness is immediate because R is one of those powers. Transitivity follows because composing an m-step chain with an n-step chain yields an $(m+n)$-step chain, and all such powers are already included in the join. Leastness follows because any transitive extension T that contains R must contain every power $R^{(n)}$ (by repeated composition), hence must contain their join. □

Remark 145 (Why the key steps work)**.** *The only real work is done by two structural facts about quantale-valued relations:*

- *composition $\circ$ is associative, so path concatenation is well-defined, and*
- *composition distributes over joins, so "take the best bridge" is compatible with "take the best path length."*

These are precisely the algebraic conditions that make composition a sensible model of propagation. Visually, one can imagine a weighted graph with two weights per edge; $\mathrm{Cl}(R)$ *is the result of allowing all paths and then assigning each pair (x, z) the best weight achievable by any path from x to z.*

Remark 146 (Hyperseed reading)**.** *The closure* $\mathrm{Cl}(R)$ *is an extremely literal toy formalization of "pattern emergence": new constraints become supported because they are* implied by compositions of already-supported constraints*.*

5.5 Miledorphic resonance and anti-resonance as cross-context coupling

We now model morphic resonance as the transport of pattern support between contexts.

Remark 147. *The phrase "morphic resonance" is historically associated with Sheldrake's speculative proposal [13]. Hyperseed uses the phrase in a more formal-and-operational spirit: it denotes a cross-context coupling that tends to make similar patterns more likely in different places, without requiring direct causal contact in the narrow sense. In this paper, the coupling is explicitly represented as an algebraic update rule on context relations (Hyperseed-Concept 115, 159).*

Definition 31 (Pointwise scaling of a relation)**.** *For $K \in V$ and a relation $R : X \times X \to V$, define $(K \otimes R) : X \times X \to V$ by*

$$(K \otimes R)(x, y) := K \otimes R(x, y).$$

Remark 148 (Intuition and example)**.** *Pointwise scaling means: take every pairwise judgment in R and attenuate (or amplify) it by the same coupling strength K. For instance, if $K = (0.9, 0.9)$ and $R(x, y) = (0.8, 0.2)$, then $(K \otimes R)(x, y) = (0.72, 0.18)$. In other words, we transmit the same "shape" of evidence but at reduced intensity.*

Definition 32 (Morphic resonance update operator)**.** *Fix a coupling strength $K \in V$. Define the resonance propagation from C_1 to C_2 by*

$$\mathsf{Res}_K(R_1 \to R_2) \;:=\; R_2 \;\oplus\; (K \otimes R_1),$$

where the join $\oplus$ and product $\otimes$ are taken pointwise on $X \times X$.

Remark 149 (Plain-language reading)**.** *The update says: "keep what C_2 already believes, but also import (a scaled version of) what C_1 believes, taking the better-supported evidence in each channel." Because $\oplus$ is a join, the update is conservative in the sense that it cannot decrease either the positive or negative evidence for any pair; it can only add support and/or add opposition. This is the algebraic core of paraconsistent transport: influence without forced consistency.*

Remark 150 (Why a join, rather than overwriting?)**.** *If one overwrote R_2 by $K \otimes R_1$, then resonance would erase local evidence and turn into domination. Using $\oplus$ instead makes resonance an inclusion-like process: new evidence accumulates. This matches the intended semantics of contexts as partially independent stances that can be coupled without being annihilated.*

Definition 33 (Anti-resonance update operator)**.** *Anti-resonance is modeled as preferential transport of opposition to the pattern. A minimal way to express this with the same quantale is to use a coupling element that acts mainly on the negative channel:*

$$K^- := (0, k^-) \in V.$$

Then define

$$\mathsf{ARes}_{k^-}(R_1 \to R_2) \ := \ R_2 \ \oplus \ (K^- \otimes R_1).$$

Concretely, $(K^- \otimes R_1)(x,y) = (0,\ k^- \, R_1^-(x,y))$, so only negative evidence is propagated.

Remark 151 (Anti-resonance as structured "no")**.** *The anti-resonance operator is not "the negation" of resonance; it is a directed transport of resistance. In terms of habit dynamics, it provides a minimal mechanism by which a context can inherit reasons* not *to instantiate a pattern that another context opposes. This aligns with the Hyperseed idea that habit reversal is not mere noise but can be driven by imported constraint pressure (Hyperseed-Concept 188, 114).*

Proposition 3 (Monotonicity of resonance and anti-resonance)**.** *For fixed K, the maps $R_2 \mapsto \mathsf{Res}_K(R_1 \to R_2)$ and $R_2 \mapsto \mathsf{ARes}_{k^-}(R_1 \to R_2)$ are monotone (order-preserving). They are also monotone in R_1 and in the coupling parameters.*

Remark 152 (What monotonicity means here)**.** *Monotonicity formalizes a simple but important ethical/epistemic constraint on the update rules: if R_2 already had* more *evidence (in either channel) than some R_2^*, then after resonance it should still have at least as much. In other words, adding evidence and then resonating should not perversely reduce what you had. This proposition says the update rules are "well-behaved" in precisely that minimal sense.*

Remark 153 (Connection to the rest of the document)**.** *This is the same monotonicity logic that underlies the sanity theorems in Section 4: weakness and pattern measures are intended to behave directionally under addition of structure. Here we ensure that the* dynamical *operators (resonance/anti-resonance) respect the same order-theoretic discipline, which becomes crucial later when iterating updates and taking fixed points.*

Proof. Each operator is built from pointwise $\oplus$ and $\otimes$, which are monotone in each argument with respect to the componentwise order on V. □

Proof sketch. The proof reduces the claim to a basic fact about the $\mathsf{p\text{-}bit}$ quantale: both $\oplus$ (join) and $\otimes$ (product) are order-preserving in each input. Since the update operators apply these operations pointwise on $X \times X$, the order-preservation lifts immediately from V to V-valued relations. □

Remark 154 (Why this matters conceptually)**.** *Order-preservation is the minimal algebraic substitute for the intuitive statement "resonance transports influence without making things worse by fiat." In paraconsistent settings, one often worries that allowing contradictory evidence will break basic reasoning. Monotonicity reassures us that the update dynamics at least respect the lattice structure that makes graded, nontrivial aggregation possible in the first place.*

Definition 34 (A simple habit-taking / habit-reversal statistic)**.** *To connect with the Hyperseed "tendency to take habits" definitions, we map a* p-bit *value* $v = (v^+, v^-)$ *to a single decision-biased probability via the truth-bias*

$$d(v) := v^+ - v^- \in [-1, 1], \qquad p_{\text{dec}}(v) \ := \ \frac{d(v) + 1}{2} \ \in [0, 1].$$

For a pattern P*, we define* $p_{\text{dec}}(P \mid R) := p_{\text{dec}}(S_R(P))$*.*

Remark 155 (Intuition and scope)**.** *This statistic is intentionally not presented as a universal "probability of truth." It is a* decision proxy*: a way of turning two-channel evidence into a single scalar that increases with net support and decreases with net opposition. One should read it as "if the system must act as if* P *holds, how disposed is it to do so?" This bridges the toy evidence algebra to the language of habit formation and reversal (Hyperseed-Concept 189, 188).*

Remark 156. *Morphic resonance tends to increase* $p_{\text{dec}}(P \mid R)$ *for patterns* P *supported in the source, while anti-resonance tends to decrease it by increasing opposition. This is the toy analogue of "tendency to take habits" versus "tendency to reverse habits".*

5.6 A concrete nontrivial instance reaching morphic resonance

We now specify concrete R_1 and R_2, compute weakness, show emergence via closure, and then show morphic resonance.

Example 1 (Initial relations in two contexts)**.** *Let* $X = \{a, b, c\}$ *and define symmetric relations* $R_1, R_2 : X \times X \to V$ *by setting the diagonal to* $e = (1, 1)$ *and*

$$R_1(a, b) = (0.90, 0.80), \quad R_1(b, c) = (0.85, 0.20), \quad R_1(a, c) = (0.10, 0.70),$$

$$R_2(a, b) = (0.20, 0.70), \quad R_2(b, c) = (0.30, 0.60), \quad R_2(a, c) = (0.10, 0.80).$$

Intuitively: C_1 *strongly supports* $a \sim b$ *(but with conflict), and supports* $b \sim c$*;* C_2 *is initially skeptical about all three pairwise identifications.*

Remark 157. *This is the smallest size where the closure phenomenon is nontrivial: with only two entities there is no room for a genuinely emergent third relation. With three entities, a two-edge chain can force an implied edge. So* $\{a, b, c\}$ *is the first stage where "emergence by composition" is visible.*

Example 2 (Weakness comparison)**.** *Use* μ *from Definition 26 and weakness from Definition 25. A short check shows:*

$$w(R_1) = (0.72, 0.80), \qquad w(R_2) = (0.16, 0.80).$$

Thus, in the bottleneck sense of Section 3.7, C_1 *is "weaker" (collapses a more important distinction) than* C_2*.*

Remark 158 (How to read the numbers)**.** *The positive weakness* 0.72 *for* C_1 *comes from combining (i) the strong positive indistinction* $R_1(a,b)^+ = 0.90$ *with (ii) the high importance weights* $\mu(a)^+ = 1$ *and* $\mu(b)^+ = 0.8$*. By contrast,* C_2 *never strongly supports an important collapse, so its positive weakness is small. The negative weakness being* 0.80 *in both contexts reflects that each contains at least one strongly opposed identification somewhere; since we used a bottleneck/max aggregator, a single strong opposition dominates.*

Example 3 (Emergence in C_1 via closure)**.** *Compute the closure* $\mathrm{Cl}(R_1) = R_1 \oplus (R_1 \circ R_1) \oplus \cdots$*. Because* X *has three elements, the first nontrivial emergent edge is* $a \to c$ *via* b*:*

$$(R_1 \circ R_1)(a,c) \;\geq\; R_1(a,b) \otimes R_1(b,c) = (0.90 \cdot 0.85,\; 0.80 \cdot 0.20) = (0.765,\; 0.16).$$

Joining with the direct edge $R_1(a,c) = (0.10, 0.70)$ *yields*

$$\mathrm{Cl}(R_1)(a,c) \;\geq\; R_1(a,c) \;\oplus\; \big(R_1(a,b) \otimes R_1(b,c)\big) = (0.765,\; 0.70).$$

So even though C_1 *initially had very low positive evidence for* $a \sim c$*, the compositional structure* $a \sim b$ *and* $b \sim c$ *causes* $a \sim c$ *to become strongly supported in the closure. This is a concrete toy instance of* emergence *as compositional implication.*

Remark 159 (Visual intuition)**.** *If one draws a triangle with vertices* a, b, c*, then* R_1 *begins with two thick edges (a–b and b–c) in the positive channel and a thin edge (a–c). Closure thickens the missing edge because the two-step walk* $a \to b \to c$ *provides an alternate route. In this toy quantale, the positive-channel strength of that route is the product of the two edge strengths.*

Example 4 (Morphic resonance transmission from C_1 to C_2)**.** *Let the coupling strength be*

$$K := (0.90, 0.90).$$

Apply the morphic resonance update (Definition 32):

$$R_2' := \mathsf{Res}_K(R_1 \to R_2) = R_2 \oplus (K \otimes R_1).$$

Compute, for example,

$$R_2'(a,b) = (0.20, 0.70) \;\oplus\; \big((0.90, 0.90) \otimes (0.90, 0.80)\big) = (0.20, 0.70) \;\oplus\; (0.81, 0.72) = (0.81, 0.72),$$

$$R_2'(b,c) = (0.30, 0.60) \;\oplus\; \big((0.90, 0.90) \otimes (0.85, 0.20)\big) = (0.30, 0.60) \;\oplus\; (0.765, 0.18) = (0.765, 0.60),$$

and

$$R_2'(a,c) = (0.10, 0.80) \;\oplus\; \big((0.90, 0.90) \otimes (0.10, 0.70)\big) = (0.10, 0.80) \;\oplus\; (0.09, 0.63) = (0.10, 0.80).$$

Thus C_2 *receives strong support for the* structure $a \sim b$ *and* $b \sim c$ *from* C_1 *even though the direct edge* $a \sim c$ *does not (yet) increase.*

Now close internally in C_2*:*

$$\mathrm{Cl}(R_2')(a,c) \;\geq\; R_2'(a,b) \otimes R_2'(b,c) = (0.81 \cdot 0.765,\; 0.72 \cdot 0.60) = (0.61965,\; 0.432).$$

Joining with the direct edge $(0.10, 0.80)$ *yields*

$$\mathrm{Cl}(R_2')(a,c) \;\geq\; (0.61965,\; 0.80).$$

So morphic resonance transmits the pattern skeleton *(the chain* $a \sim b$*,* $b \sim c$*), and then compositional closure produces the missing implied link* $a \sim c$*. This is a minimal toy model of "spatially separated habit taking":* C_2 *becomes disposed to instantiate the same cluster-pattern present in* C_1*.*

Remark 160 (What is being transmitted?)**.** *Notice that resonance did not directly increase* $R_2(a,c)^+$*, because the source itself had* $R_1(a,c)^+$ *small. What was transmitted was the* two-edge scaffold *that makes* $a \sim c$ *compositional. This is philosophically important: it models the transmission of a relational* form *rather than a single belief, which is closer to the intended "morphic" flavor (pattern-shape transfer) than naive copying of propositions.*

Example 5 (Pattern support and a habit-taking inequality)**.** *Let the pattern (constraint-set) be the chain*

$$P := \{(a,b),(b,c)\}.$$

Compute support using Definition 28. Intuitively, this pattern asks for a simultaneous "fit" of two links, $a \sim b$ *and* $b \sim c$*, so its support is a* p-bit*-valued conjunction of the two corresponding edge-values. In this toy* p-bit *quantale, the tensor* $\otimes$ *acts componentwise on* (t,f)*-pairs (so it behaves like a multiplicative "and" that propagates both positive and negative evidence along the chain).*

In C_1*:*

$$S_{R_1}(P) = R_1(a,b) \otimes R_1(b,c) = (0.765,\ 0.16).$$

In particular, the pattern-level positive support 0.765 *is the product of the two positive edge-scores in* C_1*, while the pattern-level opposition* 0.16 *is the product of the two edge-level opposition scores; hence a single weak link (small* t*) or a single strong objection (large* f*) can materially affect the combined pattern support.*

In C_2 *initially:*

$$S_{R_2}(P) = (0.20, 0.70) \otimes (0.30, 0.60) = (0.06,\ 0.42).$$

*Here the pre-update pattern has relatively low positive support (*0.06*) and comparatively high opposition (*0.42*), reflecting that both constituent constraints are, initially, not well-endorsed in* C_2*. It is sometimes helpful to look at the net inclination* $t - f$ *at the pattern level:*

$$(0.06 - 0.42) = -0.36,$$

which already indicates that the combined pattern is disfavored before any coupling.

After morphic resonance:

$$S_{R_2'}(P) = (0.81, 0.72) \otimes (0.765, 0.60) = (0.61965,\ 0.432).$$

So the resonance update has sharply increased the positive component of the pattern support (from 0.06 *to* 0.61965*) while leaving the negative component in the same general range (from* 0.42 *to* 0.432*). At the level of net inclination this changes the sign:*

$$(0.61965 - 0.432) = 0.18765,$$

so the same multi-constraint form moves from "overall opposed" to "overall favored" according to the simple difference $t - f$*.*

Using the decision probability from Definition 34,

$$p_{\mathrm{dec}}(P \mid R_2) = \frac{(0.06 - 0.42) + 1}{2} = 0.32, \qquad p_{\mathrm{dec}}(P \mid R_2') = \frac{(0.61965 - 0.432) + 1}{2} \approx 0.593825.$$

Recall that the affine rescaling $p_{\mathrm{dec}}(t,f) = \frac{(t-f)+1}{2}$ *maps the score* $t - f \in [-1,1]$ *to a number in* $[0,1]$*, so that equal support and opposition (*$t = f$*) corresponds to* $p_{\mathrm{dec}} = \frac{1}{2}$*, net support (*$t > f$*) yields* $p_{\mathrm{dec}} > \frac{1}{2}$*, and net opposition (*$t < f$*) yields* $p_{\mathrm{dec}} < \frac{1}{2}$*.*

Thus P becomes substantially more likely in C_2 after the resonance update. This is the toy analogue of Hyperseed's "tendency to take habits": the post-update probability is higher than the pre-update probability for a pattern supported elsewhere. In other words, a pattern that is already coherently instantiated in one context (C_1) can, under resonance, become easier to enact in a different context (C_2) even though C_2 initially opposed it at the multi-constraint level.

Remark 161. *In the language of graded habits, the inequality $p_{\mathrm{dec}}(P \mid R_2') > p_{\mathrm{dec}}(P \mid R_2)$ is the simplest possible signature of habit-taking: the system's disposition toward enacting a multi-constraint form increases after coupling. Note that, because the support is computed by chaining constraints with $\otimes$, the phenomenon is genuinely pattern-level rather than edge-local: one is not merely increasing confidence in a single relation, but increasing the likelihood that an entire small configuration is jointly satisfied. More sophisticated theories would track trajectories under repeated updates and study stability; this toy merely exhibits the direction of motion. One could also distinguish between (i) amplifying positive evidence for the pattern, (ii) reducing opposition to the pattern, and (iii) doing both; in the numbers above, the dominant contribution is (i), since the truth component jumps while the falsity component changes only mildly.*

5.7 Anti-resonance as habit reversal (tiny numeric demo)

Example 6 (Anti-resonance increases opposition and can reverse a habit)**.** *Let $k^- = 0.9$ and use ARes_{k^-} from Definition 33. Suppose C_2 has begun to accept $a \sim b$ with $R_2(a,b) = (0.60, 0.20)$, but a different context (or a new stream of evidence) provides strong opposition modeled as $R_1(a,b) =$* $(0.10, 0.90)$. *Conceptually, anti-resonance differs from resonance by selectively importing (scaled)* opposition *rather than support, so it acts like a controlled mechanism for "unlearning" or counter-conditioning without requiring that prior positive evidence be erased.*

Then

$$\mathsf{ARes}_{0.9}(R_1 \to R_2)(a,b) = (0.60, 0.20) \oplus \big((0, 0.9) \otimes (0.10, 0.90)\big) = (0.60, 0.20) \oplus (0, 0.81) = (0.60, 0.81).$$

Here $(0, 0.9) \otimes (0.10, 0.90) = (0, 0.81)$ illustrates the same componentwise multiplication as before: anti-resonance scales only the negative coordinate and passes no additional positive mass (the 0 in the first coordinate). Likewise, the join $\oplus$ acts componentwise as an aggregation of available evidence; in particular, the second coordinate increases from 0.20 to 0.81, capturing that the imported counter-evidence dominates the earlier, weaker opposition. Notice that the positive coordinate remains 0.60 throughout, so the update changes behavior by increasing conflict, not by deleting prior support.

The decision probability drops from

$$p_{\mathrm{dec}}(0.60, 0.20) = \frac{(0.40) + 1}{2} = 0.70 \quad \textit{to} \quad p_{\mathrm{dec}}(0.60, 0.81) = \frac{(-0.21) + 1}{2} = 0.395.$$

Equivalently, the net inclination shifts from $0.60 - 0.20 = 0.40$ (net support) to $0.60 - 0.81 = -0.21$ (net opposition), which is exactly the sense in which a "reversal" occurs in this graded setting: the sign of $t - f$ flips even though t itself does not decrease.

So anti-resonance can drive a reversal: a previously formed habit becomes less likely by importing opposition-to-the-pattern from elsewhere. In this way, ARes_{k^-} can be read as a minimal mathematical caricature of how external critique, adverse feedback, or a competing norm can suppress an emerging tendency by strengthening the "reasons against".

Remark 162 (A philosophical aside)**.** *In ordinary discourse, "reversal" sounds like negation: the mind flips from yes to no. In a paraconsistent setting, reversal is subtler: the system may keep its* *positive evidence while importing so much opposition that the net disposition changes sign. This resembles how real deliberation often feels: one does not forget the reasons* for*, but the reasons* against *become weightier. Formally, the point is that (t, f) is not collapsed to a single scalar before updating: the calculus allows t and f to vary semi-independently, so an agent can become less disposed to act even while retaining (and acknowledging) substantial supporting considerations.*

5.8 A tiny resonance score demo via paraconsistent interference

We now connect the above "transport of evidence" to a resonance score derived from the p-bit geometry.

Remark 163. *The goal of this subsubsection is to show that "resonance" can be read in two compatible ways:*

- *as an order-theoretic / quantale-theoretic propagation rule on evidence structures, and*
- *as a coherence or interference statistic after embedding evidence into a complex plane.*

This second reading echoes approaches that relate paraconsistent evaluation to oscillatory or resonant dynamics ([24]), but here it is presented only as a tiny computational demo.

Definition 35 (p-bit to complex mapping)**.** *Define $\sigma_{\mathbb{C}} : [0,1]^2 \to \mathbb{C}$ by*

$$\sigma_{\mathbb{C}}(w^+, w^-) := d + ic, \qquad d := w^+ - w^- \in [-1,1], \qquad c := (w^+ + w^-) - 1 \in [-1,1].$$

Here d is the truth-bias axis (net support vs net opposition) and c is the contradiction/ignorance axis.

Remark 164 (Geometric intuition)**.** *The map $\sigma_{\mathbb{C}}$ turns a* p-bit *value into a point in the complex plane whose real part d measures net inclination (support minus opposition), while the imaginary part c measures deviation from classical consistency. When $w^+ + w^- = 1$ (no "extra" evidence), we have $c = 0$ and the amplitude is purely real. When both channels are high, $c > 0$ and we move into the upper half-plane, marking contradiction. When both are low, $c < 0$ and we move into the lower half-plane, marking ignorance/indeterminacy. This gives a compact way to treat "truth" and "conflict" as orthogonal components.*

Definition 36 (Two-context interference (resonance) score)**.** *Given two complex amplitudes $z_1, z_2 \in \mathbb{C}$ and weights $w_1, w_2 \geq 0$ with $w_1 + w_2 = 1$, define*

$$\mathrm{Int}(z_1, z_2) := |w_1 z_1 + w_2 z_2|^2 - |w_1 z_1|^2 - |w_2 z_2|^2 .$$

Positive values indicate constructive interference (resonance), negative values indicate destructive interference (dissonance).

Remark 165 (What this formula measures)**.** *The quantity $|w_1 z_1 + w_2 z_2|^2$ is the squared magnitude of the combined amplitude. Subtracting $|w_1 z_1|^2 + |w_2 z_2|^2$ isolates the* cross term *that depends on relative phase. Thus $\mathrm{Int}(z_1, z_2)$ is zero when the two contributions are orthogonal in phase on average, positive when they align, and negative when they oppose. Interpreted back in* p-bit *terms: it measures whether two contexts "pull" in the same evidential direction after accounting for both bias and contradiction.*

Remark 166. *For $w_1 = w_2 = \frac{1}{2}$ one has*

$$\mathrm{Int}(z_1, z_2) = \frac{1}{2} \operatorname{Re}(z_1 \overline{z_2}).$$

So resonance is literally the (scaled) real part of the complex inner product, i.e. phase alignment.

Remark 167 (Why this is a reasonable toy resonance score)**.** *The interference score is not claimed as a final definition of resonance for the full theory. Its pedagogical value is that it is:*

- *symmetric in the two contexts,*
- *sensitive to both direction (truth-bias) and conflict (imaginary component),*
- *and continuous/graded.*

These are precisely the desiderata one wants when translating qualitative talk of resonance/dissonance into a computable diagnostic (Hyperseed-Concept 159, 97).

Example 7 (Resonance increases after morphic resonance update)**.** *Consider the single proposition "$a \sim b$" as evaluated in C_1 and C_2. Using Example 1 and Example 4:*

$$R_1(a,b) = (0.90, 0.80), \quad R_2(a,b) = (0.20, 0.70), \quad R_2'(a,b) = (0.81, 0.72).$$

Map to complex amplitudes via Definition 35:

$$z_1 = \sigma_{\mathbb{C}}(0.90, 0.80) = 0.10{+}0.70i, \qquad z_2 = \sigma_{\mathbb{C}}(0.20, 0.70) = -0.50{-}0.10i, \qquad z_2' = \sigma_{\mathbb{C}}(0.81, 0.72) = 0.09{+}0.53i.$$

With equal weights $w_1 = w_2 = \frac{1}{2}$:

$$\mathrm{Int}(z_1, z_2) = -0.06 \qquad \textit{(dissonant)},$$

while after the morphic resonance update,

$$\mathrm{Int}(z_1, z_2') = 0.19 \qquad \textit{(resonant)}.$$

Thus the same evidence-transport step that increases pattern support across contexts also increases an interference-derived resonance score.

One can likewise compute resonance for the pattern $P = \{(a,b),(b,c)\}$ *by using the pattern supports $S_{R_1}(P)$ and $S_{R_2}(P)$ from Example 5 and mapping those* p-bit *values through $\sigma_{\mathbb{C}}$. This again yields a negative interference score before morphic resonance and a positive one after, i.e. increased coherence at the level of the whole pattern-constraint.*

Remark 168 (What changed, structurally?)**.** *Before resonance, C_1 and C_2 assign almost opposite truth-bias to $a \sim b$: z_1 lies in the upper-right (net positive but conflicted) while z_2 lies in the lower-left (net negative and slightly ignorant). After resonance, z_2' rotates toward z_1 in both real and imaginary components. The increase in* Int *is thus a numeric witness that the contexts have become more phase-aligned on that proposition.*

Remark 169 (Toy moral)**.** *In this toy model, "morphic resonance" has two separable mathematical faces:*

1. *as a monotone, quantale-native evidence transport $R_2 \mapsto R_2 \oplus (K \otimes R_1)$ that increases pattern support across contexts without forcing consistency, and*

2. *as an increase in an interference-based coherence score after mapping* p-bit*s to complex amplitudes.*

This is exactly the bridge needed later in the paper: resonance is simultaneously a structural update in the ontology and a dynamical/energetic coherence signal.

Remark 170 (Where this is going)**.** *The toy computations show how a single algebraic move can produce: (i) transferred pattern scaffolds, (ii) emergent closure-completions, and (iii) increased coherence scores. Concretely, "transferred pattern scaffolds" can be read as the appearance of a reusable template: once a pattern is encoded as an algebraic element (or as a map between such elements), the same formal manipulation can be re-applied in a new location, effectively transporting structure along the available morphisms. In this sense the scaffold is not a new axiom but a consequence of how composition and order interact in the chosen algebra.*

Likewise, "emergent closure-completions" refers to the fact that passing to a closure (or completion) is often forced by the operations already present: an initially partial family of pattern-combinations can generate its own minimal fixed point under the closure operator, yielding a completed object in which previously missing joins/meets (or stable consequences) become available. Even when the starting data are intentionally finite and schematic, the closure step makes explicit the difference between "what is stipulated" and "what is entailed" by the algebraic rules.

Finally, "increased coherence scores" can be understood as the numerical or order-valued witness that the move has improved internal compatibility: after the transfer and closure, more constraints can be simultaneously satisfied, or the same constraints can be satisfied in a stronger way. In later sections, the same ideas are lifted to richer pattern spaces and iterated dynamics, where questions of stability, habit persistence, and controlled reversal become meaningful. Here "iterated dynamics" should be taken literally: repeating the move defines an update process, so one can ask whether repeated application converges to a fixed point, cycles among a small family of states, or bifurcates when parameters are changed. Correspondingly, "controlled reversal" anticipates the need for operations that can partially undo an update (or at least trace its provenance), so that one can distinguish irreversible closure effects from reversible transport effects. The present section should be read as the smallest "seed crystal" of that later structure. In particular, it isolates the minimal set of ingredients—a finite universe, an order-sensitive combination rule, and a coherence witness—so that later generalizations can be recognized as elaborations rather than as unrelated constructions.

Part I
Systematic reconstruction of Hyperseed concepts

6 Phenomenological primitives

Roadmap

This section turns the most primitive Hyperseed vocabulary into a small, typed interface. The guiding principle is that the primitives should be *structural* rather than verbal: the mathematics should remain invariant under renaming of symbols, choice of language, and (to a large extent) choice of representational format. In practice, "typed interface" means that each primitive comes with an explicit domain of application (what sort of experiential item it ranges over) and a codomain of evaluation (what sort of value it returns), so that later constructions can be checked for compositional well-formedness rather than defended only by prose. The intended effect is analogous to exposing an API: once the minimal signatures are fixed, alternative phenomenological stories can be layered on top without modifying the underlying formal objects. This is also why the early definitions are deliberately austere: the goal is not to capture every nuance of introspective report, but to isolate a stable core that is preserved across rephrasings, translations, and modeling choices.

Remark 171. *The philosophical stance here is deliberately Russellian in its demand for clarity: if two descriptions differ only by a renaming of symbols, then whatever is essential has not changed. But it is also Peircean in its tolerance for "signs" whose meaning depends on use: the same experiential content can be regimented differently in different contexts, without supposing that one regiment is the one true metaphysical grammar [14]. In the Hyperseed ontology [1], this structural emphasis is what permits a single formal core to underwrite multiple phenomenological and scientific readings. A useful way to reconcile these attitudes is to treat the formalism as fixing* invariants *(what must be preserved under admissible transformations), while leaving room for multiple* coordinatizations *(how those invariants are presented, narrated, or operationalized). Thus the text will repeatedly separate (i) the minimal algebraic or relational constraints that a primitive must satisfy from (ii) any particular interpretation in terms of language, imagery, embodiment, or cognitive architecture. The reader should therefore not expect the primitives to settle interpretive disputes; rather, they provide a common frame in which such disputes can be stated precisely as questions about which additional axioms, identifications, or equivalences are being assumed.*

We proceed in three steps. First we introduce *occasions of experience* as the basic carriers of primitive phenomenology, together with *contexts* that implement observer-relativity. Here "occasion" should be read neutrally as a minimal unit of phenomenal bearing (whatever ultimately plays the role of a token of experience in the theory), while "context" names the parameter that records the standpoint relative to which evaluations are made. The point of making context explicit is to prevent hidden shifts of reference: many apparent paradoxes about sameness or difference in experience dissolve once one distinguishes differences across occasions from differences induced by changing the evaluative frame. Second we define the core pairwise experiential relations (difference, distinction, repetition, variety, non-duality, non-dual variety) using p-bit-valued evaluations. The use of p-bit-valued outputs is meant to keep the interface flexible: it accommodates crisp/bivalent judgments as a special case, while also permitting graded, partial, or context-sensitive assessments without changing the type signature of the primitives. It also forces a discipline about what is being asserted: instead of saying "x and y are different" as an untyped slogan, one records *how* and *to what extent* a given context rates them as different, and one can later study how such ratings compose. Third we formalize the Peircean/Jungian numerical-metaphysical categories *First, Second, Third, Fourth* as an inductive ladder of relational constructions. The intended reading is that these categories are not introduced as mysterious primitives in their own right, but as progressively richer patterns that can be built from the earlier relational vocabulary (so that "Thirdness," for example, is expressed as a certain kind of mediated or triadic structure rather than a mere label). We conclude by formalizing *presentational immediacy* (intensity) and the *abstract/concrete* distinction. These closing notions serve two roles: they connect the relational core to phenomenological salience (why some distinctions matter more than others in lived experience), and they provide a handle for later passages where the theory must distinguish between structural descriptions and the more "felt" or "given" character of an occasion.

Hyperseed concepts covered

- Occasions of experience.
- Difference; distinction; repetition; variety; non-duality; non-dual variety.
- First; second; third; fourth.
- Presentational immediacy (intensity).
- Abstract/concrete.

The list above is meant as a contract with the reader: later sections will freely reuse these terms, but only after they have been pinned down here in a way that supports reparameterization by context and comparison across representational choices. In particular, each named relation will be introduced so that it can be applied uniformly to occasions across diverse modeling settings (introspective reports, cognitive architectures, or scientific proxies), with any domain-specific assumptions made explicit as additional structure rather than smuggled into the primitive itself.

6.1 Occasions and contexts

Hyperseed begins from *occasions of experience*: primitive experiential "atoms" that do not presuppose an external experiencer, except in the minimal sense that an occasion "is what it is" from its own inside. The mathematical reconstruction makes two moves that keep this notion precise without over-committing metaphysically:

1. We treat occasions as *objects* in a structure that only cares about identity *up to equivalence.*
2. We treat every act of distinction-making as *context-indexed* (observer-relative), implemented by explicit context data.

Definition 37 (Occasion space)**.** *An* occasion space *is a small* $(\infty, 1)$*-groupoid* $\mathcal{E}$*. Its objects* $\mathrm{Ob}(\mathcal{E})$ *are occasions. A 1-morphism* $f : o \to o'$ *represents an admissible "identification" or "transport" between occasions (e.g. recognizing the same thing under a change of viewpoint), and higher morphisms encode coherent equivalences between such identifications.*

In toy models one may replace $\mathcal{E}$ *by an ordinary groupoid, or even by a set* E *(regarding only equality), by applying the truncation* π_0*.*

Remark 172 (Intuition and examples for occasion spaces)**.** *This definition packages a simple idea: experience does not usually present us with an inflexible equality relation, but rather with a family of ways of* treating *two occasions as "the same enough." A groupoid is the algebraic prototype of this: objects are things, arrows are reversible identifications, and composition expresses chaining of identifications. The notation* $(\infty, 1)$ *indicates that we may also want to track identifications-between-identifications (and so on), because in many domains the* coherence *of how we identify things matters as much as the identification itself.*

A minimal example is a set E *of snapshots of sensory input, where the only identifications are equalities; this is the discrete groupoid case. A slightly richer example is a groupoid whose objects are images, and whose arrows are invertible transformations (e.g. rotations) that a perceptual system treats as preserving "the same object." The utility of the definition is that it gives us a disciplined place to put "sameness up to viewpoint" without prematurely choosing a metric, a probability model, or a logical theory. This is congenial to process views in the spirit of Whitehead, where the primitive units are occasions and their relations, not enduring substances [15].*

Remark 173 (Why $(\infty, 1)$?)**.** *Hyperseed uses language like "interchangeable in a context" and (later) "self-model recursion". These are naturally modeled using identity-up-to-equivalence rather than rigid equality. An $(\infty, 1)$-groupoid is the minimal formal object that (i) admits nontrivial identifications and (ii) keeps track of coherence of identifications. Nothing in the present section depends on advanced higher-categorical technology; we use the $(\infty, 1)$ language mainly to record that such coherence data* may matter *later.*

Remark 174 (Notation clarification)**.** *Here $\mathcal{E}$ denotes the occasion space;* $\mathrm{Ob}(\mathcal{E})$ *is the set (or class) of objects of $\mathcal{E}$; and a "1-morphism" $f : o \to o'$ should be read as a directed identification from o to o' (invertible up to higher structure in an $(\infty, 1)$-groupoid). The truncation π_0 is the operation that forgets higher identifications and keeps only connected components, i.e. "equivalence classes up to identification."*

Definition 38 (Contexts)**.** *A* context *(or viewpoint) is a tuple*

$$c := \big(X_c,\ \Pi_c,\ \delta_c,\ \iota_c\big)$$

where:

- X_c *is a set of* presented entities *(what the context treats as the "things" it can refer to);*
- $\Pi_c : \mathrm{Ob}(\mathcal{E}) \to X_c$ *is a* presentation map *(a coarse-graining of occasions into context-level entities);*
- $\delta_c : X_c \times X_c \to \mathbb{V}$ *is a* p-bit*-valued* distinctness evaluator*;*
- $\iota_c : X_c \times X_c \to \mathbb{V}$ *is a* p-bit*-valued* interchangeability evaluator.

We interpret $\delta_c(x, y)$ as evidence for/against the proposition "x and y are distinct (diverge)", and $\iota_c(x, y)$ as evidence for/against "x and y are interchangeable for the purposes relevant to c."

Remark 175 (Intuition, examples, and why contexts are necessary)**.** *A context c is the formal surrogate for "an observer-as-a-way-of-carving." The set X_c is what the context can even* name*; the map Π_c says which raw occasions are presented as which named entities; and the evaluators δ_c, ι_c say how the context judges difference and substitutability. This makes observer-relativity a matter of explicit structure rather than a vague proviso. It also makes room for paraconsistent judgments: a context may have simultaneously high evidence for "distinct" and high evidence for "not distinct," a point developed below using* p-bit *semantics (see also paraconsistent treatments such as [23, 24]).*

Remark 176 (Distinctness versus interchangeability)**.** *Although δ_c and ι_c are related in ordinary language, we do not assume that one is the logical negation of the other. In many practical situations a context can regard two entities as* distinct *(they differ in some tracked respect) while still treating them as* interchangeable *for the tasks at hand (the difference is irrelevant), and conversely it can regard two entities as* not distinct *in some coarse description while refusing to substitute one for the other (e.g. due to causal, temporal, or deontic constraints). Formally, allowing δ_c and ι_c to vary independently is what lets the framework represent "same object, different role" and "different object, same role" judgments without forcing a single equivalence relation to do all conceptual work.*

Remark 177 (Contexts as $\mathbb{V}$-valued relations)**.** *The evaluators δ_c, ι_c can be read as $\mathbb{V}$-valued binary relations on X_c. This viewpoint emphasizes that a context need not deliver crisp Boolean predicates but rather graded and potentially inconsistent evidence states, with $\mathbb{V}$ serving as the codomain of* *semantic values. In particular, one may later impose optional structural conditions (symmetry, reflexivity, transitivity up to evidence, etc.) when modeling a specific domain, but the present definition stays neutral: it merely provides a slot in which such constraints can be stated explicitly rather than smuggled in as informal assumptions.*

Definition 39 (Context-induced evaluations on occasions)**.** *Given a context $c = \big(X_c, \Pi_c, \delta_c, \iota_c\big)$, define the induced evaluators on occasions by*

$$\delta_c^{\mathcal{E}}(o, o') := \delta_c\big(\Pi_c(o), \Pi_c(o')\big), \qquad \iota_c^{\mathcal{E}}(o, o') := \iota_c\big(\Pi_c(o), \Pi_c(o')\big),$$

for $o, o' \in \mathrm{Ob}(\mathcal{E})$.

Remark 178 (What the presentation map is doing)**.** *The map $\Pi_c : \mathrm{Ob}(\mathcal{E}) \to X_c$ expresses the idea that a context does not have direct access to "raw occasions as such," but only to a quotient-like presentation into context-level entities. This is intentionally weaker than requiring that Π_c be invariant under all identifications in $\mathcal{E}$: an admissible identification $f : o \to o'$ in the occasion space need not be one that the context can or will recognize, and contexts may collapse distinctions that $\mathcal{E}$ retains (or refine them by remembering additional tags in X_c). In concrete models, one may nevertheless choose to impose compatibility conditions of the form "if o and o' are connected in $\mathcal{E}$, then $\Pi_c(o)$ and $\Pi_c(o')$ are judged highly interchangeable," but such requirements are part of a modeling choice rather than part of the primitive ontology.*

Remark 179 (Example patterns for contexts)**.** *Typical sources of context-dependence fit neatly into the tuple c: (a)* Resolution/attention: *X_c contains only the coarse entities available at a given resolution, with Π_c forgetting fine-grained differences between occasions; (b)* Coordinate/viewpoint choice: *Π_c factors out transformations the context treats as irrelevant, while δ_c may still register residual differences important for the task; (c)* Memory and identity-tracking: *X_c may include persistent labels ("the cup from earlier"), so that Π_c encodes a policy for binding new occasions to existing labels, and ι_c describes when substituting one label for another preserves predicted consequences. These examples illustrate why separating Π_c (what is presented) from δ_c, ι_c (how it is evaluated) is useful: the same coarse-graining can be paired with different evaluators depending on goals and background commitments.*

Remark 180. *A simple example is a vision context in which X_c is a set of tracked objects on a screen, Π_c maps pixel-level occasions to object IDs, δ_c scores how different two tracks are, and ι_c scores whether they can be swapped without changing the task outcome (e.g. two identical chess pawns in symmetric positions might be interchangeable for some purposes). Concretely, one can think of the underlying occasion space as a stream of low-level sensor events (frames, patches, keypoints, or other "glimpses"), while Π_c performs the role of a context-dependent binding/association rule that declares which of those low-level events count as evidence about which putative object. In that setting, δ_c is not required to be a metric in the strict mathematical sense; it is simply whatever evaluation the context treats as "difference-relevant," possibly combining appearance, trajectory, and role features into a paraconsistent value. Likewise, ι_c is best read as an invariance or symmetry score: it records whether exchanging two hypothesized entities preserves whatever objective or downstream action policy defines "the same outcome" for the current task. This allows the formalism to express both perceptual distinctions (two tracks are strongly non-identical) and practical equivalences (two tracks are distinct but functionally interchangeable), which need not coincide once observer goals are made explicit. The definition is useful because later notions (weakness/simplicity, patterns, resonance) require a stable place to anchor "who is distinguishing what, and under what rules" [5]. In particular, once later constructions quantify over repeated occasions, compressibility,* *or alignment across contexts, it becomes important that the act of "counting as the same thing" has been made an explicit, indexable datum rather than an implicit assumption. In Hyperseed terms, this is the structural backbone for Hyperseed-Concept 86 and Hyperseed-Concept 124.*

Remark 181 (Observer-relativity as explicit data)**.** *In this reconstruction, observer-relativity is not a philosophical afterthought; it is built in as explicit context-indexing. Different contexts can: (i) carve the same occasion space $\mathcal{E}$ into different entity sets X_c; (ii) disagree paraconsistently about whether two entities are distinct or interchangeable. The point of allowing (ii) is not merely to permit "uncertainty," but to permit structured coexistence of competing discriminations: a context may accumulate simultaneous evidence that two tracks are the same (e.g. perfect appearance match) and that they are not (e.g. mutually exclusive trajectories), without collapsing into triviality. This also clarifies that observer-relativity here includes both representational choices (what the observer treats as an entity at all) and normative choices (what differences are treated as relevant to a task, and what differences are ignored as symmetries). On this view, two contexts may share the same raw stream $\mathcal{E}$ yet implement different "grain sizes" by choosing different X_c and different binding maps Π_c, leading them to construct different object inventories from the same experiential substrate. This is the formal home for Hyperseed's claim that much of "ontology" is bookkeeping about which distinctions are made by which observers, and at what grain.*

Remark 182 (Notation clarification: $\mathbb{V}$ and p-bit-valued evaluations)**.** *The codomain $\mathbb{V}$ is the value space for paraconsistent evidence, intended to be the* p-bit *quantale (typically $[0,1]^2$ with a chosen order and monoidal product; cf. Section 3.4). When we write $\delta_c(x,y) \in \mathbb{V}$ we mean that $\delta_c(x,y)$ has (at least) two coordinates, often read as (positive-evidence, negative-evidence). Intuitively, this lets the model represent "evidence for difference" and "evidence against difference" (or, depending on the chosen polarity, "evidence for sameness" and "evidence against sameness") side by side, rather than forcing a single scalar that must trade one off against the other. Componentwise comparisons, multiplication-like combination $\otimes$, and join-like aggregation $\oplus$ then provide a disciplined calculus for combining experiential judgments. For example, if two independent cues both support distinctness, $\otimes$ can be used to accumulate that support; if two alternative cues provide competing routes to the same judgment, $\oplus$ can be used to aggregate them without prematurely discarding minority evidence. The need for this richer codomain shows up immediately when contexts are allowed to disagree or when binding is ambiguous: the system must be able to carry forward incompatible partial assessments until later constraints (task loss, additional observations, or higher-level regularities) resolve or compartmentalize them.*

6.2 Difference and distinction

Hyperseed distinguishes *difference* from *distinction*. Difference is directed: one occasion diverges from another. Distinction is symmetric: two occasions mutually diverge. In practice, the separation is useful because many cognitive and operational comparisons have an intrinsic "reference" (what is being compared *to*), even when ordinary language uses a symmetric phrasing. The context parameter c is intended to hold fixed the aspect, task, or perspective relative to which divergence is evaluated (e.g. perceptual modality, feature set, goal constraints, or a representational code), so that directedness is not conflated with merely changing evaluative criteria.

Definition 40 (Difference as a directed evaluation)**.** *Given a context c, define the* directed difference *evaluator*

$$\mathrm{Diff}_c(x \to y) := \delta_c(x,y) \in \mathbb{V}.$$

The positive channel $\mathrm{Diff}_c(x \to y)^+$ *is evidence that* x *diverges from* y*. The negative channel* $\mathrm{Diff}_c(x \to y)^-$ *is evidence that* x *does* not *diverge from* y *(e.g.* x *is absorbed into, explained by, or indistinguishable-from* y *along the relevant aspect).*

It is worth emphasizing that Diff_c is not assumed to be a metric, a distance, or even a preorder; it is simply an evaluator returning a p-bit-style evidential value. Accordingly, nothing in the definition forces $\mathrm{Diff}_c(x \to y)^+$ and $\mathrm{Diff}_c(x \to y)^-$ to be complements, and (in paraconsistent regimes) they may both be high, representing simultaneously strong reasons for divergence and strong reasons for non-divergence under different sub-aspects aggregated into the same context c. Conversely, they may both be low, representing insufficient evidence either way.

Remark 183 (Intuition and examples for directed difference)**.** *The directedness in* $\mathrm{Diff}_c(x \to y)$ *matters whenever "x differs from y" is not symmetric in the lived or operational sense. For instance, a coarse prototype* y *may "explain" a fine-grained observation* x *better than* x *explains* y*. In perception, a noisy instance may be well-absorbed into a clean template (low divergence of* x *from* y*) even though the template does not fit the instance in reverse (higher divergence of* y *from* x*) if the evaluators are aspect-sensitive.*

This definition is useful because it isolates the smallest unit in which "otherness" can appear: a directed contrast. It corresponds naturally to Hyperseed-Concept 96 and provides the raw material out of which symmetry (distinction), grouping (relations), and ultimately patterns are built [5]. A further way to read the direction $x \to y$ *is as "evaluate* x using y *as the comparator or explanatory basis": if* y *is a model, type, or hypothesis and* x *is a datum, then* $\mathrm{Diff}_c(x \to y)^+$ *expresses the degree to which the datum resists assimilation to the model, while* $\mathrm{Diff}_c(x \to y)^-$ *expresses the degree to which it is successfully covered by the model. This interpretation also clarifies why the negative channel is phrased as "does not diverge" rather than "is identical": absorption and explainability are often weaker (and more context-dependent) than identity.*

Remark 184 (Self-comparison and neutral cases)**.** *Although many applications will set* $\mathrm{Diff}_c(x \to x)^+$ *to be small and* $\mathrm{Diff}_c(x \to x)^-$ *to be large (reflecting the expectation that an occasion does not diverge from itself), the formalism does not require this. Allowing nontrivial self-difference can model temporal or perspectival drift (an "occasion" treated as a process with internal variation), sensor noise (a self-sample may not reproduce exactly), or representation mismatch (different encodings of "the same" occasion). When a context* c *is too coarse or too uncertain to decide,* $\mathrm{Diff}_c(x \to y)$ *may be near-indeterminate in both channels, which is precisely the situation later "weakness" notions are designed to register rather than forcibly resolve.*

Definition 41 (Distinction as mutual difference)**.** *Define the* (symmetric) distinction *evaluator by*

$$\mathrm{Dist}_c(x, y) := \mathrm{Diff}_c(x \to y) \otimes \mathrm{Diff}_c(y \to x),$$

where $\otimes$ *is the* p-bit *product from Section 3.4. Thus evidence that* x *and* y *are mutually distinct compounds multiplicatively (and likewise for evidence against mutual distinctness).*

Because $\otimes$ combines evidential values, Dist_c is best read as "joint support for two directed claims" rather than as an averaged similarity score. In particular, if either direction strongly fails (e.g. $\mathrm{Diff}_c(x \to y)^+$ is very low because x is thoroughly absorbed into y in context c), then the compounded support for mutual distinctness will typically be reduced. When $\otimes$ is commutative (as in standard p-bit constructions), $\mathrm{Dist}_c(x, y) = \mathrm{Dist}_c(y, x)$ holds automatically, aligning the formal object with the intended symmetric reading.

Remark 185 (Intuition and examples for distinction)**.** *The move from difference to distinction is the move from "x contrasts with y in this direction" to "x and y stand apart from each other." If one thinks geometrically,* $\mathrm{Diff}_c(x \to y)$ *is like a directed arrow recording mismatch; taking* $\mathrm{Dist}_c(x, y)$ *amounts to requiring mismatch in both directions and combining the two pieces of evidence via* $\otimes$*. In a crisp (non-paraconsistent) setting, one could imagine* $\mathrm{Diff}_c(x \to y)$ *as a Boolean; then* $\mathrm{Dist}_c(x, y)$ *reduces to conjunction.*

The definition is necessary because later measures of weakness and simplicity depend on how many distinctions a context fails to make. Distinction provides the symmetric "edge" concept needed for graphs, equivalence-like closures, and entropy-like measures such as graphtropy (cf. Hyperseed-Concept 98 and Hyperseed-Concept **??***). One can also view* Dist_c *as the minimal symmetry-enforcing operation applied to raw directed evaluations: rather than attempting to symmetrize by averaging or by taking a maximum,* $\otimes$ *encodes the idea that mutual distinctness is supported only to the extent that* both *directed divergences are supported together. This choice aligns with later graph-theoretic constructions, where an undirected edge typically represents a mutual relation that should not be present if either directed justification for separating the nodes is missing.*

Remark 186 (Paraconsistent readings of mutuality)**.** *Since values live in* $\mathbb{V}$*, mutuality can itself be conflicted: it is possible to have substantial evidence that x and y are distinct and, simultaneously, substantial evidence that they are not distinct (for example, two stimuli may differ in shape but be functionally interchangeable for the current task). Under* $\mathrm{Dist}_c(x, y) = \mathrm{Diff}_c(x \to y) \otimes \mathrm{Diff}_c(y \to x)$*, such conflicts can arise either from conflicts already present in one direction or from an interplay between directions (e.g. one direction supports divergence while the other direction supports non-divergence). This is not treated as a defect but as a faithful representation of contexts in which "making a distinction" is itself unstable, multi-aspect, or sensitive to what is taken as explanans versus explanandum.*

Remark 187 (Thresholding)**.** *To obtain a crisp "made distinction" relation (useful for counting, graphs, and later definitions of graphtropy), choose thresholds* $\tau_\delta, \tau_\iota \in (0, 1)$*. One may then declare:*

$$x \#_c y \iff \mathrm{Dist}_c(x, y)^+ \geq \tau_\delta.$$

Hyperseed frequently reasons at both levels: a fuzzy background of graded distinctions together with crisp distinctions induced by task needs. In applications, τ_δ *governs the willingness to treat weak positive evidence as sufficient to "separate" two occasions, and adjusting it changes graph density in the induced crisp distinction graph. The additional parameter* τ_ι *is naturally available for dual thresholding of the negative channel (e.g. to assert a crisp "indistinguishable" or "identified" relation when* $\mathrm{Dist}_c(x, y)^-$ *is large), allowing a context to support both separation and identification decisions with explicit, independent criteria when required by downstream constructions.*

Remark 188 (Notation clarification: channels and threshold parameters)**.** *When we write* $\mathrm{Dist}_c(x, y)^+$ *we mean the positive-evidence coordinate of the* p-bit *value* $\mathrm{Dist}_c(x, y) \in \mathbb{V}$*; similarly for* $^-$*. The thresholds* τ_δ, τ_ι *are real numbers in* $(0, 1)$ *used to turn graded evidence into crisp relations when needed. It is often helpful to keep in mind the typing discipline implicit here:* Diff_c *and* Dist_c *return objects of the same evidential type* $\mathbb{V}$*, while channel extraction* $(-)^+$ *and* $(-)^-$ *maps those objects to ordinary reals (or whatever ground scale* $\mathbb{V}$ *uses for each coordinate), which is why comparing to numerical thresholds is well-formed.*

6.3 Repetition, variety, non-duality, and non-dual variety

Beyond difference/distinction, Hyperseed elevates four additional pairwise experiential categories to the primitive level. In the present reconstruction, these are defined by combining (i) distinctness information and (ii) interchangeability information, both potentially paraconsistent. In particular, the intent is that a context may track not only "are these two presented as different?" but also "can one stand in for the other without loss for the currently salient purpose?"; the latter is a practical/operational relation rather than a purely perceptual one. Because both axes are evaluated with potentially incomplete and competing cues, it is important that the formalism can represent mixed evidence without forcing an immediate resolution.

Definition 42 (Soft interchangeability). *Given c, interpret $\iota_c(x,y) \in \mathbb{V}$ as a paraconsistent evaluation of interchangeability. We will often use its two channels as shorthand:*

$$\iota_c(x,y)^+ \text{ (evidence interchangeable)}, \qquad \iota_c(x,y)^- \text{ (evidence not interchangeable)}.$$

Remark 189 (Intuition and examples for interchangeability). *Interchangeability is not sameness. Two items can be distinct and yet substitutable for a purpose: two identical screws in a machine, two equivalent lemmas in a proof, or two tokens of a symbol-type. Conversely, two items can be nearly indistinguishable in raw perception and yet not interchangeable because of hidden constraints (one is a live wire, the other insulated). The paraconsistent reading allows both kinds of evidence to be present, which is often how real systems behave under partial information [23, 24].*

Formally, ι_c gives us a second axis beyond distinctness. This is useful because Hyperseed's later notions of pattern and emergence rely not only on detecting difference, but on discovering stable substitutions and invariances across contexts (Hyperseed-Concept 59 and Hyperseed-Concept 130).

Interchangeability should also be read as explicitly context-indexed: $\iota_c(x,y)$ can change when the operative goal, constraints, or "interface" changes. For example, two objects may be interchangeable with respect to mass distribution (balancing a scale) but not interchangeable with respect to provenance (authenticity, ownership, legal responsibility). Nothing in the primitive requires ι_c to be an equivalence relation: symmetry and transitivity may hold in some contexts (e.g. standardized parts) but can fail in others (e.g. substitutability under resource limits, one-way emulation, or asymmetric access rights). The paraconsistent two-channel representation is therefore meant to cover both well-behaved "mathematical" substitution and the more brittle substitutions encountered in empirical systems.

Definition 43 (Repetition and variety (threshold form)). *Fix thresholds $\tau_\delta, \tau_\iota \in (0,1)$. For $x \neq y$ in X_c define:*

$$\begin{aligned} \mathrm{Rep}_c(x,y) \quad &\iff \quad \mathrm{Dist}_c(x,y)^+ \geq \tau_\delta \text{ and } \iota_c(x,y)^+ \geq \tau_\iota, \\ \mathrm{Var}_c(x,y) \quad &\iff \quad \mathrm{Dist}_c(x,y)^+ \geq \tau_\delta \text{ and } \iota_c(x,y)^- \geq \tau_\iota. \end{aligned}$$

Intuitively, a repetition *is a pair that is experienced as distinct yet context-substitutable; a* variety *is distinct and non-substitutable.*

Remark 190 (Intuition and examples for repetition and variety). *A repetition is the lived form of "same pattern, different instance." Two distinct footsteps in sand may be distinct events (Dist_c^+ high) but interchangeable as tokens of one gait (ι_c^+ high). A variety is the contrary: the distinction matters. Two keys on a keyboard are distinct and not interchangeable if one is "Enter" and the other is "Escape" for the current task.*

These notions are useful because they separate mere multiplicity from structured multiplicity. Repetition is where compression begins: if many distinct things are interchangeable, a context can represent them with less descriptive effort, feeding directly into simplicity/weakness reasoning [3, 2]. Variety, by contrast, is where complexity is forced upon the system because substitutions break. This corresponds to Hyperseed-Concept 155 and Hyperseed-Concept 199.

It is worth emphasizing that the threshold presentation is a "crisping" of inherently graded judgments. The parameters τ_δ and τ_ι should be understood as knobs for when evidence becomes actionable for a context: in some regimes one may require near-certainty before treating two items as substitutable, while in others weak evidence may suffice. Because both Dist_c and ι_c have two channels, these thresholds can be used to carve out robust regions of decision even when the complementary channel is non-negligible; for instance, a system may classify $\mathrm{Rep}_c(x, y)$ based on $\iota_c(x, y)^+$ being high, while still retaining "residual" $\iota_c(x, y)^-$ as a warning that substitution is not unconditional. This separation between stored evidence (the p-bit valuation) and downstream categorization (thresholding) is part of what allows Hyperseed to represent pragmatic choice without losing contradictory or minority cues.

Definition 44 (Non-duality and non-dual variety (threshold form))**.** *Fix thresholds $\tau_\delta, \tau_\iota \in (0, 1)$. For $x \neq y$ in X_c define:*

$$\begin{aligned} \mathrm{NonDual}_c(x, y) \quad &\iff \quad \mathrm{Dist}_c(x, y)^+ \geq \tau_\delta \textit{ and } \mathrm{Dist}_c(x, y)^- \geq \tau_\delta, \\ \mathrm{NDVar}_c(x, y) \quad &\iff \quad \iota_c(x, y)^+ \geq \tau_\iota \textit{ and } \iota_c(x, y)^- \geq \tau_\iota. \end{aligned}$$

Thus non-duality *is "distinct and not-distinct" (paraconsistent distinctness), while* non-dual variety *is "interchangeable and not interchangeable" (paraconsistent substitutability).*

Remark 191 (Intuition and examples for non-duality and non-dual variety)**.** *Non-duality here is not a metaphysical decree that all things are identical; it is a disciplined way of representing a familiar phenomenological tension: the same pair can be simultaneously experienced as separate and as not-separate. In perceptual bistability (e.g. ambiguous figures), one may have strong evidence for two incompatible parsings. In social cognition, one may experience another person as "other" and yet as "part of me/us"; the formal point is that both channels can be high without forcing contradiction to trivialize the system [24].*

Non-dual variety likewise captures cases where substitution is both licensed and prohibited depending on which constraints are salient. For example, two roles in an organization may be interchangeable in a reporting chart but not interchangeable for legal responsibility. These definitions are useful because they prevent an overly classical ontology from erasing precisely the regimes where experience is richest: the zones where evidence does not settle into a single polarity (Hyperseed-Concept 121 and Hyperseed-Concept 120).

Non-dual variety can also arise in technical settings where multiple compatibility layers coexist. Two software modules may be interchangeable at the level of an interface (they implement the same signature, so ι_c^+ is high) yet not interchangeable at the level of non-functional constraints (performance, security policy, licensing, nondeterminism), yielding substantial ι_c^- as well. Similarly, in mathematics two proof steps might be interchangeable from the perspective of entailment, but not interchangeable from the perspective of constructive content, proof length, or allowed axioms; what counts as "salient" is again context-indexed, so it is natural that the evidence channels can both be high before a downstream agent commits to a choice.

Remark 192 (Non-duality as paraconsistency rather than collapse)**.** *A common mathematical temptation is to interpret "not-distinct" as strict equality. Hyperseed explicitly resists this: non-duality is not the claim that $x = y$ as symbols, but that experience supplies simultaneous evidence for and against the distinction. The* p-bit *semantics makes this precise: non-duality is simply a region of the square $[0, 1]^2$ where both channels are large. No logical explosion occurs because the logic is paraconsistent.*

The four primitives discussed in this subsection should not be read as mutually exclusive, nor as exhausting all possible evidence states. Because the underlying evidence is stored in two-channel form, it is possible (and often realistic) that $\mathrm{Rep}_c(x, y)$ holds while $\iota_c(x, y)^-$ is also nontrivial (a "normally safe" substitution with known caveats), or that $\mathrm{Var}_c(x, y)$ holds while $\iota_c(x, y)^+$ is also nontrivial (items are usually not substitutable, yet there are emergency procedures or partial substitutions). Likewise, non-duality in distinctness can co-occur with either repetition or variety judgments: one can have strong evidence for both distinction and non-distinction while also having a fairly settled stance on interchangeability (or vice versa). In this sense, $\mathrm{NonDual}_c$ and NDVar_c track tensions *within* a single evidence axis, whereas Rep_c and Var_c combine information *across* the distinctness and interchangeability axes.

A useful geometric picture is to treat each p-bit-valued predicate as placing the pair (x, y) at a point in $[0, 1]^2$ (one coordinate for positive evidence and one for negative evidence). Thresholding then selects regions: $\mathrm{NonDual}_c(x, y)$ corresponds to the "upper-right" region of the distinctness square, while $\mathrm{NDVar}_c(x, y)$ corresponds to the upper-right region of the interchangeability square. By contrast, $\mathrm{Rep}_c(x, y)$ and $\mathrm{Var}_c(x, y)$ are defined by combining one channel from the distinctness square (the positive channel) with one channel from the interchangeability square (positive or negative, respectively). This helps clarify why non-dual categories are not simply "in between" repetition and variety: they represent high-confidence conflict rather than low-confidence ambiguity.

Finally, there is a classical limit worth keeping in view. If, for a given context, the evidence is *nearly consistent* in the sense that $\mathrm{Dist}_c(x, y)^-$ is typically small whenever $\mathrm{Dist}_c(x, y)^+$ is large (and similarly for ι_c), then $\mathrm{NonDual}_c$ and NDVar_c will be rare, and the remaining categories behave more like classical dichotomies: distinct pairs separate into mostly interchangeable repetitions and mostly non-interchangeable varieties. Hyperseed retains the non-classical regimes not because they are always present, but because they become decisive precisely in settings involving partial observability, layered constraints, or competing interpretations—the same settings where pattern discovery and emergent structure are most informative.

6.4 First, Second, Third, Fourth

Hyperseed uses the numerical-metaphysical categories *First, Second, Third* (Peirce) and extends them with *Fourth* (synergy, Jungian "mandalic" structure). The key point for a rigorous ontology is that these are not mystical numerology; they are *structural levels* obtained by iterating a small set of constructions. Concretely, the intent is that each higher "number" is not an extra ingredient but a disciplined *closure step* on what came before: Firsts are carriers, Seconds are directed contrasts between carriers, Thirds are reusable organizations of such contrasts, and Fourths are higher-order organizations of multiple Thirds whose joint behavior is not reducible to separate consideration of each Third in isolation. This "iterated construction" view is what will allow later sections to treat phenomenological language as shorthand for precise mathematical objects and maps between them, rather than as a separate interpretive layer.

Remark 193. *Peirce's categories are often presented as metaphysics [14], but they are equally well read as an austere typology of how relations enter experience: firstness as suchness, secondness as reaction, thirdness as mediation/law. Hyperseed's maneuver is to make this typology operational: we identify canonical mathematical carriers for each level, so that later theorems can depend on them without importing any particular spiritual vocabulary [1]. A further benefit of making the carriers explicit is that one can compare different contexts c by comparing their associated carrier-sets X_c and the maps between them; in other words, the Peircean ladder becomes compatible with ordinary mathematical practices of translating structures across domains (e.g. from perceptual contexts to linguistic contexts) without presuming that the underlying "stuff" is the same.*

6.4.1 A minimal inductive ladder

The ladder below is "minimal" in the sense that each step adds only as much structure as needed to express the corresponding Peircean intuition. In particular, nothing forces Diff_c, V, or $\mathrm{Synergize}_c$ to have any special form beyond what is required for subsequent constructions; the framework is designed so that one may instantiate them with metrics, divergences, logical orderings, probabilistic scores, or other application-specific choices as long as they fit the declared types.

Definition 45 (Firsts)**.** *For a context c, a* First *is an entity $x \in X_c$ considered* without relating it *to anything else. Operationally, it is the unit of description before any distinctions are made.*

Remark 194 (Intuition and examples for Firsts)**.** *A First is the bare "this-such" prior to comparison: a tone as heard before labeling it as higher than another, a patch of red before classifying it as stop-sign, a number-symbol "17" before embedding it into arithmetic structure. In formal terms, it is just an element of X_c, but the point is methodological: we allow ourselves to speak of entities even when no relational judgments have yet been asserted about them.*

This is useful because it separates existence-in-a-context from structure-in-a-context. Many later constructions (weakness, abstraction, patterns) talk about how relations over X_c behave; identifying Firsts as the carriers of later relations keeps the levels clean (Hyperseed-Concept **??***). It is also helpful to read X_c as a* typed *carrier: the context c fixes what counts as an admissible "atom of discourse" at all (pixels, tokens, hypotheses, actions, etc.), and the subsequent ladder then describes increasingly structured ways of speaking about those admissible atoms, rather than silently changing the underlying domain midstream.*

Definition 46 (Seconds)**.** *For a context c, a* Second *is a directed difference event, i.e. an ordered pair $(x, y) \in X_c \times X_c$ together with its directed difference evaluation $\mathrm{Diff}_c(x \to y)$. Seconds are the smallest units at which "reaction" or "opposition" can be represented.*

Remark 195 (Intuition and examples for Seconds)**.** *A Second is what appears when a First meets resistance: "this is not that," "I cannot substitute this for that," "this pushes back." The ordered pair (x, y) records directionality: x can fail to fit y even if y fits x in some aspect-sensitive sense. In a predictive setting, one may read a Second as the primitive discrepancy between a model state and an observation.*

The definition is useful because it makes explicit the granularity at which "difference" lives: not as a global property of a system but as a local, typed datum that can later be aggregated into Thirds (relations) and Fourths (synergistic webs). This aligns with Hyperseed-Concept 163 and Hyperseed-Concept 163. One can think of $\mathrm{Diff}_c(x \to y)$ as an annotation on the arrow $x \to y$: depending on the application, it may be a real-valued cost, an element of an ordered evidence lattice, a probability of mismatch, or a logical witness of incompatibility. The only commitment at this stage is that the evaluation is part of the Second, so that later operations have access to both the fact of pairing *(x, y) and the* strength/character *of the directed contrast.*

Definition 47 (Thirds)**.** *For a context c, a* Third *is a* grouping of Seconds*. Concretely, we model a Third as a (possibly fuzzy) relation*

$$R : X_c \times X_c \to V,$$

where V is a commutative quantale as in Section 3.4. In the simplest crisp case, a Third is just a subset $R \subseteq X_c \times X_c$.

Remark 196 (Intuition and examples for Thirds). *If Seconds are individual dyadic events, then a Third is a policy, a rule, or a stable pattern of such events: "whenever x is of type A and y is of type B, treat them as distinct," or "these pairs are usually interchangeable." In the crisp case, a Third is literally a set of ordered pairs; in the V-valued case it is a graded and potentially paraconsistent assignment of evidence to each pair.*

The usefulness is twofold. First, Thirds are composable: relations can be combined, closed, propagated, and compared—all operations that become central in later discussions of patterns and emergence [5]. Second, Thirds are where weakness/simplicity naturally lives: weakness measures are aggregations over relations of which distinctions are left unmade [3, 2] (Hyperseed-Concept 190 and Hyperseed-Concept 132). It is worth emphasizing why the codomain V is taken to be a quantale: it supports a join operation (for pooling/merging evidence across sources) and a monoidal product (for chaining/propagating relational strength), so that one can later model both "either of these reasons supports the relation" and "these reasons compose along a path" in a uniform algebraic language.

Remark 197 (Relation-as-Third). *This choice is deliberately aligned with the observation that "a relation is a set of ordered pairs grouped together." The mathematical point is that the move from Second to Third is the move from isolated dyadic differences to a reusable* schema *of dyadic differences. This becomes the backbone for later constructions: patterns, rules, causal links, and interpretive frames all live at the level of Thirds. Equivalently, Seconds correspond to* tokens *of interaction, while Thirds correspond to* types *(or stable regularities) extracted from many such tokens; this token/type distinction is one of the simplest ways to see how "lawlike mediation" can be implemented without positing any additional metaphysical substance beyond the data of directed contrasts and their organization.*

Definition 48 (Fourths). *A* Fourth *is a higher-order grouping that joins multiple interconnected Thirds into a larger web in a way that can create emergent "whole is greater than the parts" behavior.*

Formally, let Thi_c denote a chosen class of Thirds (e.g. V-valued relations on X_c with finite support). A Fourth is specified by a finite diagram D in Thi_c (a network of relations together with chosen overlap maps), together with a chosen composite/colimit-like operation

$$\mathrm{Synergize}_c(D) \in \mathsf{Thi}_c.$$

The degree of Fourthness (synergy) of D is then measured by an emergence functional *(defined precisely in Section 9) comparing the "intensity" of* $\mathrm{Synergize}_c(D)$ *to the intensities of the individual relations in D.*

A diagram D should be read as more than a mere set of Thirds: the overlap maps encode how the component relations are intended to *share* variables, subdomains, or intermediate identifications, i.e. where one relation's "output" becomes another relation's "input" or constraint. In concrete applications, $\mathrm{Synergize}_c(D)$ may be instantiated as a closure operation, a pushout/pullback-like construction, an inference step that propagates constraints across the network, or any other principled mechanism that produces a new Third capturing what is jointly implied by the entire configuration. This is also the sense in which the Jungian "mandalic" image is meant: not a claim about symbolism, but a reminder that Fourths are characterized by *global coherence* arising from a structured interlocking of multiple mediations rather than from any single dyadic interaction or single law taken alone.

Remark 198 (Intuition and examples for Fourths). *A Fourth is where "mere aggregation" becomes "organization." Said differently, a Fourth is not just "many Thirds at once" but a* joint constraint system *in which the participating Thirds co-determine what counts as admissible structure. If each Third is a relational lens (a rulebook, constraint-set, or association pattern), then a Fourth is a structured conjunction of lenses whose interaction yields consequences none had in isolation. In particular, the interaction is not merely logical conjunction at the level of predicates; it includes a* chosen mode of interaction *(a way the lenses compose, interfere, reinforce, or propagate along each other).*

In a toy model, take two relations R_1 and R_2 and close them under a composition rule; the closure may entail new pairwise links, and those entailments are precisely the mathematical shadow of "emergence." Concretely, if R_1 and R_2 are viewed as permitted transitions, then closing under composition asserts that multi-step transitions are also permitted, producing new edges (x, z) from paths $(x, y) \in R_1$ and $(y, z) \in R_2$. Even when R_1 and R_2 are each individually sparse or locally meaningful, their combined closure can produce global connectivity patterns, equivalence classes, or invariants that were not readable from either relation alone.

This definition is useful because it is flexible while still principled: by making a Fourth a diagram plus a chosen universal-like composition, we ensure that Fourthness is not a vague adjective but a reproducible construction. The "diagram" component specifies which *Thirds are present and how they overlap or are glued; the "composition" component specifies* how *information is allowed to flow across that overlap. As a result, Fourthness can be tested by checking whether the composite object supports new entailments, new conserved quantities, or new effective rules that are stable under the chosen composition.*

It directly anticipates later pattern/emergence formalisms (Hyperseed-Concept **??** *and Hyperseed-Concept* **??***) and aligns with Hyperseed's emphasis on synergy as a core engine of intelligence [19]. In that framing, Fourthness is the minimal formal layer at which "synergy" becomes something we can compute, compare across contexts, and reason about via functorial or closure properties rather than by informal appeal to holism.*

Remark 199 (Why the definition is "diagram + composition")**.** *Hyperseed's description of Fourthness emphasizes* embedding *a local network of relations into a broader web. This emphasis is important: the same local Third can behave very differently when placed inside different ambient relational environments, because the ambient links provide additional paths of inference, constraint propagation, or coordination. In category theory, "a local network of composable pieces plus an embedding into a larger web" is naturally represented by a diagram and a universal construction (colimit, pushout, Kan extension, etc.). The diagram records the local pieces and their interface maps, while the universal construction enforces that the resulting composite is the* most general *object compatible with those interfaces (or, depending on direction, the* best approximation *living in a target category). This is precisely the categorical way to ensure that the composite object depends on the parts only through their specified relationships, rather than through arbitrary presentation artifacts.*

We keep the definition abstract here because different applications suggest different concrete choices of diagram shape and composition law. For example, when relations represent constraints, a colimit-like construction captures gluing constraints together; when relations represent observations, a Kan extension-like construction can express how local observations induce global predictions; and when relations represent rewrites or proofs, closure under a proof calculus implements the intended notion of inferential completion. The intended invariance is: if two diagrams are isomorphic (or equivalent up to the relevant notion of equivalence in context), their synergized outputs should be correspondingly equivalent, so that Fourthness behaves stably under re-indexing and re-description.

Remark 200 (Notation clarification: Thi_c and D)**.** *The symbol* Thi_c *is not a new axiom but a placeholder for "whatever collection of Thirds we are willing to manipulate in context c" (e.g. finite-*

support relations, measurable relations, etc.). The point of leaving Thi_c *schematic is that Fourthness should not depend on a single privileged substrate: one can instantiate Thirds as binary relations, weighted relations, stochastic kernels, logical theories, constraint graphs, or other relational objects, provided the context supplies a sensible notion of combination. In practice, the context c encodes what counts as an entity, what counts as a relation over entities, and what operations (composition, closure, saturation) are admissible or computable.*

A "finite diagram D in Thi_c*" means a finite indexing shape (a small finite category) together with an assignment of an object of* Thi_c *to each node and overlap maps along arrows. Here "finite" is primarily a technical convenience: it guarantees that the specified pattern of interaction is bounded and can be treated as a discrete schema, which is particularly relevant for computational implementations and for avoiding size issues. The "overlap maps" should be read as interface constraints: they specify how one Third is to be matched against another (e.g. shared variables, shared subrelations, restriction maps, or inclusion of a common substructure).*

The operation $\mathrm{Synergize}_c$ *is then a chosen way to combine the diagram into a single Third. It is useful to think of* $\mathrm{Synergize}_c$ *as a context-dependent "completion" or "fusion" operator: it takes multiple partial lenses and returns a single lens that reflects what is jointly implied once they are allowed to interact by the chosen rule. Depending on the application,* $\mathrm{Synergize}_c$ *may be idempotent (a closure operator), may be monotone with respect to refinement of diagrams, and may satisfy naturality properties under change of context, but these are additional structure one may impose later rather than assumptions built into the notation.*

6.4.2 A concrete set-theoretic model (optional)

Example 8 (Set-theoretic First–Fourth ladder)**.** *Fix a context c with entity set X_c. Define*

$$\begin{aligned}
\mathsf{First}_c &:= X_c,\\
\mathsf{Second}_c &:= X_c \times X_c,\\
\mathsf{Third}_c &:= \mathcal{P}(X_c \times X_c),\\
\mathsf{Fourth}_c &:= \mathcal{P}(\mathsf{Third}_c) \ \textit{(families of relations)}.
\end{aligned}$$

This ladder is intentionally coarse-grained: it treats a Third as a plain subset of pairs, so that the only built-in structure is membership. Even so, it already separates (i) entities, (ii) raw dyadic interactions, (iii) stabilized patterns of interaction (relations), and (iv) ensembles of such patterns.

A "synergy" operator might map a family of relations $\{R_i\}$ to their closure under a composition rule (e.g. relational composition, transitive closure, or closure under a proof calculus). For instance, one may define

$$\mathrm{Synergize}_c(\{R_i\}) \ := \ \mathrm{cl}\Big(\bigcup_i R_i\Big),$$

where cl *is a chosen closure operator (transitive closure, reflexive-transitive closure, or a domain-specific saturation procedure). The key point is that the closure is not merely union: it adds whatever the rulebook says must follow from jointly having those relations available.*

The resulting closure typically contains entailments that were not present in any single R_i. In graph language, new edges appear because multi-edge paths become single-step consequences under the closure rule; in logic language, new theorems appear because premises from different R_i can be combined in a single derivation. This is the simplest rigorous picture behind "the whole is greater than the parts." It also exhibits a minimal notion of "organization": the output relation can encode higher-level regularities (e.g. connectivity components, reachability, or induced equivalences) that effectively act like emergent macroscopic features of the system.

Remark 201 (Why include the set-theoretic model)**.** *The optional ladder is a sanity anchor: it shows that the definitions do not require higher category theory to be meaningful. It also makes explicit which step introduces which kind of structure: moving from* Second_c *to* Third_c *is the shift from* individual interactions *to* patterns *of interaction, while moving from* Third_c *to* Fourth_c *is the shift from* one pattern *to* interacting patterns*. Even in this elementary setting, the conceptual point survives: Fourthness corresponds to closure/interaction effects among multiple relations. Moreover, one can already ask meaningful questions such as: when does synergizing preserve symmetry, when does it generate equivalence relations, and when does it create long-range dependencies that were absent from the input family?*

This is also the simplest place to test computational toy models before lifting to enriched or higher-categorical settings [5]. For example, one can implement $\mathrm{Synergize}_c$ *as a saturation loop, measure the growth of the closure as a function of input family size, and compare different closure rules as different hypotheses about what kind of "synergy" a given domain supports. Such experiments help distinguish effects that are artifacts of representation from effects that persist under more abstract formulations.*

6.5 Presentational immediacy and intensity

Hyperseed treats presentational immediacy as a primitive correlate of "raw consciousness": some occasions are foreground, others background, and this distinction is fuzzy. We model this fuzziness as a context-indexed salience (intensity) field. In particular, the index c is meant to cover whatever factors jointly determine "what it is like right now": task demands, bodily state, sensory modality, memory activation, and ongoing control state. Nothing in this subsection presumes that the salience assignment is stable across time, agents, or tasks; it is explicitly permitted (and expected) that I_c changes as the context changes.

Definition 49 (Presentational immediacy)**.** *A* presentational immediacy *function in context c is a map*

$$I_c : X_c \to [0,1].$$

If $I_c(x)$ is near 1, x is in the foreground of experience in c. If $I_c(x)$ is near 0, x is in the background.

The choice of codomain $[0,1]$ is a normalization convention rather than an ontological claim that salience is intrinsically bounded. It allows comparisons within a context and makes later constructions (e.g., thresholds, resource budgets, and weighted graphs) notationally simple. Importantly, I_c is not intended to be a probability, and no additivity constraints are imposed; multiple entities may simultaneously have high immediacy. Similarly, we do not require $\max_{x\in X_c} I_c(x) = 1$ (although one may impose such a gauge-fixing in specific models), because contexts may differ in overall "vividness" or saturation.

Remark 202 (Intuition and examples for presentational immediacy)**.** *The function I_c is the formal shadow of the commonplace fact that experience has a figure/ground structure. While staring at a page, the letters are foreground; the pressure of one's feet is fringe; the hum of distant traffic may be nearly absent. The map $I_c : X_c \to [0,1]$ is intentionally modest: it asserts only that a context can assign graded salience to its presented entities.*

This definition is useful because it provides a primitive quantity that later theories can explain rather than assume. In later sections, intensity will be connected to effort, resource allocation, and attention dynamics (Hyperseed-Concept 138 and Hyperseed-Concept 60; see also [19] for related cognitive resource themes).

A further virtue of treating immediacy as a field over X_c is that it can, in principle, be applied uniformly across heterogeneous kinds of presented entities. For example, X_c may contain perceptual items (a letter-shape), interoceptive signals (heart rate sensations), affective tones (unease), action affordances ("turn the page"), and memory fragments (a recalled phrase). The same formalism covers all of these without committing to a single representational format. This is one reason the definition is kept at the level of a simple map rather than, say, a modality-specific vector or a hand-built attentional structure.

Remark 203 (Foreground/background is not (yet) attention)**.** *Later (Section 8 and onward) we will connect intensity to effort/energy expenditure and obtain attention as a dynamical/resource concept. Here we keep intensity primitive: it is an observational datum about what is "present" and with what degree.*

It is also useful to distinguish immediacy from related but nonidentical notions that often travel under the same name in informal discussions. For instance, an item may be highly immediate because it is perceptually intrusive (a loud bang), even if it is not selected for deliberate manipulation or report; conversely, an item may be the target of deliberate control (a rehearsed intention) while remaining phenomenologically "thin" compared to vivid sensory input. By separating (i) a phenomenological grading I_c from (ii) later dynamical and computational mechanisms, Hyperseed leaves room for models in which selection, report, working memory access, or executive control can dissociate from subjective vividness.

Definition 50 (Focus and fringe)**.** *Given a threshold* $\tau_I \in (0,1)$*, define the* focus set

$$\mathrm{Focus}_c(\tau_I) := \{x \in X_c : I_c(x) \geq \tau_I\},$$

and the fringe set

$$\mathrm{Fringe}_c(\tau_I) := \{x \in X_c : 0 < I_c(x) < \tau_I\}.$$

These are coarse operationalizations of the fuzzy foreground/fringe distinction.

Note that $\mathrm{Fringe}_c(\tau_I)$ explicitly excludes entities with $I_c(x) = 0$. This leaves open two common interpretations, both compatible with the present formalism: either (i) $I_c(x) = 0$ designates entities not presented at all in context c (outside the lived field), or (ii) it designates entities presented so weakly that they are functionally negligible for the purposes at hand. Which interpretation is appropriate can be fixed later when X_c and the mechanisms generating I_c are specified more concretely.

Remark 204 (Intuition and examples for focus/fringe thresholding)**.** *The threshold τ_I is a pragmatic bridge between graded phenomenology and discrete computation. For instance, a system may allocate symbolic reasoning only to elements in* $\mathrm{Focus}_c(\tau_I)$ *while allowing statistical/background processes to operate on* $\mathrm{Fringe}_c(\tau_I)$*. Different tasks warrant different thresholds; this is one reason Hyperseed keeps thresholding explicit rather than implicit.*

The definition is useful because many later constructions (graphs of salient entities, resource budgets, bounded planning) require finite or crisp sets even when the underlying salience is continuous. This is a standard move in cognitive architectures [19].

In practice, one may treat τ_I as a tunable interface parameter between phenomenology and computation. A high threshold yields a narrow "spotlight" that supports fast, low-branching deliberation; a lower threshold yields a broad set that supports integrative or exploratory processing at the cost of increased combinatorics. Because τ_I is explicit, the theory can later describe adaptive policies (e.g., lowering τ_I under uncertainty, raising it under time pressure) without changing the underlying meaning of I_c. One can also define multiple thresholds (e.g., $\tau_I^{(1)} > \tau_I^{(2)}$) to obtain layered bands of salience, but the single-threshold version already captures the minimal coarse-graining needed for many constructions.

Finally, although the present definitions are pointwise, they are compatible with temporal refinements. If contexts are indexed by time (or contain a time parameter), then c and c' at nearby moments may induce fields I_c and $I_{c'}$ whose changes describe shifts of lived salience. Later dynamical models can then constrain the rate or cost of such shifts (e.g., inertia in salience, hysteresis under fatigue) while preserving the basic primitive notion introduced here.

6.6 Abstract and concrete

Hyperseed distinguishes abstract experiences (e.g. the number 17) from concrete experiences (e.g. kicking a brick), while emphasizing that the same "content" may sometimes be experienced with more concreteness under unusual states. For a rigorous ontology, we need a notion of abstractness/concreteness that is: (i) context-relative, (ii) compatible with graded intensity, and (iii) compatible with the weakness/simplicity formalism. In particular, "abstract vs. concrete" here is not treated as a property of an isolated symbol or proposition, but as a property of how some collection of experienced tokens is organized *within a context* (what distinctions the context makes salient, which equivalences it tolerates, and which discriminations it refuses to carry out). This is why the definitions below are phrased in terms of maps out of X_c, rather than in terms of an intrinsic "abstractness score" assigned to a content in isolation. The graded aspect (ii) will be represented indirectly: one can move along chains in the abstraction preorder, or consider degrees of refinement/coarsening, rather than requiring a single scalar that must fit every use-case.

Remark 205. *This section's definitions deliberately echo a long-standing mathematical habit: abstraction is quotienting. To abstract is to identify; to concretize is to refuse identification unless constraints are satisfied. The point is not to reduce phenomenology to set theory, but to give a clean interface between lived categories (abstract/concrete) and later formal tools (weakness, effort, compression). See Hyperseed-Concept 51 and Hyperseed-Concept 83. A practical reading is: an "abstract experience" is one in which many token-level variations are treated as irrelevant (and therefore collapsed), whereas a "concrete experience" is one in which the system maintains, attends to, or is compelled by distinctions among tokens that might otherwise be quotiented away. On this view, unusual states can make the same nominal content feel more concrete by effectively refining the relevant context c (enlarging X_c and/or making finer discriminations available), so that fewer identifications are tolerated without experiential "error" or friction.*

6.6.1 Abstraction as quotienting of distinctions

Definition 51 (Abstraction as a quotient)**.** *Let c be a context with entity set X_c. An* abstraction *of c is a surjection*

$$q : X_c \twoheadrightarrow A$$

to a set of abstracta A. The abstraction collapses distinctions by identifying elements of the same fiber. Equivalently, q determines an equivalence relation

$$x \sim_q y \iff q(x) = q(y).$$

In this sense, the abstractum $a \in A$ can be read as the "type" corresponding to the entire equivalence class $q^{-1}(a) \subseteq X_c$ of concrete tokens that are treated as interchangeable for the purposes of the context.

Remark 206 (Intuition and examples for abstraction-as-quotient)**.** *The surjection $q : X_c \twoheadrightarrow A$ says: "many concrete tokens map to one abstract type." For example, take X_c as handwritten glyphs and let A be the set of letters; then q sends each glyph to the letter it instantiates, collapsing distinctions among different handwriting styles. Or let X_c be physical trajectories of balls and let A be a coarse state descriptor (position rounded to a grid), collapsing micro-differences.*

This definition is useful because it expresses "collapsing distinctions" in a way that composes: two abstractions can factor through one another, and the induced equivalence relations can be ordered. It connects directly to weakness: collapsing more distinctions increases undistinguished pairs, hence increases weakness in the sense used elsewhere [3, 2] (Hyperseed-Concept **??** *and Hyperseed-Concept 202). One can also read q as a formalization of an* invariance*: the map forgets differences along directions the context treats as irrelevant. In the glyph example, stylistic variation (stroke thickness, slant) becomes an "ignored degree of freedom," while in the trajectory example, micro-physical perturbations become ignorable, leaving only a coarse descriptor. This aligns with the phenomenological claim that abstraction often feels like "stability under variation": what is preserved by q is what the experience treats as the same.*

Definition 52 (Abstraction preorder)**.** *Given abstractions $q_i : X_c \twoheadrightarrow A_i$, define*

$$q_1 \preceq q_2 \quad \iff \quad \exists\, r : A_1 \to A_2 \text{ with } q_2 = r \circ q_1.$$

Thus q_2 is at least as abstract as q_1 when it factors through q_1 (i.e. collapses at least as many distinctions). Equivalently, $q_1 \preceq q_2$ means that every q_1-fiber is contained in a q_2-fiber, so the partition of X_c induced by q_2 is a coarsening of the partition induced by q_1.

Remark 207 (Intuition and examples for the abstraction preorder)**.** *The preorder $\preceq$ formalizes "is no less abstract than." If $q_2 = r \circ q_1$, then whatever identifications q_1 makes, q_2 makes them as well (and possibly more). For instance, in image recognition one might first quotient by viewpoint to get object identity (q_1), and then quotient object identities by category to get "animal vs. vehicle" (q_2). Then $q_1 \preceq q_2$ because category forgets more.*

This is useful because it gives a rigorous notion of abstraction order *without requiring a numeric scale. Later, when we attach cost/effort to abstraction, the preorder provides the qualitative backbone for those quantitative refinements. It is also useful that $\preceq$ is only a preorder: two different surjections can induce the same equivalence relation (e.g. via different codomains A_i that merely relabel classes), so antisymmetry need not hold at the level of functions even when the induced partitions are identical. If desired, one can pass to equivalence classes of abstractions under mutual factorization, yielding a partial order isomorphic to the lattice of partitions (or equivalently, of equivalence relations) on X_c. This observation is conceptually helpful later when "graded concreteness" is implemented by moving between finer and coarser partitions, rather than by changing the underlying set of tokens.*

Proposition 4 (Abstraction increases weakness)**.** *Assume a context c supplies an "undistinguished pairs" relation $H_c \subseteq X_c \times X_c$. If $q_1 \preceq q_2$ are abstractions and H_{q_i} denotes the induced relation that treats all $\sim_{q_i}$-equivalent pairs as undistinguished, then*

$$H_{q_1} \subseteq H_{q_2} \qquad \Longrightarrow \qquad w(H_{q_1}) \leq w(H_{q_2}).$$

Remark 208 (What the proposition says, and why it matters)**.** *This proposition states that "more abstraction" (in the sense of identifying more things) produces "more weakness" (in the sense of leaving more pairs undistinguished), provided the induced undistinguished-pairs sets are nested.*

Intuitively, if you agree to treat more pairs as the same, you have deliberately declined to make distinctions; weakness is designed to increase exactly in that situation [3, 2].

The result connects this section's abstract/concrete interface to Section 4, where monotonicity properties justify interpreting $w(H)$ as a coherent weakness measure. Here we see a concrete instantiation: quotienting creates inclusion of undistinguished-pair sets, and monotonicity of weakness carries the inclusion to an inequality. Phenomenologically, this captures a common pattern: as an experience becomes more abstract, it becomes "easier to satisfy" because fewer discriminations are demanded; conversely, concrete experience imposes more specific constraints (more opportunities for mismatch), which corresponds to fewer undistinguished pairs and hence lower weakness. Note that the antecedent $H_{q_1} \subseteq H_{q_2}$ is presented explicitly to keep the statement modular: in some formalisms H_{q_i} may include both the base relation H_c and the identifications induced by q_i, and the inclusion condition is then the clean hypothesis under which monotonicity of $w(\cdot)$ applies without committing to a particular construction of H_{q_i}.

Proof. The factorization condition $q_1 \preceq q_2$ implies that $\sim_{q_2}$ is coarser than $\sim_{q_1}$, hence any pair identified by q_1 is also identified by q_2, giving $H_{q_1} \subseteq H_{q_2}$. The conclusion then follows from Theorem 1. More explicitly: if $x \sim_{q_1} y$ then $q_1(x) = q_1(y)$, so $q_2(x) = r(q_1(x)) = r(q_1(y)) = q_2(y)$, hence $x \sim_{q_2} y$; therefore every $\sim_{q_1}$-identified pair is also $\sim_{q_2}$-identified, which is exactly the coarsening relationship needed to apply monotonicity of w to the induced undistinguished-pairs relations. $\square$

Remark 209 (Concretization as refinement (informal))**.** *Although the formal development here is phrased in terms of abstraction maps $q : X_c \twoheadrightarrow A$, the opposite motion—toward concreteness—can be read as moving to a* finer *quotient (i.e. reversing $\preceq$), or equivalently as refining the induced partition of X_c so that fewer tokens are treated as interchangeable. In this sense, "concretizing" does not require introducing a new primitive beyond the preorder: it can be modeled as selecting an abstraction q' with $q' \preceq q$ replaced by $q \preceq q'$ failing, i.e. by choosing q' that distinguishes more. This dovetails with graded intensity (ii): to become "more concrete" is not necessarily to jump categories, but to traverse a chain of refinements, each step adding discriminations that the context now treats as salient.*

Remark 210 (Proof sketch and commentary)**.** Proof sketch. *Factorization means that q_2 cannot distinguish anything that q_1 already identifies, so the equivalence classes (fibers) of q_2 are unions of fibers of q_1. Equivalently, every identification made by q_1 is* preserved *by q_2, because q_2 only has access to information that already passed through q_1. Hence the set of pairs declared equivalent by q_1 is contained in the set declared equivalent by q_2. In other words, $\sim_{q_2}$ is at least as coarse as $\sim_{q_1}$: it can collapse further, but it cannot "un-collapse" any pair that q_1 has already merged. Weakness is monotone under adding undistinguished pairs, so the inclusion yields the inequality. This monotonicity can be read operationally: if a quotient is allowed to forget* more *distinctions (i.e. it identifies more pairs), then it can only become weaker in the sense of losing discriminative or task-relevant structure.* $\square$

The key step is the passage from $q_2 = r \circ q_1$ to "$\sim_{q_2}$ is coarser than $\sim_{q_1}$." This is simply the observation that if $q_1(x) = q_1(y)$ then automatically $q_2(x) = r(q_1(x)) = r(q_1(y)) = q_2(y)$. It is sometimes helpful to rephrase this in terms of kernels: the relation $\sim_q$ is the kernel congruence of q, and composition enlarges kernels, i.e. $\ker(q_1) \subseteq \ker(r \circ q_1)$. Geometrically, quotienting can be pictured as merging points into blobs; factoring corresponds to merging blobs into larger blobs, so the set of merged pairs can only grow. One can also view the map r as defining a partition of the q_1-blobs, after which q_2 assigns the same label to all blobs in each part of that partition.

6.6.2 Concreteness as resistance to quotienting

The previous definitions make "more abstract" precise as "collapses more distinctions." In particular, abstraction is measured by how large a family of potentially different entities is treated as interchangeable once mapped through q. To model concreteness we add a complementary notion: some entities resist being safely quotiented away. Here "resist" is not metaphysical stubbornness but a contextual fact: in some practices, merging certain items produces errors, surprises, or loss of control. We represent this as a context-indexed constraint on admissible abstractions. The role of the context index c is to keep track of which invariances are acceptable: the same physical entity may be concrete for one task and abstract for another.

Definition 53 (Concreteness constraint)**.** *Let c be a context. A* concreteness constraint *is a predicate $\mathcal{K}_c$ on abstractions $q : X_c \twoheadrightarrow A$ specifying which quotientings count as "benign". The point of treating $\mathcal{K}_c$ as a predicate (rather than a single privileged quotient) is that there may be many acceptable ways to abstract, and concreteness is meant to be robust across that admissible family. An entity $x \in X_c$ is* concrete (relative to c) *if, for every admissible abstraction q in the sense of $\mathcal{K}_c$, the fiber $q^{-1}(q(x))$ is "small" (i.e. x is not merged with many other entities without violating $\mathcal{K}_c$). Here "small" is intentionally left schematic: depending on the application it may mean small cardinality, small measure, bounded diameter under a similarity metric, or small expected variability in downstream predictions. Conversely, x is* abstract *if there exist admissible abstractions under which x represents a large equivalence class. This existential clause captures the idea that an entity can function as a* representative *or* type *when the context licenses aggressive identification, even if other contexts would forbid it.*

Remark 211 (Intuition and examples for concreteness constraints)**.** *A concreteness constraint $\mathcal{K}_c$ encodes what a context will not allow itself to forget. Equivalently, $\mathcal{K}_c$ expresses which distinctions are treated as non-negotiable because collapsing them would damage some capability the context aims to preserve. For a robotic context, $\mathcal{K}_c$ might forbid quotienting that breaks sensorimotor prediction: two objects cannot be identified if pushing one produces different outcomes than pushing the other. More generally, any abstraction that would destroy controllability or introduce systematic prediction error would be deemed non-benign. For a mathematical context, $\mathcal{K}_c$ might be looser: many concrete instances can be safely quotiented into a single abstract structure if all proofs and computations of interest are invariant under that quotient. For example, different presentations of the same group may be quotiented together when the task concerns only group-theoretic properties, but not when the task concerns a specific representation or algorithmic cost.*

This definition is useful because it prevents a degenerate triviality: without constraints, maximal abstraction is always possible. Indeed, the quotient map that sends all of X_c to a single point is always available set-theoretically, but it is rarely benign relative to any nontrivial practice. By making admissibility explicit, we keep the abstract/concrete distinction tethered to practice and consequence. Later sections can propose specific quantitative forms of $\mathcal{K}_c$ based on effort or predictive utility, connecting to Hyperseed-Concept 100 and Hyperseed-Concept **??***. One can anticipate, for instance, that $\mathcal{K}_c(q)$ might require that some loss functional (prediction loss, control loss, or explanation loss) remain below a context-dependent threshold.*

Remark 212 (Why a constraint is necessary)**.** *If we allowed arbitrary quotient maps, every entity could be collapsed into a single point, making everything maximally abstract. This would trivialize any attempt to compare abstractions, because there would always exist a strictly coarser quotient that "wins" by collapsing more. Hyperseed's distinction between abstract and concrete presupposes that not all quotientings are experienced as legitimate. The predicate $\mathcal{K}_c$ stands in for whatever makes a quotient "valid" in a context: sensorimotor coupling, causal consequences, pragmatic stakes, or* *other constraints. In practice, $\mathcal{K}_c$ can be thought of as delimiting a feasible set of compressions: compressions outside this set are experienced as errors, category mistakes, or harmful oversimplifications. Later sections will propose quantitative candidates for $\mathcal{K}_c$ in terms of effort and predictive utility.*

6.7 Non-duality as a bridge between perspectives

Hyperseed treats non-duality as primitive and also as an organizing constraint relating (at least) first-person and third-person framings. We record one clean mathematical way to express "non-duality without collapse" using the language of context translation. In particular, the aim is to state a condition that is strong enough to prevent a translation from trivializing distinctions, while still weak enough to permit genuine coarse-graining and abstraction (as is unavoidable when moving between descriptive standpoints).

Remark 213. *In philosophical terms, this is a proposal to treat "bridging perspectives" as a problem in approximate structure-preservation rather than exact identity. One does not demand that first-person and third-person descriptions coincide; one asks instead for translations that preserve what must be preserved, blur what may be blurred, and make the extent of blurring legible as a parameter. This resonates with process-oriented and sign-oriented metaphysics (Whitehead and Peirce) in which relations and mediations are primary [15, 14]. It also anticipates later Hyperseed themes of mind–world correspondence and self/other boundaries (Hyperseed-Concept 112 and Hyperseed-Concept 165). A further motivation is methodological: if one treats "first-person" and "third-person" as two contexts with different observational capacities, then any realistic bridge must allow information loss in at least one direction, yet should still provide an auditable account of what was preserved and what was sacrificed.*

Definition 54 (Context translation and non-dual compatibility)**.** *Let c, d be contexts. A* translation *from c to d is a function $T : X_c \to X_d$. We say that T is* non-dually compatible *with c and d if for all $x, y \in X_c$ we have*

$$\delta_c(x, y) \le \delta_d\big(Tx, Ty\big) \quad \textit{and} \quad \delta_c(x, y) \le \delta_d\big(Ty, Tx\big)$$

(componentwise order on $\mathbb{V}$), i.e. d does not erase distinctions that are strong in c. Dually, a translation $S : X_d \to X_c$ is compatible if it does not create spurious distinctions.

A non-dual bridge *between c and d is a pair of translations (T, S) together with a witness that the composites $S \circ T$ and $T \circ S$ act like identities only* up to controlled weakness *(to be made precise using the quantale V and weakness ordering).*

One may read the compatibility inequalities as a minimal "no-forgetting" requirement: if $\delta_c(x, y)$ certifies that x and y are distinguishable in context c (in whichever multivalued sense $\mathbb{V}$ encodes), then translating to d should not make them *less* distinguishable. Because $\mathbb{V}$ is ordered componentwise, each component of δ (e.g. evidential strength, salience, modality-specific discriminability) is protected separately; thus a translation is allowed to blur some components only insofar as the order relation permits, and any such blurring is tracked at the level of $\mathbb{V}$ rather than hidden in informal interpretation.

Remark 214 (Intuition and examples for translations and bridges)**.** *A translation $T : X_c \to X_d$ is a recipe for re-expressing what c can talk about in the language of d. Non-dual compatibility demands that if c has strong evidence that x and y diverge, then d must not flatten that divergence after translation. In other words, T must not turn strong distinctions into weak ones. The symmetric-looking condition with (Tx, Ty) and (Ty, Tx) ensures this protection of distinction in both directions,* *matching the earlier emphasis on mutuality for distinctions. A useful way to think about this is that even when δ is not literally symmetric (e.g. if it encodes directional evidential flow, or asymmetric accessibility), the bridge should not depend on an arbitrary choice of ordering of the pair (x, y) when deciding whether a distinction has been preserved.*

A simple example is mapping a fine-grained introspective context (many subtle feelings) into a coarse behavioral context (few categories). A compatible translation cannot claim two feelings are indistinct if, in the introspective context, the evidence for their distinctness is high. The notion of a non-dual bridge then says: even if round-tripping $x \mapsto Tx \mapsto S(Tx)$ does not return exactly x, it returns something that is "the same up to controlled weakness," making the loss of detail explicit and measurable via weakness. This is the formal analogue of "non-duality without collapse" (Hyperseed-Concept 121 and Hyperseed-Concept 143; see also [3]).

A second example (closer to scientific practice) is translating from a richly parameterized dynamical model to a low-dimensional summary statistic used for prediction or control. The translation to the summary statistic is permitted to discard degrees of freedom, but it should not erase a distinction that the original model treats as robust. Conversely, the translation back from the statistic to a representative dynamical state should not hallucinate fine distinctions unsupported by the statistic, i.e. it should not "over-interpret" the coarse description as if it contained more information than it does.

In both examples, the "witness" for the bridge can be understood as a formal certificate of how far $S \circ T$ and $T \circ S$ deviate from identity in the weakness order. Concretely (at an intuitive level), one expects such a witness to amount to inequalities of the form "x is close to $S(Tx)$ up to an allowed weakening" and likewise "u is close to $T(Su)$ up to an allowed weakening," where "close" is expressed using δ and the allowed weakening is expressed using the quantale structure on V. Thus, the bridge does not pretend that translations are invertible; it instead makes non-invertibility quantitative and therefore discussable.

Remark 215. *The point of this definition is not to force an equivalence between first-person and third-person descriptions. Rather, it provides a formal knob: a bridge can preserve some distinctions while allowing others to blur, and non-dual states are those where the blurring is substantial but non-trivial structure remains. This prepares the ground for later sections where self/other boundaries, intentionality, and "mind–world correspondence" are modeled as approximate morphisms rather than strict identities. In particular, the framework makes room for the possibility that different contexts are related by many admissible bridges, not a unique privileged one; the choice of bridge can then be treated as part of the modeling assumptions, and the witness explicitly records the cost of that choice in terms of weakness. This is one way to reconcile the phenomenological insistence that perspectives are irreducible with the scientific insistence that perspectives can nonetheless constrain one another.*

7 Order, time, and becoming

Outline

- Formalize after/before as strict partial orders (and graded/paraconsistent refinements).
- Define proto-time as "time before physics-time": any experienced partial order.
- Define linear time axes as serializations/quotients/approximations of proto-time.
- Define becoming as boundary non-duality between successive occasions/entities.

- Give a paraconsistent, quantale-valued event calculus as a canonical "time reasoning" layer.
- Define event regularity predicates: persistent, continuous, increasing, decreasing, via time-context similarity.

Summary and Hyperseed concepts covered

Hyperseed treats time as built from ordering. The most primitive ingredient is an experienced after/before relation, i.e. a family of asymmetric distinctions whose transitive closure yields a (strict) partial order. Any such partial order is a *proto-time.* A linear time axis is a special case (or approximation) that serializes events; this can lose information when concurrency or branching is present.

The section then connects this ordering-first viewpoint to concrete temporal reasoning formalisms. We define a paraconsistent, quantale-valued event calculus in which predicates such as Happens and HoldsAt take values in the p-bit quantale V from the formal core. Finally, we formalize Hyperseed's qualitative temporal predicates (persistence, continuity, increasingness, decreasingness) using a notion of time-context and temporal similarity.

Hyperseed concepts covered.

- After / Before; $A < B$ implies NOT($B < A$); NOT($A < A$); transitivity.
- Proto-Time; linear time axis (serialization); "information loss under linearization".
- Becoming (boundary non-duality / non-dual variety).
- Event and process calculi; events; fluents; holds/initiate/terminate; "holds sometime in".
- Persistent / continuous / increasing / decreasing (events or fluents).
- Time context; temporal similarity.

Remark 216 (Orientation and sources)**.** *The present formalization is an intentionally austere extraction of the "ordering-first" stance on temporality used throughout the Hyperseed ontology [1]. The guiding thought is Russellian in its analytic economy: if we can explain "before/after" without presupposing a global time coordinate, we obtain a foundation that can accommodate branching, concurrency, subjective ordering, and inconsistent evidence. At the same time, the section keeps open a Whiteheadian reading in which temporal structure is a derived regularity of processes rather than a primitive container [15].*

The key methodological move is to treat "temporal talk" as downstream of a more basic relation of order. Concretely, an agent (or a theory) may register multiple local discriminations of the form "A is after B" without thereby committing to a single global clock or even to a total ordering. The strictness assumptions in the bullet list can be read as idealizations: irreflexivity NOT($A < A$) and asymmetry $A < B \Rightarrow$ NOT($B < A$) express that "after" is not meant as mere difference, while transitivity captures the compounding of experienced precedence. In practice, the motivating data may be fragmentary, cyclic, or in tension (e.g. multiple observers, noisy sensors, retrospective reconstruction), which is why the section explicitly anticipates graded/paraconsistent refinements rather than insisting on classical consistency from the start.

Calling any such partial order a *proto-time* is meant to separate two notions that are often conflated: (i) having an ordering at all, and (ii) having a privileged metric parameter with uniform units. Proto-time in this sense is compatible with incomparability (neither $A < B$ nor $B < A$), which operationally corresponds to concurrency, causal independence, or simply missing evidence. It is also compatible with branching structures, where a single event is before two mutually incomparable events, capturing divergent possible continuations or genuinely parallel processes. This emphasizes that proto-time is not merely "early physics" but rather "pre-metric order"—a notion that can appear in phenomenology, computation traces, causal graphs, and narrative accounts.

The phrase "linear time axis" is then treated as an additional construction on top of proto-time. A serialization can be understood as selecting (or synthesizing) a total order that is consistent with (some portion of) the partial order, for example by choosing a linear extension when one exists, or by imposing tie-breaking conventions when it does not. A quotient/approximation perspective is also useful: if many events are only distinguishable up to simultaneity or resolution limits, one may collapse equivalence classes and order the classes instead. Either way, "information loss under linearization" is not merely a philosophical slogan: incomparabilities and branching structure can be erased when represented on a single axis, so that distinct proto-times may project to the same linearized representation.

The concept of *becoming* is positioned as a bridge between ordering and ontology: if we speak of successive occasions/entities, the boundary between them is not treated as a hard cut but as a non-dual interface in which "earlier" and "later" partially interpenetrate. In this framing, becoming is not an extra event occurring *in* time; rather, it is the structural relation that makes a succession intelligible as a succession of occasions at all. This is why becoming is stated as "boundary non-duality": it names the continuity of inheritance/transition even when the order relation itself is strict.

Finally, the event-calculus layer is introduced as a disciplined way to reason with proto-time when evidence is inconsistent or graded. Interpreting $\mathrm{Happens}(e, t)$ and $\mathrm{HoldsAt}(f, t)$ as V-valued predicates allows the theory to track not only whether an event happens or a fluent holds, but *to what extent* and under what kind of logical status in p-bit. In particular, the quantale structure supports aggregating temporal evidence (via its join/meet structure) and sequencing/composition of supports (via its monoidal operation), which is essential when temporal claims are derived from multiple partial observations. On this basis, regularity notions such as persistence and continuity can be cast as constraints over families of contexts: a fluent is persistent when its V-valuation remains stable across sufficiently similar neighboring contexts, continuous when changes are small relative to a similarity threshold, and increasing/decreasing when there is a directional trend relative to the proto-time order. The explicit use of time-context and temporal similarity is meant to keep these predicates qualitative and robust, so that they remain meaningful even when no globally consistent linear clock is available.

7.1 After/before as strict partial order

Hyperseed's first move is to treat time as a special case of ordering. Mathematically, the minimal clean object capturing this is a *strict partial order*. This choice deliberately separates the *direction* of precedence from any further commitments about metric structure (how long something takes), topology (continuity), or global synchrony (a single shared clock). In particular, it keeps open whether time is discrete or continuous, whether it branches, and whether every pair of events admits comparison.

Definition 55 (Strict partial order)**.** *A* strict partial order *on a set T is a binary relation $<$ on T such that:*

1. (Irreflexive) for all $t \in T$, not$(t < t)$, *2. (Transitive) for all $t_1, t_2, t_3 \in T$, if $t_1 < t_2$ and $t_2 < t_3$ then $t_1 < t_3$.*

We say t_1 is before *t_2 if $t_1 < t_2$, and t_2 is* after *t_1.*

It is often convenient (and conceptually clarifying) to note that a strict order $<$ canonically induces a non-strict companion relation $\leq$ by defining $t_1 \leq t_2$ to mean "$t_1 < t_2$ or $t_1 = t_2$." This does not add structure; it simply packages the option of equality explicitly. Conversely, starting from a reflexive partial order $\leq$, one recovers a strict version by setting $t_1 < t_2$ iff $t_1 \leq t_2$ and $t_1 \neq t_2$. This standard conversion is useful later when one wants to talk about "no later than" versus "strictly earlier" without changing the underlying conceptual commitments.

Remark 217 (Intuition, examples, and why this matters)**.** *The relation $<$ is meant to capture only the irreducible directional fact "this precedes that," not necessarily measured duration. Irreflexivity forbids loops of the form "an event is before itself," and transitivity enforces that "before" composes: if t_1 is before t_2 and t_2 before t_3, then t_1 must be before t_3. Together these clauses prevent directed cycles, so the order can be read as an acyclic dependency structure (a "can-happen-before" relation).*

Two standard examples are: (i) $T = \mathbb{N}$ with the usual $<$; (ii) $T = \mathcal{P}(S)$ for a set S with $A < B$ defined as $A \subsetneq B$ (strict inclusion). In the temporal reading, the second example is suggestive: temporal precedence can behave like a refinement relation on information states. This strict-partial-order abstraction is useful because it is the weakest structure that still lets us speak rigorously about "past" and "future" without assuming that every pair of events is comparable. This aligns directly with the Hyperseed notions After and Before (Hyperseed-Concepts 52 and 63).

One can also visualize a strict partial order as a directed graph whose vertices are elements of T and whose edges indicate immediate precedence; transitivity then says that reachability agrees with $<$. In the finite case, a Hasse-style picture (showing only "cover" relations and omitting transitive edges) makes the distinction between a *chain* (a totally ordered subset) and an *antichain* (a set of pairwise incomparable elements) explicit. In temporal terms, a chain reads as a history-like thread of definite succession, while an antichain reads as a simultaneous (or mutually unrelated) slice at the resolution being modeled.

A further reason this matters is that many familiar time models implicitly assume *total* order, i.e. for all distinct t_1, t_2 one has either $t_1 < t_2$ or $t_2 < t_1$. A strict partial order drops exactly that assumption. Thus it can represent branching futures, merging causal lines, and observer-dependent coarse-grainings where the model refuses to invent an arbitrary order when the underlying situation does not warrant one.

Remark 218 (Hyperseed's asymmetry axiom)**.** *For strict partial orders, the Hyperseed clause "$A < B$ implies NOT$(B < A)$" follows from irreflexivity and transitivity: if $A < B$ and $B < A$ then transitivity yields $A < A$, contradicting irreflexivity.*

It is worth emphasizing that this derivation uses only the internal logic of the relation $<$: the contradiction is not empirical but formal. In particular, the step "$A < B$ and $B < A$ implies $A < A$" is exactly the closure property transitivity provides, so asymmetry is not an additional stipulation about time; it is a structural fact about any relation intended to behave like strict precedence.

Remark 219 (Intuition: why asymmetry is not a separate axiom)**.** *One sometimes writes "asymmetric" as a separate requirement for a strict order, but it is already latent in the two clauses given. Philosophically, this is a small instance of a broader pattern in foundational work: what appears at first as an additional metaphysical constraint can often be seen as a theorem of a simpler algebra of relations. Here, the prohibition of self-precedence and the compositionality of precedence suffice.*

Another way to say the same thing is that strict partial orders are precisely those relations whose "before" arrows cannot be followed around a directed cycle. If a theory of time wants to allow closed timelike curves or other forms of cyclic dependence, then it is not (in that region) a strict partial order; one would need a different primitive. Hyperseed's choice here therefore commits to acyclicity at the level of the basic After/Before relation, while leaving open many other possibilities (density, branching, finiteness, etc.).

Remark 220 (Incomparability and concurrency)**.** *If neither $t_1 < t_2$ nor $t_2 < t_1$ holds, then t_1 and t_2 are* incomparable. *In the time interpretation, incomparability represents concurrency, branching, or the absence of a well-defined ordering relation at the observer's grain.*

Given any $t \in T$, the strict order also induces the associated "past" and "future" sets

$$\mathrm{Past}(t) = \{s \in T : s < t\}, \qquad \mathrm{Future}(t) = \{u \in T : t < u\}.$$

These are purely order-theoretic constructions (no metric required). Incomparability between t_1 and t_2 can then be read as the failure of inclusion between their past/future profiles: neither event lies in the other's future, so the order records no precedence constraint between them. This gives a precise sense in which partial ordering supports talk of "past" and "future" locally, even when a global linear timeline is unavailable.

Remark 221 (Example: concurrency as a mathematical primitive)**.** *In a distributed system, two messages may be causally unrelated: neither is provably earlier. A strict partial order captures this directly by leaving the pair incomparable, rather than forcing a spurious choice. This is precisely the sort of "information-preserving humility" that is lost when one insists prematurely on linear time.*

In such settings, it is common to distinguish the *causal* order (the strict partial order that must be respected) from any *schedule* or *linearization* that totally orders events for execution or narration purposes. Mathematically, a schedule is a total order that *extends* the partial order: whenever $t_1 < t_2$ causally, the schedule also places t_1 before t_2. The key point is that many different extensions may exist, and their differences correspond exactly to choices made among incomparable events. Hyperseed's use of strict partial orders therefore cleanly separates what is forced by After/Before from what is merely conventional or perspective-dependent.

7.2 Proto-time as observer-relative ordering

Hyperseed's term *proto-time* refers to "every partial ordering considered as a sort of time". This can be taken literally. In particular, the proposal is that the minimal formal residue of "temporal" talk is not duration or a privileged coordinate, but an ordering relation that can support the distinctions "earlier than", "later than", and "not (yet) comparable at the present resolution". The emphasis on partial (rather than total) order is crucial: it allows the formalism to treat indeterminacy, concurrency, and limited access as first-class rather than as defects to be repaired.

Definition 56 (Proto-time)**.** *A* proto-time *is a pair $(T, <)$ where T is a set of temporal indices (e.g. occasions, events, or representations of them) and $<$ is a strict partial order on T. In other words, $<$ is irreflexive ($\neg(t < t)$ for all $t \in T$) and transitive (if $t_1 < t_2$ and $t_2 < t_3$ then $t_1 < t_3$); antisymmetry is automatic for a strict order in the sense that cycles are excluded by transitivity and irreflexivity.*

Remark 222 (Intuition and connection to experience). *Proto-time is time "before clocks": any experienced ordering of episodes, perceptions, or internal updates qualifies, regardless of whether it resembles a line. The set T is deliberately generic: it may be a set of occasions (Hyperseed-Concept 124), a set of events in an event calculus, or a set of internal representational states. The only essential ingredient is the precedence relation $<$, which records whatever the system takes to be "after" and "before" at its current resolution. The point of using a* strict *order is that it matches the phenomenological asymmetry of "before/after" without forcing an identity criterion for simultaneous or indistinguishable episodes; where equality or "same time" is needed, it can be supplied separately (e.g. via an equivalence relation or by quotienting), rather than being silently baked into the time structure. Likewise, incomparability ($\neg(t_1 < t_2)$ and $\neg(t_2 < t_1)$) need not mean "simultaneous" in any physical sense: it can mean "no ordering information available", "different narrative threads", or "the system declines to commit".*

A simple example is a causal DAG whose vertices are events and whose edges represent direct causal influence; the reachability relation induces a strict partial order. This illustrates how proto-time can be extracted from constraints rather than posited as an ambient parameter: causation (or influence) supplies the arrows, and time is the induced ordering. Another example is the "edit history" of a document with branching: commits form a partially ordered set under ancestor relation. These are proto-times in exactly the present sense, and they make vivid why a linear axis is often a lossy summary rather than the primitive. In both examples, a linear "timeline" can be recovered only by adding choices (e.g. selecting a linear extension, choosing a topological sort, or imposing additional tie-breaking conventions), and different choices may be equally compatible with the underlying proto-time. This definition operationalizes the Hyperseed notion Proto-Time (Hyperseed-Concept 142).

Remark 223 (Proto-time is local and aspectual). *Different contexts/aspects (in Hyperseed's sense) may carry different proto-times. For instance, the same collection of occasions may admit a fine-grained causal proto-time and a coarser narrative proto-time, or multiple incompatible orderings inferred from different evidence. This is one of the places where paraconsistency is not an afterthought but a design requirement. Concretely, a system may maintain one ordering for sensorimotor updating, another for autobiographical memory, and yet another for planning, even when these do not admit a single common refinement without introducing contradictions or arbitrarily discarding constraints. The locality claim can also be read computationally: proto-time is indexed by what is tracked and what is ignored, so changing resolution (e.g. by coarse-graining episodes into "chunks") can change T and thereby change which order-relations are expressible at all. In that sense, proto-time functions as an* aspectual interface*: it describes the temporal commitments of an aspect, not an absolute inventory of "all events".*

Remark 224 (Why "observer-relative" is not a concession but a method). *To say proto-time is context-indexed is not to deny a mind-independent world; it is to keep separate (i) the structure realized by whatever generates events and (ii) the structure inferred or imposed by a bounded system attempting to navigate them. Hyperseed repeatedly exploits this separation later when relating time to effort-minimization and "least-effort paths" in inference or control [21]. The methodological payoff is that one can ask two different questions without conflating them: "What ordering constraints does the world impose?" versus "Which ordering constraints does this agent (or aspect) represent, and how costly is it to refine them?". On this view, observer-relativity is not a relativism about reality, but an explicit accounting of representation: a proto-time is the agent's current ordering model, which may be revised as evidence arrives, resources change, or goals shift. It also clarifies why proto-time does not presuppose a metric, a topology, or a global "now": those are additional* *structures that may be constructed when useful, but the base concept remains the ordering relation that supports predictions, explanations, and control.*

7.3 Graded and paraconsistent temporal ordering

Hyperseed also gestures at *graded* orderings ("how long or fast the flow feels"). A simple rigorous way to do this within the formal core is to treat "before" as a p-bit-valued relation whose positive component records support for "t_1 is before t_2" and whose negative component records support against it. One can view this as replacing a single Boolean-valued edge in a temporal graph by a pair of weights: a pro-weight and a con-weight, both of which may be nonzero. The point is not merely to allow uncertainty (low support in both channels), but also to allow *tension* (simultaneously high support and high counter-support) without collapsing into triviality.

Definition 57 (p-bit-valued before-relation)**.** *Let $V = [0,1]^2$ be the* p-bit *quantale from Section 3.4. A* p-bit-valued temporal evidence relation *is a map*

$$B : T \times T \to V, \qquad B(t_1, t_2) = (B^+(t_1, t_2),\ B^-(t_1, t_2)).$$

Here $B^+(t_1, t_2)$ is positive evidence for $t_1 < t_2$, and $B^-(t_1, t_2)$ is negative evidence.

Remark 225 (Order and entailment on V)**.** *Since V is used as a codomain for evidential values, inequalities such as $B(t_1, t_3) \geq B(t_1, t_2) \otimes B(t_2, t_3)$ presuppose a comparison relation on pairs. In the basic* p-bit *setup, one typically orders $V = [0,1]^2$* componentwise*:*

$$(v^+, v^-) \leq (w^+, w^-) \quad \textit{iff} \quad v^+ \leq w^+ \textit{ and } v^- \leq w^-.$$

Under this reading, "$\geq$" means "has at least as much positive evidence and at least as much negative evidence." This is deliberately not *a reduction to a single net score: increasing v^- does not automatically decrease v^+, so the structure can represent both evidential accumulation and evidential conflict as first-class phenomena rather than as noise to be normalized away.*

Remark 226 (Notation unpacking)**.** *The symbol $V = [0,1]^2$ denotes ordered pairs (v^+, v^-) of reals in $[0,1]$. We read v^+ as "support for" and v^- as "support against" a proposition. Thus $B^+(t_1, t_2)$ and $B^-(t_1, t_2)$ are simply the two coordinate functions of B. This two-channel semantics is one concrete paraconsistent option; related four-valued approaches appear in constructible duality logics [23], and the use of such values as composable evidence is aligned with the general "paraconsistent resonance" perspective [24]. A convenient mnemonic is that $(1,0)$ behaves like "confidently yes," $(0,1)$ like "confidently no," $(0,0)$ like "no information," and $(1,1)$ like "inconsistent but fully activated," with intermediate points capturing graded mixtures of these modes.*

Remark 227 (Intuition, examples, and purpose)**.** *A crisp order says either "$t_1 < t_2$" or not; the* p-bit*-valued relation says how strongly the system leans in each direction, and allows it to record conflict explicitly. For example, a system may have sensory evidence suggesting that a stimulus s_1 preceded s_2 (high B^+), while a higher-level narrative model suggests the opposite (high B^-). A single classical truth value would force premature resolution; the* p-bit *pair preserves both pressures so that later inference (e.g. transitive closure, inertia reasoning) can integrate them. In particular, the representation supports at least three qualitatively different cases that a single probability-like scalar conflates: (i)* uncertain *(both channels near* 0*), (ii)* confident *(one channel high, the other low), and (iii)* contested *(both channels high).*

This graded form is useful because it connects time to the same algebra used for distinction, weakness, and compositional aggregation elsewhere in the document [3]. In other words, temporal *uncertainty is not treated as an exceptional problem requiring a separate probabilistic apparatus; it is folded into the same quantale-enriched calculus. From a modeling standpoint, this uniformity matters: if temporal judgments are produced by the same pipelines that produce other relational judgments (causal, spatial, conceptual), then having a common aggregation and comparison algebra makes it possible to share learning rules, regularizers, and compositional mechanisms across domains.*

Definition 58 (Coherence constraints for temporal evidence (optional))**.** *One may impose any of the following (model-dependent) constraints:*

1. *(Anti-symmetry as evidence) $B^+(t_1, t_2) \le B^-(t_2, t_1)$ for all t_1, t_2.*

2. *(Transitive support) $B(t_1, t_3) \ge B(t_1, t_2) \otimes B(t_2, t_3)$ where $\otimes$ is the quantale tensor (componentwise multiplication).*

3. *(Irreflexive support) $B^+(t, t) = 0$ for all t (while allowing $B^-(t, t)$ to encode strong evidence against $t < t$).*

We emphasize that these are constraints on evidence*, not metaphysical axioms.*

Remark 228 (Componentwise reading of the constraints)**.** *It may be helpful to unpack clause (2) in coordinates. If $\otimes$ is componentwise multiplication, then*

$$B(t_1, t_2) \otimes B(t_2, t_3) = \big(B^+(t_1, t_2)B^+(t_2, t_3),\ B^-(t_1, t_2)B^-(t_2, t_3)\big).$$

With the componentwise order on V, the inequality $B(t_1, t_3) \ge (\cdots)$ requires both

$$B^+(t_1, t_3) \ \ge\ B^+(t_1, t_2)B^+(t_2, t_3) \qquad \textit{and} \qquad B^-(t_1, t_3) \ \ge\ B^-(t_1, t_2)B^-(t_2, t_3).$$

Thus transitivity is treated as a statement about how evidence propagates along a chain in each channel, rather than as a demand that the sign *of the final verdict must be classically consistent. This makes it possible for a system to infer that a longer chain can inherit both support and counter-support, which is often exactly what happens when different subsystems contribute competing temporal cues.*

Remark 229 (Intuition and examples for the evidence constraints)**.** *Clause (1) says: evidence that t_1 is before t_2 should count as counter-evidence for t_2 being before t_1. It is a soft version of asymmetry, expressed in the vocabulary of evidence rather than in the vocabulary of facts. Clause (2) says: if we have support for $t_1 < t_2$ and for $t_2 < t_3$, then we should have at least the composed support for $t_1 < t_3$; the tensor $\otimes$ (componentwise multiplication in the* p-bit *quantale) plays the role of "and then," i.e. accumulation of evidential strength along a chain. Clause (3) enforces that the positive channel does not directly support self-precedence, while leaving room for the negative channel to record explicit rejection of it.*

These constraints are useful when B is learned or estimated: they provide regularizers that encourage temporal evidence to behave like an order without demanding perfect consistency. As a concrete numerical illustration, if $B^+(t_1, t_2) = 0.9$ and $B^+(t_2, t_3) = 0.8$, then clause (2) requires $B^+(t_1, t_3) \ge 0.72$; similarly, if both negative evidences are 0.6, it requires $B^-(t_1, t_3) \ge 0.36$. This matches an intuitive "attenuation along a path" reading: longer compositions retain only what survives repeated conjunction.

Remark 230 (Alternative tensors and modeling choices)**.** *The use of componentwise multiplication is a clean default because it is monotone and matches the usual "independent conjunction" intuition for graded evidence. However, nothing essential forces this particular t-norm: depending on the application, one might replace multiplication by* min *(for a bottleneck interpretation), by the Łukasiewicz t-norm (for a bounded-sum interpretation), or by a learned monotone aggregator, provided it remains compatible with the chosen order on V. The present subsection only needs that V is a quantale so that such aggregations compose associatively and distribute over suprema, enabling systematic propagation of temporal evidence in networks rather than ad hoc case-by-case combination.*

Remark 231 (Why keep a crisp proto-time at all?)**.** *A useful stance is: the world (or an internal simulation) may realize a crisp partial order $(T, <)$, while a bounded observer maintains only B. Alternatively, one can work entirely with B and treat "proto-time" as an emergent crisp skeleton (e.g. the set of pairs whose B^+ exceeds a threshold) when needed. This split between an (ideal) underlying order and a (bounded) evidential surrogate is also a way to separate ontological questions (what actually happened) from epistemic and computational questions (what can be inferred, stored, and composed under constraints), which is the main methodological role played here by paraconsistent grading.*

Remark 232 (A practical reading: skeletonization by threshold)**.** *In computation, one often picks a threshold θ and defines a derived crisp relation $t_1 <_\theta t_2$ iff $B^+(t_1, t_2) \geq \theta$ (or by a net score). This is not merely a convenience: it is an explicit model of the act of "making time definite" by expending effort to force a decision, a theme that reappears when simplicity and weakness are defined as observer-relative resource tradeoffs [2, 3]. One may also impose auxiliary tie-breaking rules at the skeletonization stage (for instance, requiring simultaneously that $B^-(t_1, t_2) \leq \varepsilon$ for some small ε) to avoid declaring an edge "present" precisely when the system is signaling strong internal disagreement.*

Remark 233 (From evidence to derived temporal structures)**.** *Once a crisp skeleton $<_\theta$ is extracted, standard constructions become available: one can take its transitive reduction (to obtain a Hasse-like diagram), compute its strongly connected components (to diagnose cycles created by thresholding), or topologically sort it when it happens to be acyclic. Conversely, one can remain in the enriched setting and compute a graded transitive closure by taking suprema over all intermediary chains, in direct analogy with path problems in weighted graphs, but with weights in V and composition given by $\otimes$. The purpose of these remarks is not to fix a single pipeline, but to make explicit that B is meant to be operational: it is a data structure on which one can run order-theoretic and graph-theoretic procedures, either before or after discretization, depending on the resource budget and the desired degree of commitment.*

7.4 Linear time axes as serializations and quotients

A linear time axis is a special case of proto-time: a total (linear) order. Hyperseed also suggests a specific *quotienting* move: group together events with the same "before-set" and "after-set". In the present section it is helpful to keep two distinct operations conceptually separate: *serialization* (choosing a linear order that respects a given proto-time) and *coarse-graining* (identifying events that the proto-time already fails to distinguish). The quotienting move is of the second kind: it does not "decide" any new comparisons, but only collapses redundancies in the order-theoretic description of temporal location.

Definition 59 (Linear time axis)**.** *A* linear time axis *is a proto-time* $(L, \prec)$ *where* $\prec$ *is a strict total order: for all distinct* $\ell_1, \ell_2 \in L$*, either* $\ell_1 \prec \ell_2$ *or* $\ell_2 \prec \ell_1$*. Equivalently,* $\prec$ *is irreflexive and transitive, and it satisfies totality (comparability) on distinct elements; in many texts this is packaged as a trichotomy principle for* $\prec$ *on* L*.*

Remark 234 (Intuition and examples)**.** *A strict total order is the familiar "single-file" time of classical narratives and many physics models: every two distinct times are comparable. For example,* $(\mathbb{Z}, <)$ *is a linear time axis; so is any finite list with its left-to-right order. Linear axes are computationally convenient because they allow iteration "from past to future" without branching cases. But they are also epistemically assertive: they force comparability even where proto-time may honestly have none (e.g. concurrent events). The later remark on information loss makes this precise. One may also distinguish discrete linear axes (like* $\mathbb{Z}$*) from dense ones (like* $(\mathbb{Q}, <)$*): both are linear time axes, but they support different intuitions about "next" moments and granularity. The present development does not assume discreteness; what matters is total comparability.*

Definition 60 (Past/future sets and quotient-by-indistinguishability)**.** *Let* $(T, <)$ *be a proto-time. Define for each* $t \in T$*:*

$$\mathrm{Past}(t) := \{u \in T : u < t\}, \qquad \mathrm{Future}(t) := \{u \in T : t < u\}.$$

Define an equivalence relation $\sim$ *on* T *by*

$$t \sim t' \iff \mathrm{Past}(t) = \mathrm{Past}(t') \ \textit{and} \ \mathrm{Future}(t) = \mathrm{Future}(t').$$

Let $[t]$ *denote the equivalence class of* t*, and let* $T/{\sim}$ *be the set of classes. Define a relation* $<$ *on* $T/{\sim}$ *by*

$$[t] < [t'] \iff t < t' \text{ for some (equivalently any) representatives.}$$

In order-theoretic language, $\mathrm{Past}(t)$ *is the strict down-set of* t *and* $\mathrm{Future}(t)$ *is the strict up-set of* t*. The pair* $(\mathrm{Past}(t), \mathrm{Future}(t))$ *can therefore be read as a complete "order signature" of how* t *sits inside* $(T, <)$*, ignoring any additional labels on events.*

Remark 235 (Intuition: quotienting as "time slicing")**.** *The pair* $(\mathrm{Past}(t), \mathrm{Future}(t))$ *describes the "causal address" of* t *inside the partial order: what lies strictly before it and what lies strictly after it. Two elements with the same past and future are indistinguishable with respect to the order-theoretic information available; quotienting identifies them. In temporal terms, this implements a rigorous version of "simultaneous at the current grain": if the order cannot distinguish* t *and* t'*, the quotient refuses to pretend otherwise.*

A simple example is a proto-time with two incomparable events x *and* y *occurring after an initial event* s *and before a final event* e*. Then* x *and* y *have the same past* $\{s\}$ *and the same future* $\{e\}$*, hence* $x \sim y$ *and they collapse to a single slice. This is useful as a canonical compression of proto-time prior to attempting linearization. It is worth noting that* $\sim$ *is generally finer than "incomparability": two incomparable events need not be equivalent, because they may have different sets of predecessors or successors. Thus the quotient is not merely "turn all antichains into points," but rather "merge only those nodes whose entire comparative context agrees."*

Lemma 1 (The quotient order is well-defined and strict)**.** *The relation* $<$ *on* $T/{\sim}$ *is well-defined and makes* $(T/{\sim}, <)$ *a strict partial order.*

Remark 236 (What the lemma asserts, in plain language)**.** *The definition of* $[t] < [t']$ *is only meaningful if it does not depend on which representatives* $t \in [t]$ *and* $t' \in [t']$ *we pick. The lemma* *says exactly this: the quotient construction does not introduce ambiguity, and it preserves the essential "no cycles" and "compositional precedence" properties of a strict order. This result is conceptually important because it licenses the quotient as an information-preserving coarse-graining of time: we are not smuggling in extra structure, merely collapsing what the order already cannot tell apart. In particular, after quotienting, distinct classes are automatically* order-distinguishable*: if $[t] \neq [t']$, then either their past sets differ or their future sets differ (by definition of $\sim$), so the quotient has removed precisely the "duplicate addresses" and nothing more.*

Proof. Well-definedness: suppose $t \sim s$ and $t' \sim s'$ with $t < t'$. If $s \not< s'$, then either (i) $s' = s$ (impossible since $t < t'$ and $t \sim s$ would force incompatible past/future sets), (ii) $s' < s$, which together with $t < t'$ and the equalities of past/future sets implies a contradiction with transitivity/irreflexivity in $(T, <)$, or (iii) s and s' incomparable, which again contradicts the equality of past/future sets across the $\sim$-classes once one representative is comparable. Strictness: irreflexivity and transitivity descend to the quotient because any cycle in the quotient would lift to a cycle in T. A more explicit way to see the "equivalently any representatives" clause is as follows. Assume $t < t'$ and $s \sim t$, $s' \sim t'$. Then $t \in \mathrm{Past}(t')$, hence $t \in \mathrm{Past}(s')$ because $\mathrm{Past}(t') = \mathrm{Past}(s')$. Since $\mathrm{Past}(t) = \mathrm{Past}(s)$ and $t < t'$, we also have that every predecessor of t is a predecessor of s, and conversely; in particular, the statement "t is before s'" transfers to "s is before s'" by comparing down-sets at s' and using transitivity in $(T, <)$ to rule out the alternative possibilities $s' = s$ and $s' < s$. Thus $s < s'$. This establishes that if one pair of representatives witnesses $[t] < [t']$, then all pairs do. For strictness, irreflexivity on classes follows because $[t] < [t]$ would require some representative $t < t$, impossible. Transitivity follows because if $[a] < [b]$ and $[b] < [c]$, pick representatives $a < b$ and $b' < c$ with $b' \sim b$; by well-definedness one may replace b' with b and obtain $a < b < c$, hence $a < c$ and therefore $[a] < [c]$. □

Remark 237 (Proof sketch and key ideas). *The strategy is to show that $\sim$-equivalent elements have exactly the same comparability profile. If $t \sim s$, then every element that is before t is before s, and every element after t is after s. Hence, if t is comparable to t', then s must be comparable to any $s' \sim t'$ in the same direction; otherwise the past/future sets would differ. Once well-definedness is secured, irreflexivity and transitivity are inherited because any violation in the quotient would correspond to a directed cycle among representatives in T, which cannot exist in a strict partial order.*

Visually, one may imagine the Hasse diagram of $(T, <)$: the quotient merges nodes that have identical "upward" and "downward" reachability sets. Such a merge cannot create a new directed cycle, because cycles are already forbidden in the original graph. Another way to phrase the same idea is that $\sim$ identifies vertices with identical strict principal ideals and filters; this is a standard "separation" step in order theory that removes redundant copies of the same abstract position in the poset.

Remark 238 (Why this quotient matters). *The quotient $T/\sim$ collapses "simultaneity at the observer's grain": events with the same causal/narrative placement become a single "time-slice". Even after quotienting, the resulting order need not be total; concurrency remains possible. What changes is that concurrency is no longer obscured by multiple indistinguishable nodes: the remaining incomparabilities in $T/\sim$ represent genuine branching (or genuine lack of information) that cannot be removed without making an additional modeling choice, such as selecting a linear extension.*

Theorem 5 (Finite proto-times admit linear extensions). *If $(T, <)$ is a finite proto-time, then there exists a strict total order $\prec$ on T such that $t_1 < t_2$ implies $t_1 \prec t_2$. Such a $\prec$ is called a* linear extension *(or topological sort) of $(T, <)$.*

A linear extension can be viewed as a systematic "tie-breaking" of incomparabilities: whenever the proto-time does not constrain the order of two events, the extension chooses one of the two possible orientations while keeping all required precedence relations intact. For finite T, such an extension may be constructed algorithmically by repeatedly selecting a $<$-minimal element (an event with no strict predecessors), placing it next on the linear axis, and removing it; strictness ensures no cycles, so this process terminates. The existence of multiple linear extensions is typical and is precisely one formal measure of how much concurrency or underdetermination a proto-time contains.

Remark 239 (Meaning and importance)**.** *This theorem says that for a finite proto-time we can always choose a "story order" that respects all the precedence constraints, even if the underlying structure is branching or concurrent. In practice, this is what allows one to render a partial order as a sequence for purposes of simulation, explanation, logging, or training a model that expects sequential input. The result is not that linear time is fundamental, but that linear time is always* available as a representation *for finite structures.*

A useful way to read this is: whenever the only temporal facts you insist on are of the form "t_1 must occur before t_2," you can always embed those facts into a single list, provided the system is finite and has no cycles. This is the mathematical justification behind routine engineering constructions such as topological sorting of a dependency graph, or choosing an execution order for independent tasks that still respects required prerequisites.

This connects directly to the earlier warning that linearization loses information: the theorem guarantees existence of a serialization, while the later remark clarifies that such a serialization is typically many-to-one and hence not invertible. In other words, the existence result is about compatibility *(there is at least one linear narrative that does not contradict the proto-time), whereas the information-loss warning is about* identifiability *(many different proto-times can collapse to the same linear narrative once concurrency is forced into an order).*

Proof. Induct on $|T|$. For $|T| = 0, 1$ the claim is trivial. Assume the claim holds for all smaller finite sets. Because $<$ is a strict partial order on a finite set, there exists a minimal element $m \in T$ (i.e. no $u \in T$ satisfies $u < m$). Remove m to obtain $T' := T \setminus \{m\}$, and restrict $<$ to T'. By induction, T' admits a linear extension $\prec'$. Define $\prec$ on T by placing m first and then following $\prec'$ on T'. Minimality of m ensures that no constraint $u < m$ is violated, and all constraints within T' are respected by construction.

For clarity on the existence of m: if every element had a predecessor, we could build a descending chain $t_0 > t_1 > t_2 > \cdots$ by repeatedly choosing a predecessor. In a finite set such a process must eventually repeat an element, producing a cycle, which contradicts the irreflexivity/transitivity of a strict partial order. Hence at least one element has no predecessor and is minimal. The same argument also highlights why finiteness is essential for this simple induction: in infinite posets a minimal element need not exist, so one cannot always "start" a linear narrative without adding extra choice principles or additional structure. $\square$

Remark 240 (Proof sketch, and a visual intuition)**.** *The proof is the standard "peel off a minimal element" argument: in any finite acyclic directed graph, there is at least one node with no incoming edges. Place such a node first; then repeat on the remaining graph. The inductive step works because removing a minimal element cannot destroy the strict-order property on what remains, and placing it first cannot violate any constraint since nothing was required to precede it.*

Geometrically, imagine repeatedly shaving off the "earliest" layer of events in the Hasse diagram. A linear extension is just the record of this shaving process. Different choices of minimal element at each step correspond to different linear narratives compatible with the same proto-time.

From an algorithmic perspective, this is exactly the idea behind a topological sort: at each step one selects an available event (one with no unmet prerequisites), outputs it, and deletes it from the dependency graph. The "visual intuition" is therefore not merely metaphorical; it directly encodes a constructive procedure for producing a serialization, and it makes explicit where nondeterminism enters (namely, whenever there is more than one currently-minimal event).

Remark 241 (Information loss under linearization)**.** *A linear extension preserves all constraints $t_1 < t_2$ but destroys explicit incomparability: if t_1 and t_2 were incomparable in $<$, the extension still forces either $t_1 \prec t_2$ or $t_2 \prec t_1$. Hence linearization is generally a many-to-one representation of proto-time.*

Equivalently, the linear order $\prec$ adds extra comparabilities that were not entailed by $<$. These additional pairwise decisions are exactly what a serialization must supply in order to become a total order, but they should be read as choices of presentation *rather than as new facts about precedence in the original proto-time. In applications, this is why one should treat the resulting sequence as an* annotated view *of the underlying partial order, not as a faithful encoding of all its structure.*

Remark 242 (Why "information loss" is philosophically substantive)**.** *The point is not merely technical. When a system commits to a linear axis, it is choosing one possible way of resolving concurrency and ambiguity; this choice can feed back into prediction, responsibility assignment, and causal explanation. Hyperseed treats such commitments as aspects of cognitive effort and design, not as inevitable reflections of reality [5].*

In particular, once incomparable events are forced into an order, downstream reasoning may begin to treat the imposed order as if it were evidentially supported (e.g. inferring causal direction from narrative order, or attributing agency based on who "acted first"). The philosophical weight comes from the fact that such inferences are not just errors in bookkeeping; they can systematically bias models of agency, credit, blame, or counterfactual dependence whenever concurrency is a real feature of the underlying situation.

Remark 243 (Serialization as a quotient viewpoint)**.** *It is often useful to describe the many-to-one aspect more structurally. Fixing a partial order $(T, <)$, each linear extension $\prec$ can be seen as a* choice of totalization*: it retains all required relations but adds enough additional comparisons to make every pair comparable. Conversely, if one starts from a total order $\prec$ on T and "forgets" which comparisons were merely chosen to resolve incomparability, one recovers only a coarser object—some partial order compatible with $\prec$—and many distinct partial orders may be compatible with the same $\prec$.*

From this perspective, passing from proto-time to a linear time axis behaves like quotienting by an equivalence relation that identifies structures that differ only in how they arrange events that were originally concurrent. The theorem guarantees that at least one representative exists on the linear side for every finite proto-time, while the information-loss remark explains why the projection to that quotient is not injective.

7.5 Becoming as boundary non-duality

Hyperseed defines *becoming* as a relation between temporally adjacent entities whose boundary is "non-dual": it is not crisply determined whether the two are distinct or identical near the transition.

To model this, we assume:

- a proto-time $(T, <)$,
- a set E of entities (or entity-representations),

- and a p-bit-valued *distinction* (or equivalence) relation whose value may vary by time.

Remark 244 (Proto-time versus physical time)**.** *The order* $(T, <)$ *is intentionally weak: it provides temporal precedence without committing to a metric, topology, or even continuity. This allows the same formalism to cover discrete update steps (e.g. iterations of a learning algorithm), event sequences (e.g. observations in an experiment), or continuous physical time as a special case. When additional structure exists (e.g. a topology or a metric), it can be used to make the notion of "neighborhood" in Definition 63 more explicit, but the core idea of becoming does not require it.*

Definition 61 (Time-indexed distinction relation)**.** *Let* E *be a set of entities and* T *a proto-time carrier. A* time-indexed distinction relation *is a map*

$$\mathrm{Dist} : T \times E \times E \to V,$$

where $\mathrm{Dist}(t; x, y) = (d^+, d^-)$ *records evidence at time* t *that* x *and* y *are* distinct *(positive) and evidence that they are* not distinct *(negative).*

Remark 245 (Notation and intended reading)**.** *The notation* $\mathrm{Dist}(t; x, y)$ *is a three-argument evaluation: first pick a time* $t \in T$*, then two entities* $x, y \in E$*, and obtain a* p-bit *value in* V*. The first coordinate* d^+ *supports the proposition "*x *and* y *are distinct at* t*," and the second coordinate* d^- *supports its opposition. This is an instance of the general Hyperseed notion Distinction (Hyperseed-Concept 98) made time-dependent, so that identity and difference can vary across a transition.*

Remark 246 (Optional structural constraints on Dist)**.** *The definition does not require* $\mathrm{Dist}(t; x, y) = \mathrm{Dist}(t; y, x)$*, nor any form of reflexivity such as* $\mathrm{Dist}(t; x, x)$ *being maximally non-distinct. This is deliberate: in some applications the distinction judgment is viewpoint-dependent (e.g. an asymmetric classifier, or a directed comparability relation where* x *is treated as a refinement of* y *but not conversely). When symmetry and reflexivity are appropriate, they can be imposed as modeling assumptions, for example:*

$$\mathrm{Dist}(t; x, y) = \mathrm{Dist}(t; y, x), \qquad \mathrm{Dist}(t; x, x) \approx (0, 1).$$

Likewise, some domains may benefit from a weak "triangle-type" constraint (distinctions compose), but becoming as boundary non-duality does not presuppose such coherence.

Remark 247 (Interpreting the value space V)**.** *The comparison* $\mathrm{Dist}(t; x, y) \geq (\theta, \theta)$ *presumes a coordinatewise preorder on* V *(e.g.* $(a^+, a^-) \geq (b^+, b^-)$ *iff* $a^+ \geq b^+$ *and* $a^- \geq b^-$*). Intuitively, larger* d^+ *means more support for "distinct," while larger* d^- *means more support for "not distinct." In this sense, non-duality is not the absence of information, but the presence of* competing *information. If* V *additionally supports operations such as negation, conjunction, or normalization (as many* p-bit*-style constructions do), those can later be used to define derived notions like "net distinctness" or confidence-weighted salience, but they are not required for the basic definitions here.*

Remark 248 (Intuition and examples)**.** *If* E *contains successive snapshots of a physical object,* $\mathrm{Dist}(t; x, y)$ *can be read as "how much the observer at time* t *treats the snapshot* x *as different from snapshot* y*." In cognition,* x *and* y *might be two concepts or two internal states; during learning, a system may oscillate between treating them as the same category and as different ones, yielding paraconsistent values.*

The usefulness of time-indexing is that it avoids baking identity into the entities themselves. Instead of asking "are x *and* y *the same?", we ask "under what temporal and contextual conditions does the system treat them as distinct?" This is a formal handle on the otherwise slippery boundary language used in becoming.*

Remark 249 (Context dependence and "who" is doing the distinguishing)**.** *In practice,* Dist *often aggregates multiple sources: sensory measurements, internal inference, linguistic labels, and social or institutional criteria for sameness. Time-indexing allows these sources to shift in influence: the same pair (x, y) can become more or less distinct as attention changes, as measurement resolution improves, or as the governing equivalence standard is revised. Thus, even when the underlying world-state changes smoothly, the distinction relation may change non-monotonically, which is one of the main reasons a paraconsistent representation is useful in boundary regimes.*

Definition 62 (Non-dual variety at time t)**.** *We say entities $x, y \in E$ display* non-dual variety at time t *if*

$$\mathrm{Dist}(t; x, y) \text{ is strongly paraconsistent, e.g. } \mathrm{Dist}(t; x, y) \geq (\theta, \theta)$$

for a chosen threshold $\theta \in (0, 1]$. Intuitively: there is simultaneously strong evidence for "distinct" and strong evidence for "not distinct".

Remark 250 (Alternative strong-paraconsistency criteria)**.** *The coordinatewise threshold condition is a simple sufficient test. Depending on how V is constructed, one might instead use a scalarization such as $\min(d^+, d^-) \geq \theta$, or require that both coordinates be high* relative to *total support (e.g. $d^+/(d^+ + d^-) \approx 1/2$ with large $d^+ + d^-$), distinguishing non-duality from mere uncertainty. The present definition keeps the criterion explicit and easily checked, while leaving room for domain-specific refinements.*

Remark 251 (Intuition: a boundary where both stories are true)**.** *Non-dual variety is the formal way of saying: at the boundary, the system has reasons to keep the two relata apart and reasons to identify them, and neither reason is negligible. A classic illustrative situation is a gradual morph: as a shape continuously changes from a circle to a square, there can be a region where classification as "circle" and as "not circle" both have strong support. Another is the Ship of Theseus: near certain thresholds, identity can be supported by continuity of function while non-identity is supported by replacement of parts.*

The threshold θ is a modeling choice: higher θ demands stronger simultaneous support. This definition instantiates the Hyperseed notion Non-Dual Variety (Hyperseed-Concept 120), and makes explicit why a paraconsistent truth space is convenient: it lets us represent such boundary states without collapsing into triviality.

Remark 252 (Non-dual variety versus indeterminacy)**.** *It is useful to separate* conflict *from* lack of evidence*. A boundary is "non-dual" in the intended sense when there is substantial support on both sides; this differs from a case where both d^+ and d^- are small (the system simply has not formed a judgment). In applications, this difference often corresponds to whether the system is actively maintaining competing models or interpretations (non-duality) versus being under-informed (ignorance).*

Definition 63 (Becoming along a proto-time)**.** *Fix a proto-time $(T, <)$ and a time-indexed distinction relation* Dist*. We say $x \in E$* becomes *$y \in E$ (along $(T, <)$) if there exist $t_1 < t_2$ and an interval (or neighborhood) $U \subseteq T$ with $t_1 \leq u \leq t_2$ for $u \in U$ such that:*

1. *(Temporal succession) x is salient/present up to (near) t_1 and y is salient/present from (near) t_2 onward (the salience notion can be instantiated later via pattern intensity or attention),*

2. *(Boundary non-duality) for all $u \in U$ near the transition, x and y display non-dual variety at u,*

3. *(Outside the boundary) away from U, x and y are (comparatively) more distinguishable (e.g.* $\mathrm{Dist}(t; x, y)$ *is not strongly paraconsistent).*

Remark 253 (Making "interval" and "near" precise)**.** *If T is equipped only with an order, "interval" can be read in the order-theoretic sense (e.g. a convex subset) and "near" can be treated informally as "close to the transition region in the ordering." If T has a topology or metric, one can instead take U to be an open neighborhood of a boundary time t_*, or a small window $[t_* - \varepsilon, t_* + \varepsilon]$, and interpret clause (2) as holding throughout that window. The definition is written to accommodate both discrete and continuous settings: in discrete time, U might be a short run of indices where judgments flip or overlap; in continuous time, it can represent a genuine boundary band.*

Remark 254 (Salience as a needed companion notion)**.** *Clause (1) separates* what exists in the representational universe *from* what is currently active *for the system. Without salience, x and y could both be permanently present in E (as representations) while never participating in a transition. Later formalizations can operationalize salience via attention weights, activation levels, pattern intensities, or selection functions; the present definition only requires that the model be able to say "x is what we are tracking before" and "y is what we are tracking after."*

Remark 255 (Multiple boundaries and staged becoming)**.** *The definition allows U to be any neighborhood capturing the transition; in many realistic cases, there may be several disjoint or partially overlapping boundary regions (e.g. repeated back-and-forth reclassifications during learning). One can model such cases either by taking U to include the full transition band, or by treating becoming as occurring in stages $x \to z \to y$ with successive boundary intervals. This flexibility matters in paraconsistent regimes, where the path of distinctions can be non-monotone even when the underlying process is directed.*

Remark 256 (Intuition and why this definition is structured as it is)**.** *The definition isolates three ingredients that are often conflated in informal talk about change: (i) there is a before/after placement ($t_1 < t_2$), (ii) there is a boundary region where identity is unsettled (paraconsistent non-duality), and (iii) outside that region the system regains the ability to treat the two as distinct. The third clause is crucial: without it, one might confuse becoming with permanent ambiguity or with simple synonymy.*

A simple example is phase change: "water becomes ice." Around the melting/freezing point, the system may simultaneously recognize crystalline structure (supporting distinction) and fluidity (supporting non-distinction with the earlier state), depending on measurement scale and noise. Another example is conceptual learning: a child may treat whales as fish, then as mammals; during the transition there can be a period of mixed judgments that is naturally modeled as non-dual variety.

This definition implements the Hyperseed notion Becoming (Hyperseed-Concept 62) in a way compatible with process ontology: becoming is not a primitive arrow glued onto time, but a pattern of changing distinction structure along proto-time [15].

Remark 257 (Why clause (3) matters for explanatory power)**.** *Clause (3) ensures that the boundary region functions as a* localized *site of tension rather than a global feature of the pair (x, y). In empirical terms, it supports counterfactual diagnostics: if we sample times well before and well after the transition, the model should usually predict that the system can again make a stable distinction (or stable identification) according to its standards. This makes becoming detectable from time series of judgments: one looks for a band of strong paraconsistency bracketed by regions of relative determinacy.*

Remark 258 (Sorites-style boundaries)**.** *The third clause encodes the intended "boundary" behavior: becoming is not permanent identity, but a transition region where identity/distinction is not* *crisply settled. Paraconsistent truth values let us represent such boundaries without forcing collapse to triviality.*

One can read this as a Sorites-friendly stance: across a chain of micro-variations, it is generally unreasonable to demand that each step preserve a classical predicate (e.g. "same object") while also insisting that the endpoints differ classically. The boundary region is precisely where the theory records that both continuist and discontinuist descriptions have non-negligible support. In particular, the role of a p-bit *value is not to "decide" the boundary but to keep track of how much the available constraints and observations support each side of the would-be dichotomy.*

Remark 259 (Aesthetic aside: boundary as a locus of form)**.** *There is an aesthetic dimension here: boundaries are where classification fails gracefully rather than catastrophically. In the present formalism, the boundary is not a logical defect but a region where the system explicitly represents competing commitments. This is mathematically tractable and, arguably, phenomenologically faithful (Hyperseed-Concept 53).*

More concretely: if a classification scheme is forced to return a single crisp label everywhere, then any perturbation near the boundary produces discontinuous "label flicker," which is both computationally brittle and experientially unlike how agents often cope with vague transitions. By contrast, allowing the boundary to carry structure—here, two-channel support/denial that can coexist—turns the boundary into a site where form can be articulated (e.g. by gradients of support, by competing explanations, or by alternative decompositions of a process into events). This makes the boundary a locus for further inference rather than an error condition.

7.6 A paraconsistent, quantale-valued event calculus

Hyperseed's "event and process calculi" discussion can be realized cleanly by taking the standard event calculus vocabulary and interpreting all core predicates in the p-bit quantale V. This subsection instantiates Event and Process Calculi (Hyperseed-Concept **??**) in a way that is algebraically continuous with the rest of the document.

The guiding idea is that "temporal reasoning" is not a separate module with its own ad hoc uncertainty mechanics; rather, it is another place where the same algebra of evidence is applied. In particular, we want the same operations that combine perceptual cues or conceptual constraints to also combine (i) evidence that an event occurs, (ii) evidence that it changes a fluent, and (iii) evidence that the fluent holds over an interval.

7.6.1 Signature and intended semantics

Definition 64 (Event calculus signature (paraconsistent, quantale-valued))**.** *Fix:*

- *a proto-time carrier* $(T, <)$*,*
- *a set* $\mathcal{A}$ *of actions/events,*
- *a set* $\mathcal{F}$ *of fluents (time-varying propositions).*

A p-bit*-valued event calculus assigns:*

$$\begin{aligned}
\mathrm{Happens}&: \ \mathcal{A} \times T \to V,\\
\mathrm{HoldsAt}&: \ \mathcal{F} \times T \to V,\\
\mathrm{Initiates}&: \ \mathcal{A} \times \mathcal{F} \times T \to V,\\
\mathrm{Terminates}&: \ \mathcal{A} \times \mathcal{F} \times T \to V.
\end{aligned}$$

Remark 260 (Time structure and modeling latitude). *The modest assumption "proto-time carrier $(T, <)$" is deliberately weak: in applications one may take T to be discrete (e.g. $\mathbb{N}$ for step-indexed simulation), continuous (e.g. $\mathbb{R}$ for physical time), partially ordered (for branching-time or concurrency models), or even an interval domain when the primary observations are temporally coarse. What matters for the present subsection is that $<$ provides enough structure to state propagation constraints from earlier to later times. The quantale-valued semantics then handles gradedness and inconsistency orthogonally to the choice of temporal granularity.*

Remark 261 (Notation unpacking: actions, fluents, and V). *Here $\mathcal{A}$ is the set of event-types (or action-tokens, depending on modeling choice), and $\mathcal{F}$ is the set of fluents, i.e. propositions whose holding status may vary over time. The codomain $V = [0,1]^2$ means each predicate returns a two-channel evidence value. Thus* $\text{Happens}(a,t) = (h^+, h^-)$ *is evidence for/against "event a happens at time t," and similarly for the other predicates.*

It is important that the two channels are not required to sum to 1 *(as they would in a probabilistic simplex), nor to be complements; this is what permits "boundary" and "conflict" states such as* $(0.8, 0.7)$*, which would otherwise be disallowed. Conversely, complete ignorance may be represented by something like* $(0,0)$*, where neither support nor denial is available.*

Remark 262 (Intuition, examples, and why this signature is useful). *In classical event calculus,* $\text{HoldsAt}(f,t)$ *is Boolean; here it is graded and paraconsistent. This matters precisely at boundaries: a fluent like "the door is open" may have conflicting evidence from different sensors; an initiation rule may be supported by a learned model but contradicted by a physics-based model. By putting all these predicates in the same quantale-valued space, we can aggregate evidence compositionally rather than by ad hoc priority rules.*

As a minimal example, let $\mathcal{F} = \{f\}$ and $\mathcal{A} = \{a\}$. If $\text{Happens}(a,t)$ *is high and* $\text{Initiates}(a,f,t)$ *is high, we can infer support for* $\text{HoldsAt}(f,t')$ *at later times, subject to clipping/termination evidence. This provides a concrete "time reasoning" layer compatible with Hyperseed's broader pattern-based cognitive architecture [19].*

A slightly richer example illustrates the boundary use-case directly. Suppose a is "push door" and f is "door open." A camera may support $\text{HoldsAt}(f,t)$ *while a latch sensor denies it; simultaneously, the dynamics model may support* $\text{Initiates}(a,f,t)$ *while a safety interlock model supports* $\text{Terminates}(a,f,t)$ *(e.g. the push triggers a mechanism that closes the door). In a Boolean setting this can force inconsistent axioms; here it yields a controlled state of tension that can be resolved (if at all) by additional evidence, temporal propagation, or explicit bias terms.*

Remark 263 (Why p-bit values here?). *In realistic temporal reasoning, the boundary of when an event happens, whether a fluent holds, and whether an action initiates/terminates a fluent are all uncertain and can be mutually conflicting. The* p-bit *representation makes these conflicts explicit and composable.*

Technically, the point is that the same algebraic operations used elsewhere in the document (e.g. $\otimes$ for conjunction-like composition and $\oplus$ for proof/evidence accumulation) can be reused here without special casing time. This uniformity is what makes the approach "algebraically continuous": temporal inference becomes another instance of quantale-enriched constraint propagation rather than an isolated logical subsystem.

7.6.2 Monotone rule evaluation over a quantale

A convenient semantics for Horn-style rules over a quantale is: conjunction is interpreted by the tensor $\otimes$, and alternative proofs are aggregated by join $\oplus$ (in V this is componentwise max). This yields a monotone "proof accumulation" logic.

Remark 264 (Connection to standard event calculus axioms). *Classical event calculus is often presented with axiom schemata for persistence (inertia), initiation, termination, and "clipping" (events that end a fluent's holding). The present subsection does not repeat the full axiom inventory; instead it isolates the evaluation principle that makes those axioms computationally well-behaved in the quantale-valued setting. When the familiar axiom schemata are added, each becomes a Horn-style rule (or a family of such rules) whose body combines pieces of evidence, and whose head accumulates whatever support those bodies provide.*

Definition 65 (Quantale-valued implication schema). *Let $P, Q_1, \ldots, Q_n$ be predicate symbols with appropriate arities. A* quantale-valued rule *has the form*

$$P(\vec{x}) \ \Leftarrow\ Q_1(\vec{x}_1) \ \wedge\ \cdots\ \wedge\ Q_n(\vec{x}_n),$$

and is evaluated pointwise by

$$[\![P(\vec{x})]\!] \ \geq\ [\![Q_1(\vec{x}_1)]\!] \otimes \cdots \otimes [\![Q_n(\vec{x}_n)]\!].$$

If multiple rules (or multiple instantiations) derive the same head, their contributions are joined using $\oplus$.

Remark 265 (Reading the inequality direction). *The use of "$\geq$" reflects that rules provide* lower bounds *on the evidence for the head: any derivation gives at least some support/denial profile for $P(\vec{x})$, and additional derivations can only increase that profile via joins. This matches the fixpoint view where one starts from minimal information and iteratively accumulates consequences until closure. In proof-theoretic terms, the model is the least assignment that satisfies all such inequalities.*

Remark 266 (Intuition: proofs as resources that accumulate). *The tensor $\otimes$ plays the role of "and": to support the head, we must support each body literal, and the combined support is the multiplicative accumulation of those supports. The join $\oplus$ plays the role of "or": multiple derivations contribute, and we keep the strongest support (componentwise maximum in the* p-bit *quantale). This is the algebraic analogue of how one informally reasons with multiple pieces of evidence: a chain is only as strong as its weakest link (multiplication attenuates), but parallel arguments compete and the best available argument dominates (maximum selects).*

The usefulness of this schema is that it yields a monotone immediate-consequence operator, enabling least-fixpoint semantics and iterative computation, a theme reused later when stability properties of self-modifying systems are studied via fixpoints [10].

In the p-bit *case, the same rule simultaneously propagates positive and negative information. For instance, if one body literal strongly denies a condition, then the negative channel can propagate through $\otimes$ in a controlled way. This is exactly the mechanism that lets "boundary" regions be stable under inference: the system can accumulate both pro and con evidence without exploding into triviality, while still allowing later evidence to tilt the balance.*

Remark 267 (Negation and non-monotonicity). *Classical event calculus uses negation-as-failure (e.g. "not clipped") and circumscription. In the present paper we keep the* algebraic core *monotone and represent negative information explicitly via the negative component of* p-bit *values. Non-monotone defaults (frame assumptions) are then expressed by an additional* weakness bias *(Section 8), rather than by embedding classical negation-as-failure into the core semantics.*

This separation is especially relevant for temporal reasoning because inertia is a default: in a purely monotone setting, one does not want the mere absence *of termination evidence to behave* *like a hard fact. Instead, "persistence" can be treated as a defeasible contribution whose weight is governed by effort/weakness tradeoffs, while explicit termination evidence contributes on the same algebraic footing as other sources of information.*

Remark 268 (Why monotonicity is a design choice)**.** *Monotonicity means: adding evidence cannot invalidate previous inferences, it can only enrich them. This is not how human default reasoning always behaves; however, it is how the present algebraic layer behaves so that computation and compositional semantics remain tractable. Departures from monotonicity are pushed to explicit bias terms and effort/weakness tradeoffs [3, 2], which makes the source of "non-monotone behavior" inspectable.*

From an implementation perspective, monotonicity also aligns with streaming and incremental updates: as new observations arrive, one can update Happens *or* HoldsAt *values and rerun (or incrementally maintain) the immediate-consequence operator without needing to retract inferences at the algebraic level. Any retraction-like behavior is then a matter of shifting bias, discounting stale evidence, or changing the governing rules—all of which are explicit modeling moves rather than hidden in the semantics of negation.*

7.6.3 Clipping and inertia (paraconsistent sketch)

We now give one clean paraconsistent way to express inertia. First define a derived predicate $\mathrm{Clipped}(f; t_1, t_2)$ meaning that between t_1 and t_2 there is evidence that some action terminates f.

Definition 66 (Clipped (derived; paraconsistent sketch))**.** *Define the* p-bit *value*

$$\mathrm{Clipped}(f; t_1, t_2) := \bigoplus_{\substack{a \in \mathcal{A} \\ u \in T: \\ t_1 < u < t_2}} \mathrm{Happens}(a, u) \otimes \mathrm{Terminates}(a, f, u).$$

When $\mathrm{Clipped}^+$ *is high there is strong evidence that f was terminated in* (t_1, t_2)*. When* $\mathrm{Clipped}^-$ *is high there is strong evidence against such termination.*

Remark 269 (Intuition and a simple example)**.** *This definition says: f is clipped on the interval if there exists some event a at some intermediate time u that both happens and terminates f; the degree of evidence is aggregated over all such candidates by $\oplus$ (max). If there are multiple possible terminating events, we keep the strongest combined evidence among them.*

For example, suppose two events might terminate a fluent, but only one is strongly supported by sensor data; then $\mathrm{Clipped}^+$ *will reflect the stronger candidate. Conversely, if we have explicit evidence that no terminating events occurred (perhaps from a reliable log), this can raise* $\mathrm{Clipped}^-$ *and thereby later support inertia.*

We then express inertia as: if f holds at t_1 and there is no (or weak) evidence that it was clipped before t_2, then f holds at t_2.

Definition 67 (Inertia update operator (paraconsistent sketch))**.** *Define an operator Φ on assignments to* HoldsAt *by*

$$(\Phi\,\mathrm{HoldsAt})(f, t_2) := \mathrm{HoldsAt}_0(f, t_2) \;\oplus\; \bigoplus_{\substack{t_1 \in T: \\ t_1 < t_2}} \mathrm{HoldsAt}(f, t_1) \otimes \neg\mathrm{Clipped}(f; t_1, t_2),$$

where $\mathrm{HoldsAt}_0$ *encodes initial conditions and $\neg$ is the* p-bit *involution* $\neg(v^+, v^-) = (v^-, v^+)$*.*

Remark 270 (Notation and meaning of $\neg$ in this setting)**.** *The involution $\neg(v^+, v^-) = (v^-, v^+)$ simply swaps positive and negative evidence channels. Thus $\neg\text{Clipped}(f; t_1, t_2)$ is evidence for/against "unclipped" obtained by swapping the channels of the clipped evidence. This is not classical negation; it is a bookkeeping operation appropriate to the* p-bit *evidence interpretation, and it is compatible with the monotone proof-accumulation semantics described above.*

Remark 271 (Intuition: inertia as propagation through gaps)**.** *The update says: f holds at t_2 either because it is an initial fact $\text{HoldsAt}_0(f, t_2)$, or because there exists an earlier time t_1 where f held and the interval (t_1, t_2) carries counter-evidence to termination. One may view this as a kind of temporal path propagation: holding status flows forward unless clipped, and the quantale operations determine how strongly it flows.*

This is the temporal analogue of closure constructions used elsewhere (e.g. composition/closure of relations in the toy model section): local constraints propagate globally by repeated application of a monotone operator until a fixpoint is reached [7].

Remark 272. *Using $\neg$Clipped here is not "absence of evidence"; it is the explicitly represented counter-evidence (or support for "unclipped"). This is consistent with the paraconsistent stance: one can simultaneously carry evidence that a termination occurred and evidence that it did not, and inertia will then yield a correspondingly paraconsistent holding status.*

Theorem 6 (Existence of least fixpoint for monotone temporal inference)**.** *Assume T is finite and all event-calculus rules are built using only $\oplus$, $\otimes$, and monotone operations on V. Then the induced immediate-consequence operator (e.g. Φ above) is monotone on the complete lattice of assignments $(V^{\mathcal{F}\times T}, \leq)$ and hence has a least fixpoint.*

Remark 273 (What the theorem says and why it matters)**.** *The theorem guarantees that the iterative "accumulate evidence until stable" procedure is not merely heuristic: there exists a least stable assignment of truth values consistent with the rules. This is crucial for making the event calculus a well-defined semantic object rather than just a collection of update equations. It also connects temporal reasoning to the same fixpoint machinery used elsewhere in Hyperseed-style analyses of stability and self-reference [10]: time inference becomes a special case of order-theoretic stabilization.*

Proof. $V^{\mathcal{F}\times T}$ is a complete lattice under pointwise order. Each clause contribution is monotone because $\otimes$ and $\oplus$ are monotone in each argument, and joins over index sets preserve monotonicity. Therefore the overall operator is monotone. By the Knaster–Tarski theorem, a monotone operator on a complete lattice has a least fixpoint. $\square$

Remark 274 (Proof sketch and intuition)**.** *The high-level strategy is: (i) identify the space of all candidate interpretations as an ordered set, (ii) show the update operator never reverses order (monotonicity), and then (iii) invoke the general fixpoint theorem. Pointwise order on $V^{\mathcal{F}\times T}$ means: one assignment is $\leq$ another if it assigns $\leq$-smaller* p-bit *values to every fluent-time pair. Monotonicity follows because $\otimes$ and $\oplus$ are monotone operations and because taking a join (supremum) over any family of monotone expressions preserves monotonicity. A visual intuition is to imagine starting from the bottom assignment (no evidence anywhere) and repeatedly applying Φ to "grow" the set of supported conclusions. Because the update can only add or strengthen evidence (never retract it), the sequence ascends in the lattice and must stabilize in finitely many steps when T is finite. The stabilized point is the least fixpoint. In more algebraic terms, this is the familiar picture behind Kleene iteration for monotone operators: starting at $\perp$ and iterating Φ yields an increasing chain whose supremum is a fixpoint, and when the underlying carrier is finite (or,* *more generally, when the lattice has finite height) the chain cannot strictly increase forever. The least-fixpoint characterization is important conceptually because it encodes a minimality principle: nothing is concluded unless it is forced by the update rules, and no extra evidence is introduced beyond what is generated by repeated rule application.*

7.7 Time contexts and temporal similarity

Hyperseed defines several important "event regularity" notions using the idea that each timepoint comes with a *time context* (what holds then), and that nearby/similar timepoints have similar time contexts. The key modeling move is to treat temporal structure as being (at least partly) induced by patterns in fluent valuations: rather than assuming a fixed external metric on T, we derive a notion of proximity from how the world is described at those times. This is especially natural when T is a proto-time carrier (e.g. a partially ordered or otherwise non-metric structure) and when different observers may coarse-grain or refine what distinctions matter.

Definition 68 (Time context)**.** *Fix an event calculus instance with fluent set $\mathcal{F}$ and proto-time carrier T. The* time context *at time $t \in T$ is the vector of fluent truth values*

$$\mathrm{TimeCtx}(t) \ := \ \big(\mathrm{HoldsAt}(f,t)\big)_{f\in\mathcal{F}} \in V^{\mathcal{F}}.$$

Remark 275 (Intuition and example)**.** $\mathrm{TimeCtx}(t)$ *is the full "state description" of what is (paraconsistently) true at time t, as far as the chosen fluent vocabulary can express. For example, if $\mathcal{F} = \{\mathsf{DoorOpen}, \mathsf{LightOn}\}$ then* $\mathrm{TimeCtx}(t)$ *is the ordered pair of* p-bit *values assigned to these two propositions at time t. This concept operationalizes the idea that a timepoint is not merely a coordinate but a bundle of conditions; it is an explicit bridge between ordering-based time and state-based dynamics. Note that* $\mathrm{TimeCtx}(t)$ *depends on the chosen fluent set $\mathcal{F}$: refining the vocabulary (splitting one fluent into several more specific ones) generally increases the dimension of $V^{\mathcal{F}}$ and can make previously indistinguishable timepoints separable, while a coarser vocabulary can collapse distinct situations into the same apparent context. In this sense, a "time context" is not a metaphysically complete state of the world but an observer-relative description at a particular granularity.*

Definition 69 (Truth-value projection and similarity)**.** *Choose any monotone scalar projection $\pi : V \to [0,1]$; two useful examples are*

$$\pi_{\mathrm{pos}}(v^+,v^-) = v^+, \qquad \pi_{\mathrm{net}}(v^+,v^-) = \frac{1}{2}\big(1 + (v^+ - v^-)\big).$$

Define a similarity on V by

$$\mathrm{sim}_V(v,w) \ := \ 1 - |\pi(v) - \pi(w)|.$$

Define time-context similarity for $t_1, t_2 \in T$ by

$$\mathrm{sim}_T(t_1,t_2) \ := \ \frac{1}{|\mathcal{F}|}\sum_{f\in\mathcal{F}} \mathrm{sim}_V\big(\mathrm{HoldsAt}(f,t_1),\, \mathrm{HoldsAt}(f,t_2)\big).$$

Remark 276 (Notation and modeling choice)**.** *The map π compresses a two-channel* p-bit *value to a single scalar in $[0,1]$ so that we can use a simple absolute-difference similarity. π_{pos} measures similarity of positive support only; π_{net} measures a signed "net support" that discounts negative* *evidence. Different projections correspond to different stances about how to treat contradiction: one may focus on what is supported, or on the balance between support and opposition.*

The similarity $\mathrm{sim}_T(t_1, t_2)$ *is just the average similarity across all fluents; it is a computable proxy for "how similar the world looks at* t_1 *and* t_2 *in this vocabulary." Because* sim_V *takes values in* $[0, 1]$*, so does* sim_T*, and the endpoints have a clear reading:* $\mathrm{sim}_T(t_1, t_2) = 1$ *exactly when* $\pi(\mathrm{HoldsAt}(f, t_1)) = \pi(\mathrm{HoldsAt}(f, t_2))$ *for every* $f \in \mathcal{F}$*, while smaller values quantify the average magnitude of disagreement under the chosen projection. The monotonicity requirement on* π *(with respect to the lattice order on* V*) ensures that strengthening evidence in* V *cannot perversely decrease the projected scalar in a way that would invert comparisons; this makes similarity judgments stable under the "adding evidence" dynamics of the underlying paraconsistent calculus.*

Remark 277 (Why similarity is defined via projection rather than directly in V)**.** *One could define a similarity directly on* $V = [0, 1]^2$ *using a 2D metric, but the projection method makes explicit which aspect of the paraconsistent value is being compared. This is philosophically in the spirit of Hyperseed: similarity is not an absolute given but an observer-relative construction, and the choice of* π *is part of the observer model. Technically, the projection also makes it easy to swap in alternative scalar summaries without changing the surrounding definitions: for instance, one could use* $\pi(v^+, v^-) = \max(v^+, 1 - v^-)$ *to privilege "unopposed support," or* $\pi(v^+, v^-) = 1 - v^-$ *to track absence of counterevidence. Each such choice corresponds to a different operational meaning of "two truth values being close."*

Remark 278 (Basic properties of the induced similarities)**.** *For any fixed projection* π*,* sim_V *is symmetric and satisfies* $\mathrm{sim}_V(v, v) = 1$ *for all* $v \in V$*, hence* $\mathrm{sim}_T(t, t) = 1$ *for all* $t \in T$*. However,* sim_V *(and therefore* sim_T*) is generally not transitive when turned into a crisp relation via thresholding: it is possible to have* t_1 *similar to* t_2 *and* t_2 *similar to* t_3 *while* t_1 *is not similar to* t_3*, especially when similarity is defined by an average across fluents and disagreements are distributed across different coordinates. This non-transitivity is not a bug in the present setting: it reflects the familiar phenomenon that "looks similar" is typically a neighborhood notion rather than an equivalence relation, and it supports a flexible notion of continuity that does not require global clustering.*

Definition 70 (Temporal similarity)**.** *Fix a threshold* $\tau \in (0, 1]$*. Define*

$$\mathrm{TemporalSimilarity}(t_1, t_2) \textit{ to hold if } \mathrm{sim}_T(t_1, t_2) \geq \tau.$$

Remark 279 (Intuition and example)**.** $\mathrm{TemporalSimilarity}(t_1, t_2)$ *is a derived crisp predicate that says: the system treats the two timepoints as "close enough" in state-space. For instance, if* $\tau = 0.95$*, then only timepoints with very similar fluent valuations are considered temporally similar. This definition is useful because it allows qualitative temporal predicates (like "continuous") to be stated without assuming a numeric metric on* T*; similarity is derived from what holds, not from an external clock. In particular, one can speak about "local smoothness" of a trajectory* $t \mapsto \mathrm{TimeCtx}(t)$ *by requiring that successive or causally adjacent timepoints (as given by the proto-time structure) satisfy* $\mathrm{TemporalSimilarity}$*, even when there is no canonical notion of successor in* T*.*

Remark 280. *Other choices are possible and sometimes preferable: e.g. using a weighted average over fluents, or using quantale weakness (Section 8) to measure how many distinctions between time contexts are collapsed by a given observer. The present choice is intentionally simple and computable. A weighted average can encode domain knowledge (some fluents are more salient or more reliably sensed) by assigning larger weights to dimensions that should dominate similarity judgments, and it can also mitigate the effect of many irrelevant fluents washing out a small but* *important change. Likewise, replacing the absolute-difference form with a different scalar similarity (e.g. a kernel) can change how sharply similarity decays, which in turn affects which temporal patterns count as regularities.*

Remark 281 (Connection to weakness and observer-dependent coarse-graining). *If an observer collapses many differences between time contexts (Hyperseed-Concept 202), then many pairs* (t_1, t_2) *will become temporally similar under that observer's projection and aggregation scheme. This provides a direct route from effort/simlicity theory to the phenomenology of "time flowing smoothly" versus "time being jagged" [3]. Concretely, weakening can be understood as reducing effective resolution in* $V^{\mathcal{F}}$*: distinct vectors of* p-bit *values that would be separated by a high-effort observer may map to nearby (or identical) projected summaries under a low-effort observer, thereby increasing* sim_T *on average. Under this lens, temporal coarse-graining is not merely subsampling in* T*; it is a transformation of the state-description map* $t \mapsto \mathrm{TimeCtx}(t)$ *that changes which variations are treated as signal versus noise.*

7.8 Persistent, continuous, increasing, decreasing

Hyperseed lists several meta-predicates about events/fluents. We implement these as constraints on the trajectory $t \mapsto \mathrm{HoldsAt}(f, t)$ relative to the proto-time order and the temporal similarity relation. In this reading, these meta-predicates are not additional primitive symbols; rather, they are properties of an interpreted event-calculus model, checkable from the induced HoldsAt relation together with whatever auxiliary similarity/projection structure the modeler provides.

Definition 71 (Continuous fluent (relative to a proto-time)). *A fluent* $f \in \mathcal{F}$ *is* continuous *(relative to* $(T, <)$, TemporalSimilarity*) if for all* $t_1, t_2 \in T$,

$$\mathrm{TemporalSimilarity}(t_1, t_2) \;\to\; \mathrm{sim}_V\big(\mathrm{HoldsAt}(f, t_1),\, \mathrm{HoldsAt}(f, t_2)\big) \;\geq\; \eta$$

for a chosen threshold $\eta \in (0, 1]$.

It is often convenient to read $\mathrm{TemporalSimilarity}(t_1, t_2)$ as designating a class of "small" or "contextually close" temporal transitions, even when T is discrete or only partially organized by $<$. Similarly, sim_V can be instantiated as a kernel, a cosine similarity on embeddings, or $1 - \mathrm{dist}_V(\cdot, \cdot)$ for some value-space distance; the point is that continuity is asserted in the value space V rather than in T. Note also that η acts as a tunable tolerance: taking $\eta = 1$ forces invariance of HoldsAt on all temporally similar pairs, whereas smaller η permits controlled variation.

Remark 282 (Intuition and example). *Continuity here is not about infinitesimals; it is about stability under the chosen notion of temporal similarity. If* t_1 *and* t_2 *look similar in their overall time contexts, then* f *should not change much between them. For example, if "temperature" is represented as a fluent and the system regards two moments as similar in relevant conditions, then the temperature fluent should have similar values at those moments. This captures a qualitative sense of continuity appropriate to proto-time, where* T *may not carry a metric topology.*

The definition is useful because it separates "what counts as a small time change" (encoded by TemporalSimilarity*) from "what counts as a small fluent change" (encoded by* sim_V *and* η*). Both are observer-relative and can be tuned.*

A useful operational consequence is that continuity can be evaluated as a family of constraints, one per temporally-similar pair, and therefore can be implemented either as a hard logical axiom or as a soft penalty in a probabilistic/optimization layer. For instance, in a weighted setting one may penalize violations by a hinge loss $\max\{0, \eta - \mathrm{sim}_V(\mathrm{HoldsAt}(f, t_1), \mathrm{HoldsAt}(f, t_2))\}$ whenever $\mathrm{TemporalSimilarity}(t_1, t_2)$ holds, thereby allowing noisy observations while still encoding the intended smoothness bias.

Definition 72 (Persistent fluent (relative to a proto-time))**.** *A fluent $f \in \mathcal{F}$ is* persistent *if it is continuous and, additionally, its truth-value varies only weakly across the entire interval between initiation and termination, i.e. there exists $\epsilon \geq 0$ such that whenever $t_1 < t_2$ and f holds "throughout" $[t_1, t_2]$ (as determined by the event calculus instance), then*

$$|\pi(\mathrm{HoldsAt}(f, t_1)) - \pi(\mathrm{HoldsAt}(f, t_2))| \ \leq \ \epsilon.$$

The phrase "holds throughout" can be understood in the event-calculus sense: f is supported on the interval because it is initiated at or before t_1, not terminated before t_2, and inertia (or the chosen persistence axioms) propagate its holding status across intermediate times. When T is dense or when HoldsAt is only partially observed, this "throughout" condition is best viewed as a model-relative judgment rather than a syntactic universal quantification over all $t \in [t_1, t_2]$; the intended meaning is that the theory treats the interval as one of uninterrupted holding.

Remark 283 (Intuition and why persistence is stronger than continuity)**.** *Continuity constrains local change: nearby time contexts should not flip the fluent abruptly. Persistence adds a global bound: across any span where the fluent is considered to hold, its projected value should not drift by more than ϵ. For example, "the light is on" may be persistent if it remains stably supported from switch-on to switch-off, even if minor sensor noise causes small fluctuations. By contrast, a fluent like "the music is loud" might be continuous but not persistent if it rises and falls gradually.*

This definition is useful because it lets us distinguish steady conditions from smooth evolutions. The parameter ϵ makes explicit how much variation is tolerated before we stop calling the fluent persistent.

Two limiting cases help orient the parameter choices. If $\epsilon = 0$ and π is chosen so that $\pi(\mathrm{HoldsAt}(f, t))$ is Boolean-valued, then the persistence constraint forces literal invariance of the projected value on any "holding" span, which aligns with the classical intuition of a fluent remaining true until terminated. At the other extreme, if ϵ is large (e.g. $\epsilon = 1$ for $\pi : V \to [0, 1]$), the additional persistence clause becomes vacuous and persistence collapses back toward continuity; in that regime, the distinction between "steady" and "smoothly varying" is pushed back into the choice of η and TemporalSimilarity.

Definition 73 (Increasing/decreasing fluent)**.** *Fix a scalar projection $\pi : V \to [0, 1]$. A fluent f is* increasing *(relative to $(T, <)$) if for all $t_1 < t_2$,*

$$\pi(\mathrm{HoldsAt}(f, t_1)) \ \leq \ \pi(\mathrm{HoldsAt}(f, t_2)).$$

Similarly, f is decreasing *if for all $t_1 < t_2$,*

$$\pi(\mathrm{HoldsAt}(f, t_1)) \ \geq \ \pi(\mathrm{HoldsAt}(f, t_2)).$$

In proto-time, $<$ need not be a complete order; it may be a partial order encoding precedence. The above monotonicity clauses should then be read as applying to all comparable pairs $t_1 < t_2$. In particular, if t_1 and t_2 are incomparable (neither $t_1 < t_2$ nor $t_2 < t_1$), the definition does not constrain $\pi(\mathrm{HoldsAt}(f, t_1))$ versus $\pi(\mathrm{HoldsAt}(f, t_2))$, which matches the idea that monotone "change over time" is only meaningful along directed temporal reachability.

Remark 284 (Intuition and examples)**.** *Monotonicity is stated after projection to a scalar because "increasing" is inherently a scalar notion. For example, if f represents "confidence that a goal is achieved," one might take $\pi = \pi_{\text{pos}}$ and ask that positive support does not decrease over time. If f represents "amount of fuel remaining," one might impose decreasingness.*

This is useful as a compact way to express directed change, and it can be combined with the earlier event calculus machinery: one can infer monotone trends from initiation/termination patterns and inertia, then check them against observed HoldsAt *values as a consistency constraint.*

It is also useful to note the interaction between increasing and decreasing: if a fluent is both increasing and decreasing with respect to the same π and order $<$, then $\pi(\text{HoldsAt}(f, t))$ must be constant on each chain in $(T, <)$ (i.e. on each totally ordered subset). This captures the idea that "no upward drift" together with "no downward drift" yields stability, but only relative to the comparabilities present in proto-time.

Remark 285 (Non-persistent events)**.** *Hyperseed notes that continuous/increasing/decreasing are most relevant for non-persistent events. In our formalization, persistence is the strong constraint (low total variation over a span), while continuity and monotonicity constrain only local or directional change. Thus a non-persistent fluent may be continuous yet non-constant, or increasing yet not persistent.*

One can also mix these predicates to express common qualitative regimes. For example, "warming up" can be modeled as (i) continuous with respect to a chosen temporal similarity and (ii) increasing with respect to a temperature projection π, without being persistent; conversely, "being connected to WiFi" might be persistent (small ϵ) but neither increasing nor decreasing (no directed trend is intended, only stability when it holds).

Remark 286 (A conceptual bridge to emergence)**.** *When a fluent violates persistence but satisfies continuity, it suggests the presence of a smooth transformation rather than a stable condition. Such smooth transformations are often where new patterns become detectable (emergence as a change in compressibility), foreshadowing the pattern and emergence layer in Section 9 [5].*

In particular, continuity provides a baseline expectation of "no abrupt jumps" under the system's own notion of temporal neighborhood, so sustained deviations from persistence can be interpreted as structured drift rather than noise. This is precisely the regime in which higher-level descriptions (e.g. a slowly varying latent factor, a staged process, or a new macro-variable) can become more compressive than a frame-by-frame account, making the persistence/continuity distinction serve as an interface between low-level event calculus dynamics and later pattern-level analyses.

7.9 Process view: becoming as functorial evolution (bridge to process calculi)

Event calculus is one way to reason about change; a complementary way is to treat the world (or mind) as a *process indexed by proto-time.* In this second lens, "becoming" is not primarily a list of event-occurrences but a rule that assigns, to each experienced position in an order, a structured state together with coherent transition maps. The emphasis is on how successive situations hang together (compositionally), rather than on how a theory entails that a fluent holds.

Definition 74 (Becoming as a time-indexed process (functorial sketch))**.** *Let $(T, <)$ be a proto-time. Consider the thin category $\mathbf{T}$ whose objects are elements of T and with a unique morphism $t_1 \to t_2$ iff $t_1 < t_2$. A* process *over T is a functor*

$$S : \mathbf{T} \to \mathbf{Sys}$$

into a chosen category of system states **Sys** *(e.g. sets, measurable spaces, or V-enriched structures). In particular, the functoriality condition forces compatibility with the proto-temporal order: if $t_1 < t_2 < t_3$, then the induced maps satisfy $S(t_1 \to t_3) = S(t_2 \to t_3) \circ S(t_1 \to t_2)$, so that multi-step becoming factors into successive becomings without ambiguity.*

Remark 287 (Notation and categorical intuition)**.** *A* thin category *is a category with at most one morphism between any two objects; here the existence of a morphism $t_1 \to t_2$ encodes exactly the relation $t_1 < t_2$. A functor S assigns to each timepoint t an object $S(t)$ (a "state") in* **Sys***, and to each precedence $t_1 < t_2$ a morphism $S(t_1) \to S(t_2)$ (an "evolution map"). Thus, time becomes a parameter indexing structure-preserving transformation, rather than a numerical axis labeling states. Equivalently, one can regard* **T** *as the categorical packaging of the proto-time order and S as a representation of that order inside* **Sys***.*

This is a canonical formalization of Process (Hyperseed-Concept 140) and clarifies how proto-time supports process calculi: the order supplies composable arrows, and the functor turns them into composable state transitions. From this viewpoint, the "laws of motion" (broadly construed) are precisely the chosen morphisms in **Sys** *that witness admissible change; changing* **Sys** *changes what counts as a lawlike update (deterministic function, stochastic kernel, simulation relation, refinement map, etc.).*

Remark 288. *This functorial viewpoint is the categorical form of "becoming": morphisms represent allowed transformations along the experienced order. It also makes explicit what is often only implicit in informal talk about time: the content is not merely that there are states at moments, but that there are coherent translations between them that respect the proto-temporal composition. In later sections, this will interact with pattern webs and mind-world correspondence by replacing* **Sys** *with a category of pattern-flow structures and by admitting approximate morphisms. Concretely, "approximate" can be implemented by moving to an enriched or metric setting in which morphisms carry a notion of distortion (or error budget), so that becoming can be stable under coarse-graining, attention limits, and perceptual noise.*

Remark 289 (Why include both event calculus and functorial process views?)**.** *Event calculus emphasizes* logical entailment *about discrete events and fluents; the functorial view emphasizes* structured evolution *and compositionality. They are complementary lenses on the same phenomenon: one can often derive an event calculus from a process model by extracting predicates from states, and conversely one can build a process model from an event calculus by taking time contexts as states. Keeping both views available supports later synthesis with pattern-based cognition and with the more explicitly process-ontological themes that trace back to Peircean and Whiteheadian traditions [14, 15]. The bridge to process calculi is particularly transparent in the functorial picture: many calculi distinguish between (i) the space of configurations and (ii) the step relation or transition system, and the functor packages exactly this distinction while enforcing associativity of successive steps via categorical composition. When proto-time is taken as a partial order (rather than a total one), the same construction supports branching and concurrency: incomparable elements of T represent independent or unordered developments, while comparable elements represent precedence constraints, aligning the categorical skeleton with causal or dependency structure rather than with a single global clock.*

8 Effort, resistance, and simplicity

Outline

- Represent "effort" as a resource/cost structure suitable for compositional reasoning.

- Model resistance/submission and opening/closing as (directed) changes to a system's distinction policy.
- Define observer-relative simplicity in terms of effort minimization and (dually) weakness maximization.
- Define compositional simplicity as a least-fixed-point/dynamic-programming object over a combination system.
- Connect these notions to generalized Kolmogorov complexity and to structural (grammar-like) complexity.

To reduce ambiguity, the word "effort" will be treated as a *typed* magnitude rather than an informal proxy for time, energy, or difficulty. In particular, the goal is to support reasoning of the form: (a) a task can be achieved by alternative constructions, (b) each construction incurs effort, (c) effort accumulates along chains of sub-operations, and (d) "simplicity" is the selection of low-effort constructions relative to a given system/observer. This subsection is therefore preparatory: it fixes the algebraic shape of the quantity that later sections will propagate through patterns, habits, and predictive correspondence.

The five bullet points above should be read as a progression from *local* to *global* structure. First we choose a representation of effort that supports addition (doing things in sequence) and comparison/minimization (choosing among alternatives). Then we interpret certain phenomenological notions—opening/closing and resistance/submission—as structured transformations whose costs can be measured in the same effort space. Finally, we define two notions of simplicity: one that is observer-relative ("simple for this system") and one that is compositional ("stable under building wholes from parts"), and we relate both to established complexity measures.

Summary and Hyperseed concepts covered

Hyperseed treats *effort* as primitive and observer-relative: what is "simple" is what a particular system can do, represent, or predict with low effort (Hyperseed-Concept 100). To make this mathematically usable, we represent effort via a cost quantale and use it to define (i) simplicity as minimum representational effort (Hyperseed-Concept 169), and (ii) compositional simplicity as a stability property under building wholes from parts (Hyperseed-Concept 82). We then formalize *opening/closing* (Hyperseed-Concepts 125, 72) as relaxing/tightening distinction policies (Hyperseed-Concept 98) and *resistance/submission* (Hyperseed-Concepts 158, 183) as the effort gradient associated with such changes.

More concretely, a *cost quantale* is used because it simultaneously provides (i) an order expressing "no more effort than," (ii) an operation expressing sequential composition of efforts, and (iii) a notion of "taking the best available option" as an infimum/meet (or, dually, "taking the worst" as a supremum/join, depending on conventions). This avoids committing to effort being numeric; it could be vector-valued (time, risk, attention), partially ordered (incomparable trade-offs), or even extended with an "impossible" element representing infeasible constructions. The essential requirement is that effort can be *propagated* through a composite description and then *optimized* over the space of descriptions.

The phrase "minimum representational effort" should be read as a design principle that converts a descriptive problem into an optimization problem. Given a target object (a percept, prediction, explanation, or action plan), and a family of available representational strategies (codes, models, grammars, decompositions), the simplicity of the target *for the observer* is identified with the least effort among those strategies. This makes simplicity explicitly dependent on the observer's repertoire: an object can be simple for one system (because it has an efficient internal code) and complex for another (because it lacks the relevant decomposition).

The "distinction policy" viewpoint is intended to make opening/closing precise. A distinction policy is a rule (implicit or explicit) for which differences in the world are treated as relevant, and which are collapsed as irrelevant. Opening corresponds to a directed change that *admits more distinctions* (finer discrimination, increased sensitivity, more degrees of freedom in representation), while closing corresponds to a directed change that *forbids distinctions* (coarser discrimination, compression, or ignoring degrees of freedom). Because these changes alter what can be represented at all, they naturally induce changes in feasible effort: certain representations become available/unavailable, and the costs of existing representations may change.

Within this frame, resistance/submission is not introduced as a separate primitive but as the *effort landscape* associated with changing the policy. Resistance expresses the additional effort required to move in a certain direction in policy-space (for example, to open when a system is currently closed, or to close when it is currently open), while submission expresses the relative ease of moving with the local gradient (the direction that decreases effort or increases weakness, depending on the dual convention). Thus "resistance" is not merely a psychological label; it is a measurable asymmetry in how effort changes under directed transformations of the system's discrimination and control structure.

The dual phrase "weakness maximization" is included to emphasize that effort minimization can be equivalently presented as maximizing what a system cannot (or does not need to) do. On the effort-minimizing view, a simple representation is one that requires little work. On the weakness-maximizing dual view, a simple representation is one that *intentionally leaves many distinctions unresolved* while still being adequate for the task, thereby preserving slack and avoiding commitment. This duality will matter later when discussing robustness: sometimes a system becomes more capable by refusing to overfit distinctions, i.e. by choosing policies that remain weak in the right directions.

Finally, compositional simplicity is treated as a least-fixed-point/dynamic-programming object because "building wholes from parts" introduces recursion and shared substructure. If a system can construct complex objects by combining simpler ones, then the effort to represent an object is not just a property of the object in isolation but depends on the best decomposition into sub-objects, the costs of the combination operations, and the reuse of previously constructed components. A fixed-point characterization captures the stable assignment of minimal effort to each constructible object under these combination rules, and it aligns with standard dynamic-programming logic: compute the cost of a whole by minimizing over ways of assembling it from cheaper parts.

The link to generalized Kolmogorov complexity is then conceptual rather than merely analogical. In classical Kolmogorov complexity, simplicity is the length of the shortest program producing a string, relative to a universal machine. Here, "program length" is replaced by the observer's effort quantale, and "universal machine" is replaced by the observer's available representational operations and distinction policy. Structural (grammar-like) complexity enters when representations are not flat codes but compositional descriptions (grammars, rules, factor graphs, rewrite systems), in which case the least-effort description typically reflects reusable structure rather than mere shortest encoding.

Remark 290. *Philosophically, this section attempts to treat "effort" not as a metaphor but as a formally composable magnitude: something one can add along a chain of operations, minimize over alternatives, and propagate through a system as a constraint. This makes effort play a role analogous to "energy" in physics, but interpreted as an experiential-cognitive primitive rather than* *a physical conserved quantity. The intended application is that later layers (patterns, habits, mind-world correspondence) can talk about simplicity and resistance without silently switching between incompatible notions of cost.*

Remark 291. *The intended level of generality is deliberately higher than "effort equals time" or "effort equals number of steps." Some observers have parallelism, caching, or learned shortcuts; others face bottlenecks such as attention, working memory, or sensorimotor precision. A quantale-based treatment is meant to keep these possibilities open while still enforcing the minimum structure needed for compositional proofs: monotonicity (more demanding tasks should not cost less), compositionality (doing two things should cost at least doing each), and optimizability (alternatives can be compared). This is also what makes it possible to talk about "effort gradients" for resistance/submission without presupposing differentiability or even numeric effort.*

Hyperseed concepts covered.

- Effort.
- Resistance/submission; opening/closing.
- Simplicity; compositional simplicity.
- (Generalized) Kolmogorov complexity; structural complexity.
- Minimum representational effort (as a design principle).

8.1 Effort as a cost structure

Hyperseed begins from the experiential primitive "effort" and then builds a derived notion of simplicity. In a mathematical reconstruction, it is useful to represent effort using a compositional algebra that supports: (i) sequential composition of acts/inferences/operations, (ii) choice among alternatives, and (iii) taking minima over competing decompositions.

One may view (iii) as the formal expression of "search over plans": a single high-level act can often be realized by many different decompositions into subacts, and effort should select the best available decomposition by taking an infimum over a (possibly infinite) family of candidates. The framework below is deliberately permissive about cardinality: in many realistic settings (e.g. continuous control, approximate inference, or anytime algorithms) the relevant set of decompositions is naturally infinite, so the availability of arbitrary infima is not merely a technical luxury but the algebraic counterpart of "optimize over all available implementations."

A standard choice (also used implicitly in shortest-path and dynamic programming) is the *Lawvere* cost quantale.

Definition 75 (Effort quantale)**.** *Let*

$$\mathcal{E} := ([0,\infty], \geq, \inf, +, 0),$$

where the order is reversed (so that $a \leq_{\mathcal{E}} b$ means $a \geq b$ as real numbers), the join in the quantale order is inf *(ordinary minimum), and the monoidal product is $+$ (sequential composition of costs). Then $\mathcal{E}$ is a commutative quantale: $+$ distributes over arbitrary infima.*

It is sometimes helpful to keep in mind why $[0,\infty]$ (with ∞ included) is used rather than $[0,\infty)$. Allowing ∞ provides a canonical value for "impossible" or "unavailable" processes within a context, and it ensures that arbitrary infima always exist in the underlying complete lattice structure. This aligns the formalism with optimization practice: if an operation cannot be performed under the current constraints, it can be assigned effort ∞, and taking minima over alternatives then correctly ignores it whenever a finite alternative exists.

Remark 292. ***Notation unpacking.*** *The tuple* $([0,\infty], \geq, \inf, +, 0)$ *should be read as follows: the underlying set is the extended nonnegative reals* $[0,\infty]$*; the order relation used for the quantale is the* reversed *real order (so "smaller effort" becomes "larger element" in the quantale order); the quantale join (least upper bound in the quantale order) is* inf *in the usual real order; the monoidal operation is* $+$ *with unit* 0*. Saying "+ distributes over arbitrary infima" is exactly the familiar identity*

$$a + \inf_i b_i \;=\; \inf_i (a + b_i),$$

which is what makes dynamic programming algebraically natural.

One can also read the distributivity law operationally: if one has a fixed prefix act of cost a and then must choose an optimal continuation among many options with costs b_i, the optimal total cost is obtained by adding a once and then optimizing the remainder, rather than re-solving the whole problem from scratch for each candidate continuation. This is precisely the algebraic skeleton behind Bellman-style optimal substructure.

Remark 293. ***Intuition.*** *The reversed order is a small but important conceptual maneuver: we want "better" to mean "easier," i.e. lower cost. But many later constructions (especially those expressed in quantale language, including weakness; Hyperseed-Concepts 202, 143) are more naturally written as monotone statements in an order where "better" corresponds to "larger." So we flip the order once and then keep monotonicity statements in their natural direction; this is consonant with the quantale-based treatment of weakness in [3] (and also with the broader Hyperseed ontology presentation [1]).*

A related perspective (useful later, though not required here) is that $\mathcal{E}$ is the canonical "cost domain" used in Lawvere's approach to generalized metric spaces and enriched categories: addition plays the role of path concatenation, and infimum plays the role of taking the best path among many. This connection is one reason the same algebra reappears across shortest-path problems, program semantics, and compositional models of planning.

Remark 294. ***Examples.*** *If a system can solve a task by either: (1) doing method A costing* 3 *units, or (2) doing method B costing* 5 *units, then "choosing among alternatives" corresponds to* $\inf(3,5) = 3$*. If it must do two steps in sequence costing* 3 *and* 5*, then the sequential effort is* $3 + 5 = 8$*. Thus, even before one speaks of "minds," this algebra captures the basic grammar of optimization.*

It is also worth emphasizing that the "alternative set" over which inf is taken need not be limited to two options. For instance, if a process can be implemented by selecting an integer parameter k (say, the number of refinement iterations) and the effort scales as $f(k)$, then the best available implementation corresponds to $\inf_{k\in\mathbb{N}} f(k)$. If the infimum is not achieved by any finite k (a common situation in asymptotic approximations), the formalism still cleanly represents "arbitrarily close" improvements, which is often the right abstraction when one separates idealized capability from finite-resource constraints.

Remark 295. *We use the reversed order so that "better" (lower cost) corresponds to "larger" in the quantale order. This makes formulas with* inf *and* $+$ *align with the algebra of optimality:*

choosing among alternatives corresponds to taking inf*, and composing steps corresponds to adding costs.*

Definition 76 (Effort of a process)**.** *Let $\mathcal{P}$ be a set of processes available to an observer in a fixed context C. An* effort assignment *is a map*

$$\mathrm{Eff}_C : \mathcal{P} \to [0, \infty]$$

satisfying (as modeling assumptions):

- *(Sequential subadditivity)* $\mathrm{Eff}_C(p; q) \leq \mathrm{Eff}_C(p) + \mathrm{Eff}_C(q)$ *whenever $p; q$ denotes running p then q,*
- *(Choice) if p can be implemented by choosing between p_1 and p_2, then* $\mathrm{Eff}_C(p) = \min(\mathrm{Eff}_C(p_1), \mathrm{Eff}_C(p_2))$*.*

The definition intentionally separates two layers: the abstract quantale $\mathcal{E}$, which specifies the algebra of combining and comparing costs, and the concrete map Eff_C, which instantiates that algebra for a particular observer and context. In categorical language (not required for later sections, but conceptually clarifying), Eff_C behaves like a *lax* monoidal measure of sequential composition: it respects the monoidal operation $+$ up to an inequality rather than on-the-nose equality, reflecting that real implementations can reuse intermediate results, amortize setup costs, or exploit structure.

Remark 296. ***Intuition.*** *An effort assignment is an observer-indexed bookkeeping device: it says, within context C, how costly it is for the observer to execute certain operations. The inequalities are deliberately weak. Sequential subadditivity says that doing two things in sequence should not cost* more *than paying for each separately (because one can always execute them in the naive way). In real systems there may be* synergies *(the combined act costs less than the sum) or* frictions *(overheads not modeled here); the subadditivity axiom allows synergies and leaves room to represent frictions elsewhere (e.g. via t_C later).*

One can also interpret context dependence explicitly: the same "nominal" process p may have very different effort in different contexts C because the observer's available tools, cached state, permissions, training, or environmental affordances differ. This is part of why the effort assignment is not treated as an intrinsic property of p alone. For example, access to a GPU, a precomputed index, or a specialized library can change $\mathrm{Eff}_C(p)$ by orders of magnitude without changing the abstract specification of p.

Remark 297. ***Examples.*** *If p is "load a dataset" and q is "train a model," then $p; q$ is the sequential procedure. If training reuses cached preprocessing from loading, then $\mathrm{Eff}_C(p; q)$ may be strictly less than $\mathrm{Eff}_C(p) + \mathrm{Eff}_C(q)$. For "choice," if p is "sort a list" and p_1 is quicksort while p_2 is mergesort, then the observer may treat $\mathrm{Eff}_C(p)$ as the cheaper of the two implementations available in that context.*

A further example of frictions (not captured by subadditivity alone) is a fixed setup cost: suppose running any nontrivial process incurs a one-time initialization overhead (allocating memory, starting a service, warming a cache). Then one may have $\mathrm{Eff}_C(p; q) \approx \mathrm{Eff}_C(p) + \mathrm{Eff}_C(q) -$ (shared setup), which is synergy-like, but in other regimes one may see the opposite effect if the environment forces repeated setup (e.g. sandboxing, rate limits), motivating later context parameters that explicitly model such overheads.

Remark 298. ***Usefulness.*** *These axioms are the minimal interface needed to make later definitions (simplicity as an infimum; compositional simplicity as a least fixed point) behave the way one expects of optimization problems. They permit a clean separation between (i) the algebraic form of "effort reasoning" and (ii) the empirical or architectural details of what an observer can actually do, as emphasized in [19].*

In particular, because "choice" is modeled by a minimum and sequential composition is modeled (at the quantale level) by addition, later notions of simplicity can be defined as the cost of the cheapest description, explanation, or program that achieves a target. The present section therefore fixes the cost calculus that makes such infimum-based definitions well-typed and compositional: one can substitute equivalent subprocedures, refine a plan by expanding a step into substeps, and still reason algebraically about the resulting effort.

8.2 Distinctions as policies; opening and closing

Hyperseed's account of simplicity is inseparable from the idea that an observer may or may not make certain distinctions. We model this using a *distinction policy*, conveniently represented by an *indistinction* relation (the pairs the observer treats as the same for the task at hand). In particular, the policy is meant to be *task-relative*: the same underlying observer may adopt different policies for different contexts C, and even within a fixed C may move along a spectrum from very fine to very coarse discrimination.

Definition 77 (Indistinction policy)**.** *Fix a finite universe X (of entities, states, events, or features relevant in context C). An* indistinction policy *is a subset $H \subseteq X \times X$, interpreted as:*

$$(x, y) \in H \quad \text{means “the observer does not (currently) distinguish } x \text{ from } y \text{ in context } C\text{.”}$$

Write $\mathcal{H}_C \subseteq \mathcal{P}(X \times X)$ for the set of admissible policies for context C.

Remark 299. ***Scope and admissibility.*** *The set $\mathcal{H}_C$ is left abstract on purpose: in some applications, not every relation should be allowed. For example, an engineered sensor might be required to treat indistinction symmetrically, or a legal/organizational setting might impose that indistinction respects certain categories (e.g. cannot collapse "approved" with "unapproved"). Conversely, allowing $\mathcal{H}_C$ to include non-equivalence relations makes it possible to represent partial, asymmetric, or temporarily inconsistent discrimination patterns that occur under time pressure, noise, or conflicting heuristics.*

Remark 300. ***Intuition.*** *An indistinction policy is the observer's current answer to the question: "Which differences matter here?" (Hyperseed-Concept 96) and, more sharply, "Which distinctions will I actually enforce?" (Hyperseed-Concept 98). Representing it as a subset $H \subseteq X \times X$ emphasizes that the policy is a* relation*, not necessarily an equivalence relation. We are not assuming symmetry, transitivity, or reflexivity; an observer may be inconsistent or paraconsistent about what it merges, and later sections allow more graded/quantale-valued versions.*

Remark 301. ***Extremes and calibration.*** *Two boundary cases help calibrate the interpretation. If $H = \varnothing$, then no pairs are explicitly treated as indistinct, corresponding to an idealized stance of "distinguish everything from everything" (maximal discrimination, typically high effort). If $H = X \times X$, then every pair is treated as indistinct, corresponding to "everything is the same for this task" (maximal collapse, typically low effort but also low discriminatory power). Most realistic policies sit between these extremes, and the framework is designed to let later sections quantify the cost/benefit of moving within this lattice of relations.*

Remark 302. ***Examples.*** *If X is a set of colors and the observer cannot distinguish nearby shades, then H contains pairs of shades it treats as the same for the present task. If X is a set of world-states and the observer ignores microphysical details, then H contains pairs of microstates that are collapsed into one macrostate. In the most classical special case, H could be the graph of an equivalence relation corresponding to a partition (coarse-graining), matching the probabilistic coarse-graining discussion in Section 10.2.*

Remark 303. ***Relation to representation maps.*** *It is often helpful to think of a policy as being implemented by some representation or measurement map $\pi\colon X \to R$ into a smaller set of reports R, where $(x, y) \in H$ whenever $\pi(x) = \pi(y)$. This produces an equivalence relation (the kernel of π), but the present definition is broader: it also covers situations where the observer's "same/different" judgments depend on direction, history, or limited local comparisons (e.g. x is treated as indistinct from y for one subroutine but not vice versa). Keeping H as an arbitrary relation allows these cases to be discussed without forcing a premature commitment to partitions.*

Remark 304. ***Usefulness.*** *Making the policy explicit allows later constructions to talk about* changing *what is distinguished: opening and closing are then simply inclusion relations. This is a way to treat "attention," "granularity," and "resolution" as first-class mathematical objects rather than informal modifiers (cf. Hyperseed-Concept 60).*

Remark 305. ***Order-theoretic viewpoint.*** *Because policies are subsets of $X \times X$, they inherit the inclusion partial order. This gives a simple, compositional notion of "more indiscriminating" versus "more discriminating" without requiring a numeric measure. Later, numeric notions of effort or simplicity can be layered on top of this order (e.g. by assigning costs to relations or to their generators), but the inclusion order is the minimal structural scaffold needed to compare policies.*

Definition 78 (Opening and closing)**.** *Given two policies $H, H' \in \mathcal{H}_C$:*

- *The transition $H \to H'$ is an* opening *(relaxation of distinctions) if $H \subseteq H'$.*
- *The transition $H \to H'$ is a* closing *(tightening of distinctions) if $H' \subseteq H$.*

Remark 306. ***Intuition.*** *Opening means: "I will now treat* more *pairs as indistinct," i.e. I will collapse more distinctions (Hyperseed-Concept 125). Closing means: "I will now treat* fewer *pairs as indistinct," i.e. I will enforce more distinctions (Hyperseed-Concept 72). It is useful to note the direction: $H \subseteq H'$ is an opening because H' is a* bigger set of collapsed pairs*.*

Remark 307. ***Monotonic consequences.*** *Under any reasonable downstream use of H (e.g. defining which states are treated as interchangeable, or which features are ignored), opening is monotone in the sense that anything permissible under H remains permissible under H' when $H \subseteq H'$. Closing is the reverse move: it may invalidate previous simplifications by reintroducing distinctions that must now be tracked, measured, stored, or acted upon. This monotonicity is what makes openings/closings suitable as "policy moves" in later optimization and dynamical-control discussions.*

Remark 308. ***Examples.*** *If X is the set of pixel configurations and the observer switches from "full image" to "only average brightness," the new policy collapses many more pairs of images and is thus an opening. Conversely, switching from "only average brightness" to "average brightness plus edge map" is a closing: fewer pairs remain indistinct.*

Remark 309. ***Sequential changes.*** *Openings and closings compose in the expected way along inclusion chains. For instance, $H_0 \subseteq H_1 \subseteq H_2$ corresponds to successively coarsening discrimination, while $H_2 \supseteq H_1 \supseteq H_0$ corresponds to successively refining it. If a system alternates between opening and closing, the resulting path may not be monotone; such non-monotone trajectories are precisely what one expects when attention is reallocated over time (e.g. zooming out to gain tractability, then zooming in on a salient subproblem).*

Remark 310. ***Why needed.*** *The opening/closing distinction is the bridge from phenomenological vocabulary to optimization: it provides the partial order along which effort and weakness can be compared. In later sections, opening/closing also becomes a dynamical control lever: a system can spend effort to close (gain precision) or open (gain tractability), echoing the tradeoff themes emphasized in [9].*

Remark 311. *Opening increases the set of collapsed distinctions (more pairs treated as "the same"); closing decreases it. In Hyperseed terms: opening generally reduces representational effort (but may reduce control/predictive sharpness), whereas closing generally increases effort (but may increase control/predictive sharpness).*

Remark 312. ***Link to resistance and simplicity.*** *Within this section's theme (effort, resistance, and simplicity), the policy language allows a clean separation between (i) what the world presents (the complexity of X and its dynamics) and (ii) what the observer commits to tracking (the chosen H). Resistance can then be modeled as the cost of maintaining a closing against pressures to open (e.g. noise, limited bandwidth, competing tasks), while simplicity can be treated as the availability of effective openings that do not destroy task performance. This sets up later formalizations in which simplicity is not merely "small description length," but "small description length relative to a tolerated indistinction policy."*

8.3 Effort of distinctions; resistance and submission

To connect policies to effort, we assume the observer incurs effort to maintain or compute distinctions. This can be modeled in many ways; for this section we only require the *directionality* to match the intended interpretation. Concretely, the partial order by inclusion on $\mathcal{H}_C$ is read as an "at least as discriminating as" relation: $H \subseteq H'$ means that H keeps (at least) all the constraints/distinctions that H' keeps, so H' is a coarsening (an opening) of H. In many realizations one can think of H as a partition, a σ-algebra, a hypothesis class, or a set of admissible histories; in each case, enlarging H corresponds to allowing more states to be treated as equivalent, hence reducing the informational or computational burden of maintaining sharp boundaries.

Definition 79 (Policy effort and marginal effort)**.** *A* policy effort functional *for context C is a map*

$$\mathrm{Eff}_C : \mathcal{H}_C \to [0, \infty]$$

that is antitone *with respect to inclusion:*

$$H \subseteq H' \quad \Longrightarrow \quad \mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(H').$$

Define the marginal effort *of changing policy from H to H' as*

$$\Delta\mathrm{Eff}_C(H \to H') := \max\big(0,\ \mathrm{Eff}_C(H') - \mathrm{Eff}_C(H)\big).$$

Remark 313. ***Domain/codomain choices.*** *Allowing Eff_C to take values in $[0, \infty]$ (rather than only $[0, \infty)$) makes it possible to represent policies that are, in context C, effectively unrealizable for the observer (e.g. a discrimination requiring unattainable sensor resolution or unbounded computation). No further regularity (continuity, convexity, additivity, etc.) is assumed here: the framework is designed so that later sections can specialize Eff_C according to the application.*

Remark 314. ***Notation and conventions.*** *The symbol Eff_C has been used above as an effort assignment on processes; here it is specialized to an effort assignment on* policies $H \in \mathcal{H}_C$. *This* *is intentional: the policy is itself something the observer must implement (by allocating computation, attention, measurement, memory, etc.). Also note that* $\max(0, \cdot)$ *makes* $\Delta\mathrm{Eff}_C$ *a one-sided "increase only" measure; it is a minimal operational proxy for resistance rather than a full signed gradient. A signed analogue* $\mathrm{Eff}_C(H') - \mathrm{Eff}_C(H)$ *could be introduced if one wanted to track both "relief" (negative changes) and "load" (positive changes), but for resistance the positive part is the invariant needed.*

Remark 315. ***Intuition.*** *Antitonicity expresses the central phenomenological claim that fine-grained discrimination is costly: if you collapse more distinctions (opening), you should not pay* more *effort. The model is deliberately permissive: it does not insist that opening strictly decreases effort, only that it does not increase it. Equivalently, if one reads* $\subseteq$ *as a refinement order, then* Eff_C *is monotone with respect to "refinement makes things harder": adding constraints cannot make the observer's implementation problem easier.*

Remark 316. ***Examples.*** *If* H *represents "distinguish 100 categories" and* H' *represents "distinguish only 10 categories," then* $H \subseteq H'$ *and* $\mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(H')$ *says that maintaining 100 categories requires at least as much effort as maintaining 10. If closing from* H' *to* H *demands extra memory or sensory precision, then* $\Delta\mathrm{Eff}_C(H' \to H)$ *quantifies the added cost. A concrete toy family is* $\mathrm{Eff}_C(H) = \log|\Pi(H)|$ *when* H *induces a finite partition* $\Pi(H)$ *(or, more generally, a description-length/MDL-type functional); then coarsening reduces the number of cells and does not increase* Eff_C*. Another common choice in probabilistic settings is to let* $\mathrm{Eff}_C(H)$ *track the expected coding or inference cost of operating with policy* H *under a context-dependent distribution; antitonicity then expresses that enforcing additional distinctions cannot reduce expected operational load.*

Remark 317. ***Usefulness.*** *This is the smallest assumption needed to define "resistance" without psychologizing it. It also prepares the ground for more elaborate, history-dependent models of resistance (habits) where opening can become costly because the system has invested in a high-resolution policy and must now "unlearn" it. In particular, the present definition isolates an "instantaneous" effort requirement associated to a policy as such; later, additional state variables can encode sunk costs, commitments, or stabilizing feedbacks that make effort depend on the trajectory by which* H *was reached.*

Remark 318. ***Context dependence.*** *The index* C *is essential: the same abstract policy* H *can have different effort in different environments, embodiments, or task regimes (e.g. a classification with 100 categories may be easy with a fast lookup table but hard if the categories must be inferred from raw sensory streams). Formally, nothing forces* Eff_C *and* $\mathrm{Eff}_{C'}$ *to be comparable across contexts; the intended reading is that effort is observer-and-situation indexed, and comparisons are meaningful only within a fixed* C *unless an explicit identification is provided.*

Remark 319. *If* $H \to H'$ *is an opening (*$H \subseteq H'$*), antitonicity implies* $\mathrm{Eff}_C(H') \leq \mathrm{Eff}_C(H)$*, hence* $\Delta\mathrm{Eff}_C(H \to H') = 0$*: opening does not* require *additional effort in this minimal model (it releases constraints). If* $H \to H'$ *is a closing (*$H' \subseteq H$*), then* $\Delta\mathrm{Eff}_C(H \to H')$ *measures the added effort required to enforce more distinctions. A richer model (used later when habits are introduced in Section 12) adds "habit penalties" so that opening may also be resisted. Note that no path-additivity is assumed: even with a fixed* Eff_C*, one need not have* $\Delta\mathrm{Eff}_C(H \to H'') = \Delta\mathrm{Eff}_C(H \to H') + \Delta\mathrm{Eff}_C(H' \to H'')$*; this absence of a required triangle law is deliberate, because resistance will later be allowed to depend on intermediate reorganizations and nonlocal reparameterizations of policy.*

Definition 80 (Resistance and submission (minimal operationalization))**.** *For a directed policy change $H \to H'$ in context C:*

- Resistance *is identified with* $\Delta\mathrm{Eff}_C(H \to H')$.
- Submission *(in this minimal operationalization) occurs when the system follows a policy update that does not increase required effort, i.e. when* $\Delta\mathrm{Eff}_C(H \to H') = 0$.

Remark 320. ***Intuition.*** *Resistance (Hyperseed-Concept 158) is treated here as the "extra effort demanded" by a change, and submission (Hyperseed-Concept 183) as the special case where no extra effort is demanded. This minimal reading is intentionally behavioristic: it does not claim to capture the whole phenomenology of resistance, only an invariant that can be transported into later mathematics. In particular, it separates (i) the* direction *of a policy update in the lattice/order of distinctions from (ii) the* load *required to implement that update for a given observer in context C.*

Remark 321. ***Examples.*** *If a system is asked to refine its model (closing) and this requires additional computation, memory, or sensing, then $\Delta\mathrm{Eff}_C > 0$ and the change is resisted in this operational sense. If it is asked to simplify (opening) and this reduces constraints, then $\Delta\mathrm{Eff}_C = 0$ and the change is "submitted to" without additional load. In later dynamical models, opening may also incur cost because simplifying can break internal commitments (learned habits), leading to nonzero resistance even for openings. One can also interpret $\Delta\mathrm{Eff}_C(H \to H')$ as an* activation barrier*: the policy H' might be globally "simpler" than H in a static sense, yet transitioning to it can still be difficult if the model is extended to include switching/rewiring costs not captured by the static* Eff_C *alone.*

Remark 322. ***Why this definition matters.*** *One can view this as a precise analogue of a thermodynamic gradient: forcing a system into a more constrained configuration costs work, and that "work" is what resistance measures. This resonates with the "least-effort" orientation in [21] while staying purely formal and observer-indexed. The analogy is structural rather than literal:* Eff_C *is not assumed to be physical energy, but it plays the same mathematical role of a potential whose increases quantify the minimal additional "input" required to sustain tighter constraints.*

Remark 323. *Hyperseed's phenomenological language distinguishes several kinds of resistance/submission (somatic, cognitive, affective, spiritual). The formalization above is deliberately thin: it isolates a single load-bearing invariant that will matter throughout the ontology:* tightening distinctions is effort-consuming*. Later sections add dynamical structure to represent different "channels" of resistance. The point of starting thin is that the ontology can then refine (rather than revise) the concept: richer models may decompose* Eff_C *into multiple terms (e.g. sensing vs. inference vs. memory), but antitonicity and the resulting operational meaning of* $\Delta\mathrm{Eff}_C$ *remain stable.*

8.4 Simplicity as minimum representational effort

Hyperseed's simplicity is observer-relative and task-relative: an object is simple for an observer if it can be handled (represented, predicted, manipulated) with low effort. This framing treats "simplicity" not as an intrinsic geometric or syntactic attribute of x, but as a property of the best interface an observer can construct between x and the demands of context C. In particular, what counts as "handling" can vary: the same x may be easy to *store* but hard to *simulate*, easy to *predict* but hard to *control*, etc., and these differences are absorbed into the choice of admissible representations and the effort functional.

We therefore define simplicity as an *infimum over representations.* The use of an infimum (rather than, say, an arbitrary chosen representation) emphasizes that simplicity is an *optimal* notion: $s_C(x)$ records the best achievable effort among all admissible representational strategies in C. It also allows that the "best" representation may be approached only in the limit (e.g., by increasingly refined approximations), which is often the realistic case in continuous or resource-bounded settings.

Definition 81 (Representations and representational effort)**.** *Fix a context C and a domain of items $\mathcal{X}_C$ (entities, states, experiences, or patterns). Let $\mathcal{R}_C(x)$ denote the set of admissible representations of $x \in \mathcal{X}_C$. Assume an effort assignment* Eff_C *on representations. Define the* (subjective) simplicity *of x in context C by*

$$s_C(x) := \inf\{\mathrm{Eff}_C(r) : r \in \mathcal{R}_C(x)\}.$$

Remark 324. ***Notation unpacking.*** *Here $\mathcal{R}_C(x)$ is a set (possibly large) of alternative representations r that "stand for" x in context C. The functional* $\mathrm{Eff}_C(r)$ *measures the cost of using representation r (storage, computation, inference, sensing, etc.). The infimum* inf *is taken in the ordinary real order: $s_C(x)$ is the best (least costly) representation effort available. When $\mathcal{R}_C(x)$ is rich, it is helpful to read "$r \in \mathcal{R}_C(x)$" as encoding both an* encoding language *(what forms representations may take) and a set of* acceptability constraints *(what counts as representing x well enough for the purposes of C).*

Remark 325. ***Intuition.*** *This definition turns "simplicity" into a controlled form of compression: x is simple if there exists a cheap way to represent it. The philosophy is close in spirit to algorithmic information theory—the object is "simple" if it has a short description—but we have replaced "short" with a general observer-dependent effort measure. This observer-relativity is central in Hyperseed (Hyperseed-Concept 169) and aligns with the broader pattern/emergence approach in [5]. One can also view $s_C(x)$ as a generalized "minimum description length" objective in which description length, compute time, energy, bandwidth, or even required sensor acuity may all contribute to effort, depending on what the context regards as scarce.*

Remark 326. ***Examples.*** *A circle is simple for a context that has the concept "circle" and can store "center + radius" cheaply; it may be complex for a context that can only store point clouds. A large integer like 10^{100} is simple for a context that allows exponent notation, and less simple for a context that requires explicit decimal expansion. Similarly, a periodic signal may be simple for a context that admits Fourier representations (a few coefficients) but complex for a context restricted to raw time-series samples; conversely, a sharply localized transient may be cheaper as a sparse time-domain description than as a global frequency expansion.*

Remark 327. ***Why useful.*** *By making simplicity an infimum, we obtain a quantity that behaves well under optimization and can be compared across tasks once adequacy constraints are imposed. This is also the mathematical doorway through which patterns will enter in Section 9: a pattern is, roughly, a representation whose effort is much smaller than some baseline. In practice, this invites a two-part modeling stance: first choose what counts as an admissible representation (the hypothesis class, the interface, the "vocabulary"), then measure the best achievable effort within that class. Changing $\mathcal{R}_C(x)$ (e.g., by adding a new representational primitive) can strictly decrease $s_C(x)$, formalizing the idea that learning new concepts can make previously complex items simple.*

Remark 328. *Low $s_C(x)$ means "x is simple for C." Different contexts yield different simplicity orderings. This formalizes the Hyperseed claim that simplicity is not an absolute property of the world but is indexed by an observer's capacities and goals. In particular, if two contexts C and C' differ only by resource budgets (time, memory, precision), then $s_C(x)$ can be interpreted as a* *context-indexed "resource complexity" of x. Also note that, depending on conventions, it is natural to allow $s_C(x) = +\infty$ when no admissible representation exists (e.g., $\mathcal{R}_C(x) = \varnothing$ or all candidates have unbounded effort), which captures the possibility that some items are effectively unhandleable in a given context.*

8.5 Simplicity as weakness: the dual perspective

Section 3.7 defined a quantale-valued *weakness* $w(H)$ for an indistinction policy H: weakness increases as more (and/or more important) distinctions are collapsed (Hyperseed-Concepts 202, 143; see also [3, 2] for related motivation). This provides an algebraic dual to effort-based simplicity. In particular, it lets us speak about "being simpler" either in an operational sense (less work is required to maintain fine-grained distinctions) or in a semantic/informational sense (fewer distinctions are being asserted at all). The point of introducing w is that the latter can be aggregated and compared even when an explicit effort model is unavailable or context-dependent.

The key relation is monotonic: *opening decreases effort and increases weakness*, while *closing increases effort and decreases weakness*. Here "opening" is the order-theoretic operation of enlarging H by adding more pairs declared indistinct, i.e. moving upward in the inclusion order on $\mathcal{H}_C$; "closing" is the reverse movement. Because both w and Eff_C are defined as order-respecting maps (but in opposite directions), this monotonicity is not an extra axiom: it is the compatibility condition that makes the two notions of simplicity track the same qualitative phenomenon. We record the abstract monotonic facts as a sanity theorem, to be used later.

Theorem 7 (Effort–weakness monotonicity)**.** *Fix a context C with admissible indistinction policies $\mathcal{H}_C$. Assume:*

1. *$w : \mathcal{H}_C \to V$ is monotone with respect to inclusion (as in Theorem 1 specialized to C),*

2. *$\mathrm{Eff}_C : \mathcal{H}_C \to [0, \infty]$ is antitone with respect to inclusion (Definition 79).*

Then for any $H \subseteq H'$ in $\mathcal{H}_C$ we have

$$w(H) \leq w(H') \qquad \textit{and} \qquad \mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(H').$$

Thus opening simultaneously increases weakness and decreases effort. Equivalently, along any inclusion chain

$$H_0 \subseteq H_1 \subseteq \cdots \subseteq H_n,$$

the sequence $\big(w(H_i)\big)_{i=0}^n$ is nondecreasing in the quantale order, while $\big(\mathrm{Eff}_C(H_i)\big)_{i=0}^n$ is nonincreasing in the usual order on $[0, \infty]$.

Remark 329. ***What this says, in plain language.*** *If you merge more cases together (open the policy), then you become "weaker" in the precise quantale sense (you assert fewer distinctions), and you also do not have to spend more effort maintaining distinctions. This theorem is not deep; its value is that it makes the duality between two kinds of "simplicity talk" explicit and checkable. In particular, it rules out the pathological possibility that a policy could be simultaneously "more indiscriminate" (collapsing distinctions) and yet require strictly* more *effort to implement, or vice versa, at least at the level of the abstract order-theoretic interface.*

Remark 330. ***Why it matters.*** *Later sections will compose policies across subsystems and contexts. Weakness is designed to compose well (quantale aggregation), while effort is designed to support minimization. This theorem is the hinge connecting those two calculi: it guarantees that* *one is not optimizing a quantity that behaves perversely with respect to the other. A typical use is: if a construction (composition, relaxation, marginalization) is known to correspond to opening in $\mathcal{H}_C$, then one immediately gets a one-line comparison statement for both w and Eff_C without unpacking their internal definitions in that particular setting.*

Remark 331. ***Connection to the rest of the document.*** *In Section 9, pattern intensity is defined by comparing effort (or weakness) before and after a representational move. In that setting, one often wants to reason with whichever quantity composes more conveniently; the monotonic relation here lets one translate qualitative conclusions across the two viewpoints. For example, if a representational move is shown (by construction) to only ever open the operative policy, then it cannot increase effort; if instead it is shown to strictly close the policy, then it cannot decrease weakness. These translations are intentionally "direction-only": they preserve the sign of comparisons even when the magnitudes live in different codomains (V versus $[0,\infty]$).*

Proof. The weakness inequality is exactly monotonicity of w under adding undistinguished pairs. The effort inequality is the assumed antitonicity of Eff_C. One can also view the statement as the conjunction of two functoriality properties: w is order-preserving and Eff_C is order-reversing on the poset $(\mathcal{H}_C, \subseteq)$. $\square$

Proof sketch. The argument is purely definitional: "opening" means $H \subseteq H'$. Monotonicity of weakness turns inclusion into $w(H) \leq w(H')$, while antitonicity of effort turns the same inclusion into $\mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(H')$. There is no hidden construction; the point is to record that the intended phenomenological directionality has been built into the formalism. A useful way to remember the variance is: weakness measures what you *give up* by collapsing distinctions, so it grows when you add collapses; effort measures what you *must supply* to maintain distinctions, so it shrinks when you stop maintaining them. $\square$

Remark 332. *A useful image is to imagine a knob controlling perceptual or conceptual resolution. Turning the knob toward coarser resolution corresponds to opening: more things look the same. Weakness increases (more indistinction), and effort decreases (less computation/attention). Turning the knob toward finer resolution corresponds to closing: more things must be told apart, which costs effort. At the extremes, the fully open end of the knob corresponds to a maximally indiscriminate policy (everything relevant is treated as the same), which should intuitively have high weakness and low effort; the fully closed end corresponds to a maximally discriminating policy (no additional identifications beyond those forced by admissibility), which should have low weakness and high effort. The theorem does not assume such extrema exist in $\mathcal{H}_C$, but whenever they do, the inequalities specialize to immediate upper/lower bounds.*

Remark 333. ***Order conventions and interpretability.*** *The inequality $w(H) \leq w(H')$ is taken in the intrinsic order of the quantale V. In many concrete quantales used for aggregation (e.g. $([0,\infty], \geq, +, 0)$ with the* reverse *order, or a powerset quantale ordered by inclusion), it is worth checking once which direction corresponds to "more severe" weakness. The present statement fixes that convention by insisting that opening corresponds to* increasing *weakness in the chosen order; all later comparisons inherit this convention. Similarly, the effort inequality uses the standard order on $[0,\infty]$, so "decreases effort" always means "numerically no larger."*

Corollary 1 (No free lunch in both directions)**.** *If $H \subseteq H'$ and $w(H') < w(H)$ (strictly, in the order of V), then such a pair cannot occur under the stated assumptions; likewise, if $\mathrm{Eff}_C(H') > \mathrm{Eff}_C(H)$, then $H \subseteq H'$ cannot hold. In other words, under opening one cannot simultaneously get strictly* less *weakness, nor strictly* more *effort.*

8.6 Minimum representational effort as constrained weakness maximization

In applications, an observer typically cannot open indefinitely: too much collapsing of distinctions destroys predictive power and control. Hyperseed's "minimum representational effort" principle is therefore a *constrained* minimization: among all policies/representations that are adequate for a task, prefer those requiring the least effort (cf. [2, 19] for related design principles). In particular, the "constraint" is not an incidental add-on: it is the mathematical device that prevents the trivial solution "represent nothing" (or "distinguish nothing") from being optimal.

Definition 82 (Task constraint and feasible policy set)**.** *Let a task constraint in context C be a predicate $\mathsf{Adeq}_C(H) \in \{\text{true}, \text{false}\}$ meaning: "policy H is adequate for the task (prediction/control objective)". Define the feasible set*

$$\mathcal{F}_C := \{H \in \mathcal{H}_C : \mathsf{Adeq}_C(H)\}.$$

Remark 334. ***Intuition.*** *The predicate $\mathsf{Adeq}_C(H)$ is where "what the observer is trying to do" enters. Without it, the cheapest policy would typically be the maximally open one (collapse everything), which is useless for prediction/control. Adequacy formalizes the idea that some distinctions are not optional because the task depends on them (Hyperseed-Concept 186).*

Remark 335. ***Examples.*** *If the task is to predict whether a system will fail, then collapsing distinctions that separate failure states from non-failure states makes the policy inadequate. If the task is image classification among a small set of labels, then distinctions within each label class may be safely collapsed without harming adequacy.*

Remark 336. ***Why needed.*** *This definition isolates a general optimization shape that will recur in more elaborate guises (Pareto frontiers, tradeoff theorems, multi-objective feasibility). It is the formal core of what the Hyperseed overview treats as "do not spend representational effort unless you must" [1].*

Remark 337. ***Well-posedness.*** *The feasible set $\mathcal{F}_C$ can be empty if the task is impossible under the observer's available policy class $\mathcal{H}_C$ (or if the adequacy predicate is too strict). In that case the principle in Definition 83 becomes a diagnosis: either enlarge $\mathcal{H}_C$ (more expressive policies), weaken/relax Adeq_C (approximate adequacy, probabilistic success, slack constraints), or change the task/context C. This mirrors practical learning systems where "no model fits" is handled by revising the hypothesis class or by moving from hard constraints to soft penalties.*

Definition 83 (Minimum representational effort principle)**.** *An observer in context C satisfies* minimum representational effort *if it preferentially selects*

$$H^* \in \arg\min_{H \in \mathcal{F}_C} \mathrm{Eff}_C(H).$$

Remark 338. ***Intuition.*** *Among all adequate policies, choose the one that costs the least effort to maintain/compute. This is a cognitive analogue of an Occam-style constraint, but framed in terms of the observer's actual expenditures rather than a language-invariant notion of description length.*

Remark 339. ***Example.*** *Suppose two policies are adequate for a classification task: one distinguishes 1,000 fine-grained categories and then maps them to labels, while the other distinguishes only the labels directly. The minimum representational effort principle picks the latter, provided both are adequate for the actual objective.*

Remark 340. ***Usefulness.*** *This principle provides a normative and (later) dynamical bias: it tells us which policies are preferred in equilibrium, and it suggests learning dynamics that drift toward lower effort subject to constraints. Such dynamics are central in cognitive architectures that explicitly manage resource tradeoffs [19].*

Remark 341. *This is a formalization of a central Hyperseed slogan: "simplicity is what costs less effort." Note that "adequacy" may itself be paraconsistent, fuzzy, or multi-objective; the definition above only assumes we can describe a feasible region.*

Remark 342. ***Effort as an internal cost functional.*** *The point of writing* $\mathrm{Eff}_C(H)$ *rather than a syntactic complexity measure is that effort can include costs that are not captured by descriptions alone: latency, memory footprint, sampling cost, training instability, energy expenditure, or (in embodied settings) sensor/actuator wear. Thus two extensionally equivalent policies (same input–output behavior) may differ in effort because they are implemented differently in the observer. This is also why the context subscript* C *matters: what is "cheap" depends on available hardware, priors, and interaction regime.*

Under mild closure assumptions, minimum-effort selection is equivalent to selecting the *maximally open* adequate policy, hence the *maximally weak* adequate policy. Here "mild" is primarily the assumption that adequacy is monotone with respect to opening, i.e., once the task can be done, discarding additional distinctions that the task does not use will not break adequacy.

Theorem 8 (Maximally open adequate policy under upward closure)**.** *Assume* $\mathcal{F}_C$ *is* upward closed *under opening:*

$$H \in \mathcal{F}_C \text{ and } H \subseteq H' \implies H' \in \mathcal{F}_C.$$

Let

$$\widehat{H} := \bigcup_{H \in \mathcal{F}_C} H.$$

Then:

1. $\widehat{H} \in \mathcal{F}_C$*,*

2. *for all* $H \in \mathcal{F}_C$*, we have* $H \subseteq \widehat{H}$*,*

3. *if* Eff_C *is antitone, then* $\widehat{H}$ *minimizes effort over* $\mathcal{F}_C$*,*

4. *if* w *is monotone, then* $\widehat{H}$ *maximizes weakness over* $\mathcal{F}_C$*.*

Remark 343. ***What this says, in plain language.*** *If adequacy is preserved when you open further (collapse extra distinctions that the task does not need), then there is a single "most open" adequate policy: take the union of all adequate policies. This most open adequate policy is automatically the least-effort one (because effort decreases under opening) and the most weak one (because weakness increases under opening).*

Remark 344. ***Why it is important.*** *The theorem turns an optimization problem (minimize effort subject to adequacy) into a purely order-theoretic construction (take a union). This is conceptually valuable: it says that, in the upward-closed regime, the hard part is not optimization but specifying adequacy correctly. It also foreshadows later fixed-point reasoning about stable policies and goal systems (cf. [10] for a related fixed-point style in a different layer).*

Remark 345. ***Connection to weakness.*** *This theorem makes precise the slogan "minimum effort equals maximum weakness subject to task constraints," at least when $\mathcal{F}_C$ is upward closed. This is one of the main reasons weakness is useful: it can be maximized compositionally across contexts, while effort is minimized.*

Remark 346. ***Proof sketch (unpacking the order-theoretic steps).*** *Item (2) holds by construction: every $H \in \mathcal{F}_C$ is a subset of the union of all such H. For item (1), pick any $H_0 \in \mathcal{F}_C$ (when $\mathcal{F}_C \neq \emptyset$); then $H_0 \subseteq \widehat{H}$, and by upward closure $\widehat{H} \in \mathcal{F}_C$. For item (3), antitonicity of Eff_C means $H \subseteq H'$ implies $\mathrm{Eff}_C(H') \leq \mathrm{Eff}_C(H)$, so combining $H \subseteq \widehat{H}$ with antitonicity gives $\mathrm{Eff}_C(\widehat{H}) \leq \mathrm{Eff}_C(H)$ for all feasible H. Item (4) is analogous: monotonicity of weakness means $H \subseteq H'$ implies $w(H) \leq w(H')$, hence $w(H) \leq w(\widehat{H})$ for all feasible H. The content is therefore not a delicate inequality, but the existence of a* greatest *element (a maximal opening) in the feasible set once it is upward closed.*

Remark 347. ***When upward closure is reasonable (and when it can fail).*** *Upward closure is natural for tasks whose adequacy depends only on retaining certain* necessary *distinctions: if a policy is adequate, then merging additional states that are irrelevant to the objective will keep it adequate. It can fail for tasks where the representation itself must satisfy side-constraints that are not monotone under opening (e.g., "must separately track two protected groups" or "must retain a diagnostic variable for auditing"), or where opening changes action selection in a way that violates a safety constraint even if prediction remains acceptable. In such cases, $\mathcal{F}_C$ need not have a single maximally open element, and minimum-effort selection may involve genuine optimization over incomparable feasible policies rather than the union construction.*

Remark 348. ***Interpretation in common representational formalisms.*** *If policies correspond to partitions (or σ-algebras) over a state space, "opening" corresponds to* coarsening *the partition (forgetting distinctions). The union $\widehat{H}$ then corresponds to the coarsest partition that is still adequate: it merges every pair of states that can be merged without breaking the task. This matches the informal idea of "keep exactly the distinctions the task forces you to keep" and discard the rest.*

Remark 349. ***Algorithmic reading.*** *Although Theorem 8 is stated extensionally (via a union over all feasible policies), it suggests an intensional procedure: repeatedly open (merge distinctions) while checking adequacy, stopping only when any further opening would violate Adeq_C. In learning settings, this corresponds to a bias toward representational compression with constraint checks (or constraint penalties), which is a common pattern in resource-bounded inference and control.*

Proof. (1) Upward closure implies that since each $H \in \mathcal{F}_C$ satisfies $H \subseteq \widehat{H}$, we have $\widehat{H} \in \mathcal{F}_C$. To make the inclusion $H \subseteq \widehat{H}$ explicit, recall that $\widehat{H}$ is defined as the union of the feasible policies (in particular, $\widehat{H} = \bigcup_{G \in \mathcal{F}_C} G$), so every element of a given $H \in \mathcal{F}_C$ is, by definition of union, an element of $\widehat{H}$. Thus $\widehat{H}$ is an upper bound for $\mathcal{F}_C$ in the inclusion order, and upward closure then upgrades this pointwise upper-boundedness into feasibility of the upper bound itself.

(2) Trivial from the definition of union. More concretely, if some relation/distinction/permission x is in $\widehat{H}$, then $x \in H$ for at least one feasible H, and conversely any $x \in H$ for a feasible H must lie in $\widehat{H}$; this is the sense in which $\widehat{H}$ aggregates all the "openings" present in any adequate policy.

(3) If $H \subseteq \widehat{H}$ and Eff_C is antitone, then $\mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(\widehat{H})$ for all $H \in \mathcal{F}_C$, so $\widehat{H}$ is an effort minimizer. Here antitone means that moving upward in $(\mathcal{H}_C, \subseteq)$ cannot increase effort: whenever $H \subseteq H'$, one has $\mathrm{Eff}_C(H) \geq \mathrm{Eff}_C(H')$. Since every feasible H is below $\widehat{H}$, the inequality specializes to show that $\widehat{H}$ achieves effort no larger than any other feasible candidate, i.e. it is a minimizer

over the feasible set. In particular, $\widehat{H}$ is not merely locally improving along a chain; it is globally extremal because it is a (feasible) top element among all feasible policies under inclusion.

(4) If w is monotone and $H \subseteq \widehat{H}$ then $w(H) \leq w(\widehat{H})$ for all feasible H, hence $\widehat{H}$ is a weakness maximizer. Monotonicity means weakness is aligned with openness: enlarging H (collapsing more distinctions) cannot decrease w. Thus, because $\widehat{H}$ contains every feasible H, it achieves weakness at least as large as any feasible policy. Equivalently, $\widehat{H}$ realizes the maximum of w over $\mathcal{F}_C$ provided $\mathcal{F}_C$ is nonempty, and the argument shows that this maximum is witnessed by the same union object that witnesses minimal effort under antitonicity. $\square$

Proof sketch. The strategy is to build a candidate policy that is "at least as open as any adequate one," namely the union $\widehat{H}$. Intuitively, $\widehat{H}$ is constructed by taking every permission/identification that appears in some adequate policy and allowing it simultaneously; it is therefore the least restrictive object that still stays within the closure assumptions. Upward closure guarantees adequacy is preserved when moving upward in the inclusion order, so $\widehat{H}$ remains feasible. This step is the only place where closure is used: without it, the union could overshoot the feasible region even if each constituent policy is feasible. Then antitonicity/monotonicity convert the inclusion comparisons $H \subseteq \widehat{H}$ into the desired extremal properties for effort and weakness. In other words, once $\widehat{H}$ is known to be a feasible upper bound, order-respecting objective functions automatically turn that upper bound into an optimizer: antitone objectives favor higher elements, while monotone objectives reward higher elements. $\square$

Remark 350. *A visual way to think of this is to picture the poset $(\mathcal{H}_C, \subseteq)$ as a landscape of policies. The feasible region $\mathcal{F}_C$ is a subset of this landscape. Upward closure means $\mathcal{F}_C$ is a "cone" pointing upward: once you are feasible, moving upward (opening) stays feasible. The union $\widehat{H}$ is then the apex of this cone. In order-theoretic terms, $\widehat{H}$ functions as a greatest element (or at least a canonical maximal element) of $\mathcal{F}_C$ with respect to $\subseteq$, because every feasible H lies below it. This is why the optimization statements become essentially immediate: if the objective is compatible with the order (antitone for effort, monotone for weakness), then an extremum is attained at such an apex.*

Remark 351. *The upward-closure assumption formalizes a natural regime: if a policy is already adequate, then collapsing* additional *distinctions that the task does not depend on remains adequate. This corresponds to the intuition that adequacy depends only on preserving distinctions that matter for C; any extra granularity is gratuitous and can be removed without harming performance. Later sections refine this using pattern-intensity and emergence: adequacy can fail under excessive opening because emergent patterns may disappear. In that refined regime, $\widehat{H}$ may cease to be feasible, so the existence of a single "most open adequate" policy is no longer guaranteed, and the extremal argument must be replaced by a constrained optimum that balances these competing effects.*

8.7 Compositional simplicity

Hyperseed insists that simplicity must be *compositional* to support a serious theory of pattern. We formalize compositional simplicity in a way that is compatible with the effort-quantale viewpoint and later categorical constructions.

Remark 352. ***Why "compositional" is a substantive constraint.*** *A non-compositional simplicity score can always be defined by fiat (e.g. "declare the objects we like to be simple"). Requiring a recursive upper bound in terms of parts forces simplicity to be* witnessable *by an explicit construction history, and thereby makes simplicity sensitive to the structure induced by the context C (available building blocks, allowable compositions, and their overheads).*

Definition 84 (Combination system and overhead)**.** *A* combination system *is a tuple* $(\mathcal{X}_C, *, e)$ *where:*

- $\mathcal{X}_C$ *is a set of items in context* C*,*
- $* : \mathcal{X}_C \times \mathcal{X}_C \to \mathcal{X}_C$ *is a (not necessarily associative) combination operation,*
- $e \in \mathcal{X}_C$ *is an identity-like element (when applicable).*

An overhead *is a function* $t_C : \mathcal{X}_C \times \mathcal{X}_C \to [0, \infty]$ *representing the extra effort needed to "glue"* y *and* z *into* $y * z$*.*

Remark 353. ***On non-associativity.*** *Allowing* $*$ *to be non-associative is not a technicality: in many realistic contexts,* $(y * z) * w$ *and* $y * (z * w)$ *represent different assembly orders with different intermediate artifacts and different integration burdens. The framework therefore treats a decomposition as implicitly* tree-shaped *rather than simply set- or multiset-based, and later "parse tree" viewpoints make this explicit.*

Remark 354. ***On the role of*** e**.** *The element* e *is included to support contexts where there is a natural "do nothing" or "empty" item (empty string, empty program module, empty diagram, etc.). When a true unit does not exist or is not meaningful, one can still include a distinguished baseline element for which* $s_C(e) = 0$ *expresses a normalization convention. This normalization prevents degenerate admissible solutions obtained by shifting all costs down by a constant.*

Remark 355. ***Intuition.*** *A combination system abstracts the idea that complex items can be built from simpler ones. The overhead* $t_C(y, z)$ *isolates the cost of composition itself: bookkeeping, interface matching, coordination, translation between formats, etc. In cognitive terms, even if you can represent* y *and* z *cheaply, combining them may require additional work (aligning contexts, resolving conflicts, finding a common schema).*

Remark 356. ***Examples.*** *If* $*$ *is concatenation of strings,* t_C *might be* 0 *(gluing is free). If* $*$ *is merging two knowledge graphs,* t_C *may be substantial because entity alignment is nontrivial. If* $*$ *is composing two programs,* t_C *can represent integration overhead such as type conversions or interface code.*

Remark 357. ***Usefulness.*** *By making overhead explicit, we can distinguish "intrinsic simplicity" of parts from "integration simplicity" of wholes. This becomes important when discussing emergence and pattern: sometimes a whole is simple not because its parts are simple, but because there is a low-overhead way to organize them.*

Remark 358. ***Overhead as a contextual parameter.*** *In practice,* t_C *is often where the context* C *enters most strongly. For example, the same pair of modules* (y, z) *may have small overhead in a shared ecosystem (common protocols, shared ontologies) and large overhead across ecosystems. Thus compositional simplicity is not intended to be an intrinsic property of an abstract object alone, but of an object* as situated *in a particular representational and operational environment.*

Definition 85 (Compositional simplicity functional)**.** *Let* $(\mathcal{X}_C, *, e)$ *be a combination system with overhead* t_C*. A function* $s_C : \mathcal{X}_C \to [0, \infty]$ *is* compositionally admissible *if:*

1. $s_C(e) = 0$,

2. for all $x \in \mathcal{X}_C$,

$$s_C(x) \le \inf_{\substack{y,z \in \mathcal{X}_C \\ y*z=x}} \big(s_C(y) + s_C(z) + t_C(y,z)\big),$$

with the understanding that $\inf \emptyset = \infty$*.*

Define the compositional simplicity s_C^* *to be the least (pointwise) function satisfying these constraints.*

Remark 359. ***Why an inequality (rather than equality).*** *The admissibility condition requires that $s_C(x)$ not exceed the best available two-part construction cost. This leaves room for x to be even simpler for reasons not captured by binary decomposition alone (e.g. if x is deemed primitive, or if x has a special direct representation not modeled as $*$-composition). Taking the* least *admissible solution s_C^* then eliminates arbitrary slack: any simplicity that cannot be justified by the recursive constraints is removed.*

Remark 360. ***The "no decomposition" case.*** *If x cannot be expressed as $y * z$ for any pair (y,z), then the right-hand side is* $\inf \emptyset = \infty$*, and the inequality becomes $s_C(x) \le \infty$, i.e. imposes no upper bound. This is deliberate: whether such an x should have finite simplicity is determined by the global least-solution requirement, not by forcing every item to decompose. Consequently, items can be treated as primitives in a given system (finite or infinite cost depending on what is consistent with the rest of the constraints).*

Remark 361. ***Notation unpacking.*** *The set under the infimum is the set of all pairs (y,z) that decompose x via the operation $*$. For each such decomposition, we assign a candidate cost $s_C(y)+s_C(z)+t_C(y,z)$. Then we take the best (minimum) cost among decompositions, via* $\inf$*. If x has no decomposition at all (empty set), we set* $\inf \emptyset = \infty$*, meaning "cannot be built compositionally (within this system)".*

Remark 362. ***Intuition.*** *This is a Bellman-style optimality condition: the simplicity of a whole should be no more than the best way to build it from parts, paying the simplicity of parts plus integration overhead. Taking the* least *solution s_C^* says we are not allowed to assign arbitrary low costs; we want the smallest costs consistent with the recursive constraints. In effect, s_C^* is "the cost of the cheapest parse" of x.*

Remark 363. ***Fixed-point viewpoint (effort-quantale compatibility).*** *Define an operator F on functions $s : \mathcal{X}_C \to [0,\infty]$ by setting $F(s)(e) = 0$ and, for $x \ne e$,*

$$F(s)(x) = \inf_{\substack{y,z \in \mathcal{X}_C \\ y*z=x}} \big(s(y) + s(z) + t_C(y,z)\big),$$

interpreting $\inf \emptyset = \infty$ *as above. Then compositionally admissible s are precisely (pointwise)* post-fixed points *of F (i.e. $s \le F(s)$), and s_C^* is the least post-fixed point. This framing matches the quantale intuition: $[0,\infty]$ with $+$ and $\le$ supports monotone recursion, and* inf *plays the role of taking best achievable effort among alternatives.*

Remark 364. ***On existence and computability.*** *Because $[0,\infty]$ is complete under arbitrary infima, one can construct the least admissible solution by taking the pointwise infimum over all admissible functions, or (under mild finiteness/well-foundedness assumptions on decomposition) by iterative improvement reminiscent of dynamic programming. When there are cycles of decompositions, s_C^* still exists as a least consistent assignment, but it may take the value ∞ on elements that cannot be finitely justified without circularity.*

Remark 365. ***Examples.*** *If items are arithmetic expressions and $*$ combines subexpressions, $s^*_C(x)$ measures the minimal cost of a derivation tree of x. If items are designs built from components, it measures the cheapest assembly plan accounting for component simplicity and assembly overhead.*

Remark 366. ***Further example (segmentation).*** *If $\mathcal{X}_C$ is a set of strings, $*$ is concatenation, and $t_C \equiv 0$, then s^*_C can be read as the best achievable cost under all binary segmentations of a string into substrings. Different binary parenthesizations correspond to different parse trees, but because $t_C = 0$ and concatenation is associative, the best cost is effectively governed by the best segmentation into primitive or previously-simplified pieces.*

Remark 367. ***Why needed.*** *Hyperseed's pattern theory requires not just that some objects are simple, but that simplicity behaves predictably under composition. Otherwise "pattern intensity" would not be stable when patterns are nested or combined. Compositional simplicity is one way to enforce this stability, and it aligns with the hierarchical/heterarchical pattern-web perspective in [5].*

Remark 368. *The recursion above is the effort-quantale analogue of the informal Hyperseed sketch (see the motivating discussion around compositional simplicity in the Hyperseed overview). The "least" solution corresponds to the best achievable decomposition costs, i.e. dynamic programming over all factorization trees.*

Remark 369. ***Binary vs. multiway composition.*** *Only binary composition is built into the definition, but multiway composition is implicitly covered by iterating $*$ along a tree. The overhead function t_C then determines how integration costs accumulate across intermediate stages, which is precisely why parenthesization can matter when $*$ is non-associative or when overheads depend strongly on the intermediate artifacts.*

Proposition 5 (Immediate subadditivity bound)**.** *For any $y, z \in \mathcal{X}_C$ we have*

$$s^*_C(y * z) \leq s^*_C(y) + s^*_C(z) + t_C(y, z).$$

Remark 370. ***What this says, intuitively.*** *Even if there might exist a cleverer way to build $y * z$ than "build y, build z, glue them," the naive plan is always available. Therefore the optimal cost of $y * z$ cannot exceed the cost of that naive plan. This is the compositional counterpart of the basic subadditivity property of effort.*

Remark 371. ***Connection.*** *This proposition is a one-step corollary of the defining inequality of compositional admissibility. It is also the local inequality that later becomes global when we interpret $s^*_C(x)$ as the minimum over parse trees in Theorem 9.*

Remark 372. ***When the bound is informative.*** *If $t_C(y, z)$ is small (or zero), the proposition says that simplicity is nearly subadditive under composition, so building larger structures from simple parts does not incur disproportionate penalty. If $t_C(y, z)$ is large, then even very simple parts can yield a complex whole, capturing the common phenomenon that "integration dominates implementation."*

Proof. In the definition of $s^*_C(y * z)$, the infimum is taken over all decompositions of $y * z$. One admissible decomposition is precisely (y, z), hence the infimum is bounded above by the corresponding cost. $\square$

Proof sketch. The proof simply points to one specific candidate decomposition inside the infimum defining $s^*_C(y * z)$. An infimum over many candidates is always less than or equal to any particular candidate. Concretely, the defining inequality for $s^*_C(x)$ (as the least solution of the compositional recursion) considers *all* pairs (y, z) with $y * z = x$; selecting the specific pair that actually witnesses the composition $y * z$ gives an admissible term in that infimum, hence an immediate upper bound. This is the same one-line argument that underlies subadditivity bounds for shortest-path or dynamic-programming value functions: "evaluate at a specific action" bounds the optimum. □

Remark 373. *A geometric metaphor is useful: think of all decompositions of x as offering different "routes" to construct x, each with a cost. The simplicity $s^*_C(x)$ is the cost of the cheapest route. The particular route "split into y and z" provides an upper bound on the cheapest route, because it is one of the routes under consideration. Equivalently, if one imagines a landscape of candidate constructions, then $s^*_C(x)$ is the lower envelope of their costs, and any explicitly described construction gives a point on that landscape. This perspective also clarifies why such bounds are often easy to produce: it is typically simpler to describe* one *feasible construction than to certify optimality among all constructions.*

Theorem 9 (Compositional simplicity equals minimum parse-tree cost (finite case))**.** *Assume $\mathcal{X}_C$ is finite, and for each $x \in \mathcal{X}_C$ the set of decompositions*

$$\mathrm{Dec}(x) := \{(y, z) \in \mathcal{X}_C \times \mathcal{X}_C : y * z = x\}$$

is finite. Assume also $t_C(y, z) \geq 0$ for all (y, z) and $s^*_C(e) = 0$. Define the cost of a full binary parse tree T evaluating to x by summing t_C over internal nodes and 0 on leaves labeled by e (or by primitive atoms assigned fixed base costs, if desired). Then $s^*_C(x)$ equals the minimum cost among all such parse trees for x. Moreover, in this finite setting the minimum is attained by at least one parse tree (so the statement is not only an "infimum equals infimum" claim, but an actual minimum over a finite search space of well-formed derivations).

Remark 374. ***Plain-language meaning.*** *In the finite case, $s^*_C(x)$ is exactly what you would compute by enumerating all ways of parenthesizing/decomposing x into binary combinations, adding up the overhead at each combination, and taking the cheapest total. So the abstract least-solution definition really does coincide with the familiar notion of "minimum derivation cost" from parsing and dynamic programming. In particular, the recursion for s^*_C can be read as the usual dynamic-programming recurrence: the best way to build x is to choose a last split (y, z) that yields x and pay the best costs for y and z plus the overhead $t_C(y, z)$.*

Remark 375. ***Why it matters.*** *This theorem justifies calling s^*_C "compositional simplicity" rather than an arbitrary fixed-point artifact. It says the definition matches an operational procedure: build x by a tree of compositions and pay overhead at each internal node. This is the form in which simplicity will interface with grammar-like structural complexity (Hyperseed-Concept 181) and, later, with pattern hierarchies. It also means that many standard intuitions about parsers carry over: sharing subcomputations, reusing repeated substructures, and excluding impossible decompositions correspond to pruning the parse-tree search and thus computing s^*_C efficiently when the finite assumptions hold.*

Remark 376. ***Connection to later sections.*** *Pattern recognition often constructs candidate explanations via hierarchical decompositions. The parse-tree interpretation implies that if patterns supply cheap decompositions of observations, then they also supply low compositional simplicity. This will be used implicitly when emergence is defined by comparing pattern intensities under combination in Section 9. A useful way to keep the linkage in mind is: patterns propose "good splits"* *(low t_C and/or low child costs), and the theorem formalizes that repeatedly choosing such splits corresponds exactly to building a low-cost derivation tree.*

Proof. Because $\mathcal{X}_C$ is finite and each $\mathrm{Dec}(x)$ is finite, the recursion defining s_C^* reduces to a finite system of Bellman-style optimality equations over a finite directed hypergraph. Standard dynamic-programming arguments imply that the least fixed point assigns each x the minimum cost among all finite derivations (parse trees) that construct x from e using $*$, with per-node cost t_C. One convenient way to make this precise is to define the Bellman operator B on functions $f : \mathcal{X}_C \to [0, \infty]$ by

$$(Bf)(x) = \inf_{(y,z)\in\mathrm{Dec}(x)} \big(f(y) + f(z) + t_C(y, z)\big),$$

together with the boundary condition $f(e) = 0$ (and any chosen base costs for other primitives, if the variant with primitives is used). In the finite nonnegative-cost setting, iterating B from the pointwise-zero (or pointwise-minimum admissible) function produces a monotone nondecreasing sequence that stabilizes at the least fixed point, and that limit coincides with the minimum over all finite parse trees because each application of B corresponds to adding one more internal-node layer to a partial derivation. □

Proof sketch. The high-level strategy is: (i) view the decomposition relation $y * z = x$ as a finite hypergraph of production rules; (ii) interpret the defining inequality for s_C^* as the Bellman optimality condition for that hypergraph; (iii) invoke the standard fact that, in finite nonnegative-cost settings, the least fixed point of the Bellman operator yields the minimum cost over all finite derivations, i.e. parse trees. If one wants a slightly more operational phrasing, step (iii) can be seen as: dynamic programming on a finite acyclic-or-nonnegative-cost graph cannot benefit from infinite unfolding, so optimal values are witnessed by finite trees, and the least solution is exactly the one computed by taking minima over all finite unfoldings. □

Remark 377. *The key step is the identification of "least solution of recursive inequalities" with "minimum over trees." Nonnegativity of t_C prevents pathological negative-cost cycles, and finiteness ensures the relevant minima are achieved among finitely many candidate derivations. The "directed hypergraph" phrasing is simply the combinatorial shadow of the binary constructor: each equation $x = y*z$ is a hyperedge from (y, z) to x. It may also help to note that the hypergraph viewpoint cleanly separates* syntax *(which decompositions are allowed, i.e. which hyperedges exist) from* weights *(the overheads t_C), and s_C^* is exactly the induced shortest-derivation-cost function in that weighted hypergraph.*

Remark 378. *A visual intuition is to imagine building x by repeatedly merging pieces. Each merge has an overhead cost. A parse tree records the history of merges. The theorem says: among all possible merge histories that end at x, the least fixed point $s_C^*(x)$ picks the cheapest. In this picture, internal nodes correspond to merge operations, leaves correspond to the simplest available building blocks (here normalized so that e has zero cost), and the total cost is additive along the merge history, mirroring how many compositional systems accumulate "effort" across steps.*

Remark 379. *The theorem is stated in a minimal form to emphasize the intended interpretation. In the full development one typically assigns base costs to a set of primitives and allows leaves to be any primitive, not only e; the same proof pattern applies. The only substantive change in that extension is that the base-cost function contributes an additional leaf term in the tree-cost sum, while the internal-node contributions remain exactly the overheads t_C.*

8.8 Generalized Kolmogorov complexity and structural complexity

Classical Kolmogorov complexity measures the length of the shortest program that outputs an object (Hyperseed-Concept **??**; see [16]). Hyperseed's observer-relative simplicity suggests a more general construct: replace "program length" by *effort* measured in whatever resources the observer actually expends.

Remark 380. ***A small but important shift.*** *In the classical setting, the observer fixes (implicitly) a reference machine and a bitlength measure; both are taken as background structure. Here, the context C makes that background structure explicit: the observer not only chooses a decoding procedure, but also chooses which objects count as admissible descriptions and which expenditures count as cost. This makes it possible to speak about complexity in settings where "programs" are not the natural currency (e.g. physical actions, laboratory protocols, or interactive strategies), without losing the essential "best available redescription" character of Kolmogorov-style definitions.*

Definition 86 (Generalized description systems)**.** *A generalized description system for context C consists of:*

- *a set of descriptions (programs, proofs, encodings) $\mathcal{D}_C$,*
- *a partial decoding map $\mathsf{Dec}_C : \mathcal{D}_C \rightharpoonup \mathcal{X}_C$,*
- *an effort assignment $\mathrm{Eff}_C : \mathcal{D}_C \to [0, \infty]$ satisfying $\mathrm{Eff}_C(d_1 d_2) \leq \mathrm{Eff}_C(d_1) + \mathrm{Eff}_C(d_2)$ for a suitable concatenation/combination operation on descriptions.*

Remark 381. ***Notation unpacking.*** *The arrow $\rightharpoonup$ denotes a partial function: not every description must decode successfully. The expression $d_1 d_2$ denotes a chosen notion of concatenation/combination of descriptions (for instance, string concatenation, program composition, proof concatenation). The inequality $\mathrm{Eff}_C(d_1 d_2) \leq \mathrm{Eff}_C(d_1) + \mathrm{Eff}_C(d_2)$ is the same sequential subadditivity idea as before, now applied to description objects.*

Remark 382. ***What "partial" buys you.*** *Allowing Dec_C to be partial captures several common situations: ill-formed strings, programs that do not halt, proofs that fail to check, circuits with undefined behavior under the chosen simulator, or sensory-motor policies that fail to reach a terminal state. Formally, partiality lets $\mathcal{D}_C$ include a broad space of candidates while keeping Dec_C as the filter that determines which candidates are meaningful for the observer. This mirrors the classical use of partial computable functions (universal machines) but does not restrict Dec_C to that regime.*

Remark 383. ***Effort as a resource preorder.*** *The codomain $[0, \infty]$ is chosen so that infeasible descriptions can be assigned infinite effort, and so that infima of effort sets always exist (possibly as ∞). The subadditivity condition is deliberately weak: it says only that performing two description-steps in sequence should not cost* more *than paying for each step separately. In many concrete models one expects an additional fixed overhead (e.g. for glue code, delimiters, or interface adaptation), and this can be incorporated either by modifying the combination operation or by absorbing the overhead into the definition of Eff_C (as is done later via t_C in compositional systems).*

Remark 384. ***Intuition.*** *A description system is a general "language + interpreter + cost" triple. Kolmogorov complexity chooses a specific universal programming language and uses bitlength as cost; we instead allow any description language that an observer in context C can actually use, and any cost model that tracks the observer's real expenditures. This is one way to reconcile the philosophical power of algorithmic information with the Hyperseed insistence on observer-relativity [1].*

Remark 385. ***Examples.*** *$\mathcal{D}_C$ could be: binary strings interpreted by a fixed machine; formulas decoded by a parser; circuits decoded by a simulator; or proofs decoded by a proof checker. Effort could count length, runtime, energy, memory, or a weighted blend (Hyperseed-Concept 100).*

Remark 386. ***Two clarifying example patterns.*** *If $\mathcal{D}_C$ is a set of plans (action sequences) and Dec_C maps each plan to its realized outcome in an environment model, then $K_C(x)$ becomes the least action-cost required to produce x. If $\mathcal{D}_C$ consists of probabilistic model specifications together with random seeds, and Dec_C is "run the sampler and return its sample," then effort can represent expected compute and $K_C(x)$ becomes a best-effort generative route to x (where the partiality can encode non-termination or rejection conditions). These are not classical program-length settings, but they still instantiate the same abstract "search for cheapest description that yields x" template.*

Remark 387. ***Why needed.*** *Later, when patterns are defined as effort-reducing redescriptions, we need the notion of "description" to be context-dependent: the patterns available to a symbolic reasoner differ from those available to a sensory-motor controller. Generalized description systems are the formal slot where that dependence lives.*

Remark 388. ***On comparability across contexts.*** *Because K_C depends on $\mathcal{D}_C$, Dec_C, and Eff_C, values $K_{C_1}(x)$ and $K_{C_2}(x)$ are not automatically commensurate. This is a feature rather than a bug: Hyperseed uses C precisely to record which tools, priors, and resource-accounting conventions the observer is using. When cross-context comparisons are needed, they must be mediated by explicit translations between description systems (e.g. an embedding of $\mathcal{D}_{C_1}$ into $\mathcal{D}_{C_2}$ with controlled overhead), which is the generalized analogue of the classical invariance discussion around universal machines [16].*

Definition 87 (Generalized Kolmogorov complexity)**.** *Given a generalized description system, define*

$$K_C(x) := \inf\{\mathrm{Eff}_C(d) : d \in \mathcal{D}_C,\ \mathsf{Dec}_C(d) = x\}.$$

Remark 389. ***Well-definedness and edge cases.*** *If there is no description d with $\mathsf{Dec}_C(d) = x$, then the set inside the infimum is empty and, by the usual convention, $K_C(x) = \infty$. If there are descriptions achieving arbitrarily low effort without attaining a minimum (e.g. due to a limiting process in Eff_C), the infimum still exists even though no optimal description exists. Thus K_C should be read as an "optimal achievable bound" rather than a guarantee of an attained optimum.*

Remark 390. ***Intuition.*** *This is the same infimum-over-descriptions pattern as the simplicity definition $s_C(x)$, but with an explicit decoding map. It is therefore best read not as a single universal complexity, but as an observer-indexed family of complexities K_C.*

Remark 391. ***Examples.*** *If x is an image and $\mathcal{D}_C$ contains generative-model parameters plus a decoder that renders images, then $K_C(x)$ measures the cheapest generative explanation of x available to C. If x is a theorem statement and $\mathcal{D}_C$ consists of proofs in a formal system, then $K_C(x)$ measures the cheapest proof effort to derive x (relative to that system).*

Remark 392. ***Interpreting "cheapest" in non-length models.*** *When Eff_C is time or energy, $K_C(x)$ is not a static measure of description* size *but of description* feasibility*. In such cases $K_C(x)$ is naturally paired with a specific execution model (the Dec_C dynamics) and may depend sensitively on implementation details (e.g. hardware assumptions, parallelism, or available caches). This dependence is exactly what is wanted in observer-relative analysis: two observers with different hardware, training, or libraries can legitimately assign different complexities to the same x.*

Remark 393. ***Usefulness.*** *This definition provides a rigorous bridge between the classical "shortest program" perspective [16] and the Hyperseed "least effort" perspective. It allows later claims about simplicity/patterns to be interpreted either as compression statements or as resource-allocation statements, depending on the chosen* Eff_C.

Remark 394. *If* $\mathcal{D}_C = \{0,1\}^*$, $\mathrm{Eff}_C(d) = |d|$ *is bitlength, and* Dec_C *is a universal Turing machine, then* K_C *reduces (up to an additive constant) to classical Kolmogorov complexity. If* Eff_C *counts time, energy, memory, proof steps, or a weighted blend, one obtains different observer-relative complexity notions.*

Remark 395. ***Relationship to classical invariance (informal).*** *The "additive constant" caveat in the classical case comes from comparing two universal machines via compiler overhead. In the generalized setting, analogous comparison statements require explicit assumptions: a translation* $\tau : \mathcal{D}_{C_1} \to \mathcal{D}_{C_2}$ *such that* $\mathsf{Dec}_{C_2}(\tau(d)) = \mathsf{Dec}_{C_1}(d)$ *and* $\mathrm{Eff}_{C_2}(\tau(d)) \leq \mathrm{Eff}_{C_1}(d) + \kappa$ *(or a multiplicative/affine variant). When such a translation exists, one can transport upper bounds on* $K_{C_1}(x)$ *into upper bounds on* $K_{C_2}(x)$ *with controlled overhead, which is the operational content of invariance in this observer-relative language.*

Proposition 6 (Structural complexity as compositional complexity)**.** *Suppose* $\mathcal{D}_C$ *is generated by a finite set of primitives and a binary constructor corresponding to* $*$ *(with overhead* t_C*) so that every description induces a parse tree whose yield is* $x \in \mathcal{X}_C$. *Then the generalized complexity* $K_C(x)$ *coincides with a compositional simplicity functional of the form* $s^*_C(x)$ *(up to fixed base costs for primitives).*

Remark 396. ***Plain-language meaning.*** *When your description language is essentially "build objects by repeatedly combining primitives," then the cheapest description is the cheapest parse tree. So structural complexity (Hyperseed-Concept 181) is not a separate mystery: it is compositional simplicity under a particular choice of description system.*

Remark 397. ***Proof idea (informal).*** *Under the hypothesis, any* $d \in \mathcal{D}_C$ *corresponds to a finite parse tree whose leaves are primitives and whose internal nodes are applications of the binary constructor. If* Eff_C *assigns each primitive a fixed base cost and each constructor application the overhead* t_C *(possibly plus child costs), then* $\mathrm{Eff}_C(d)$ *is (up to constants) the same as the recursively defined compositional cost of the induced tree. Taking the infimum over all* d *yielding* x *is therefore the same optimization as taking the infimum over all* $*$*-parse trees yielding* x, *which is exactly what* $s^*_C(x)$ *encodes. The "up to fixed base costs" clause accounts for the choice of primitive-cost normalization, which shifts all complexities by a bounded amount when the primitive set is finite.*

Remark 398. ***Why it matters.*** *This proposition explains why grammar-like notions of complexity appear naturally once one takes compositionality seriously. It also clarifies how the later pattern layer can speak simultaneously about "compression" and "structure": both are costs of derivations in appropriate description systems [5].*

Remark 399. ***Connection to grammars and circuits.*** *When primitives are terminals and the constructor corresponds to applying production rules, parse trees are exactly derivations in a grammar, and* $K_C(x)$ *becomes a least-derivation-cost measure. When primitives are gates and the constructor corresponds to wiring subcircuits, parse trees become circuit expressions, and* $K_C(x)$ *becomes a size/energy/time cost of realizing the circuit that yields* x. *These familiar "structural" complexity measures are therefore instances of the same generalized template, differing only in what counts as a primitive, what the constructor does, and how effort is tallied.*

Remark 400. ***Connection to Theorem 9.*** *The proposition reduces an infimum over descriptions to a minimum over parse trees, and Theorem 9 identifies that minimum with the least fixed point s^*_C. So the chain is: descriptions $\to$ parse trees $\to$ fixed point. More explicitly, the description language can be viewed as a syntactic presentation of the same compositional data encoded by a derivation/parse tree: the leaves specify which primitives are used, and each internal node records one application of the binary constructor (together with any side-information required by the combination system). The key point is that the objective being optimized (effort) is* structural*: it depends only on the multiset of leaves (base costs) and the pattern of internal nodes (overhead), so it is invariant under switching between these two representations.*

Proof. Each description corresponds to a finite parse tree in the combination system, whose effort is the sum of base costs and overhead costs. Taking the infimum over descriptions is therefore equivalent to taking the minimum over parse trees. By Theorem 9, this is exactly the compositional simplicity $s^*_C(x)$ (with the appropriate base-cost initialization). To make the equivalence precise, note that the decoding map from descriptions to objects factors through the induced tree: once a description is parsed, it determines (i) the primitive labels at the leaves and (ii) the recursive bracketing specifying how the binary constructor is applied. Conversely, given any finite labeled parse tree that evaluates to x under the combination rules, one can encode it as a description by writing down the corresponding parenthesized expression (together with the same primitive labels), so the two optimization domains are coextensive up to the chosen encoding/decoding conventions. Moreover, because effort is defined additively—a leaf contributes its base cost and each internal node contributes the constructor overhead for that particular combination step—the effort assigned to a description coincides with the effort assigned to its tree. Under this identification, optimizing over descriptions or over trees is the same optimization problem, and Theorem 9 supplies the value of that optimum as the least fixed point s^*_C with the stated initialization. □

Proof sketch. The proof strategy is a change of variables. Instead of optimizing over descriptions directly, we optimize over their induced parse trees. Because the description language is generated by primitives and a binary constructor, descriptions and parse trees carry the same information up to the chosen decoding. Effort additivity over constructors becomes summation of overhead along internal nodes, so the best description is the cheapest tree, which Theorem 9 already characterizes as s^*_C. In other words, the apparent "infimum over strings" is not an additional analytic complication here: the strings are merely a linearization of a finite tree-shaped derivation. Once we switch to the tree view, the cost decomposition aligns directly with the dynamic-programming/fixed-point viewpoint: the cost of a node is the overhead for combining its two children plus the costs already assigned to those children, so the global optimum is obtained by choosing, at each object, the cheapest available decomposition into subobjects. This is exactly the recursion captured by the operator whose least fixed point is s^*_C. □

Remark 401. *One can think of this as a Russellian move: replace an informal notion ("structure") by an explicit construction ("a derivation tree in a generating grammar") and then observe that the resulting measure of complexity is just the optimization problem already solved by the compositional simplicity fixed point. From this perspective, "structural complexity" is not an extra ingredient beyond the grammar/combination system: it is the minimal cost of a witness that x can be generated by the primitives via the constructor. The move is useful because it separates (a) the* representational *choices (how we write down derivations as descriptions) from (b) the* invariant *content (which derivations exist and what costs they accrue), and it is the latter that the fixed-point characterization computes.*

8.9 Discussion: how this feeds later Hyperseed layers

This section provides the minimal mathematical "landing zone" for several later constructs: In particular, the goal is to make the informal notions of "trying," "difficulty," and "having a good way to see something" available in a form that can be transported into later layers without reintroducing hidden anthropomorphic assumptions. The emphasis on *relative* effort (relative to a baseline, relative to an observer, relative to an available policy class) is deliberate: later Hyperseed layers will repeatedly compare systems that differ in representational resources, history, or control authority, and the present setup makes those comparisons explicit rather than tacit. One may also read this section as fixing a common currency for subsequent tradeoffs: whenever a later construct is said to be "simpler," "more natural," or "more learnable," the intended operational meaning is that some decomposition or control objective can be achieved with systematically reduced effort, possibly after a change of representation.

- **Patterns (Section 9).** A pattern will be a representation r of x that yields a significant reduction in effort relative to a baseline. Pattern intensity will compare baseline effort to achieved effort (or dually compare baseline weakness to achieved weakness). This links the present material to the theory of pattern and emergence in [5]. In this sense, a "pattern" is not merely a regularity in x, but a *useful* regularity: it is evidenced by an improved effort profile when the agent adopts (or is given) the representation r. The baseline is crucial: the same r may be intensely patterned for one observer (who lacks alternative efficient decompositions) and nearly trivial for another (who already possesses a better policy or representation class), which is exactly the observer-relativity that later emergence arguments rely upon. When later sections speak of the "strength" or "salience" of a pattern, the intent is that such terms can be cashed out in the effort/weakness comparison induced by substituting r into a fixed task family, rather than by appealing only to descriptive compression in the abstract.

- **Habits and morphic resonance (Section 12).** Habit formation will be modeled as repeated updates to a distinction policy (or to the representations supported by a policy) that progressively reduce effective effort for certain decompositions. Resistance/submission will become dynamical (history-dependent) rather than purely static. (For the broader ontological framing of habit and resonance, see [13] alongside the Hyperseed presentation [1].) The core addition in the habit layer is that "effort" is not treated as fixed by the current task alone: instead, the system carries a trajectory of learned biases, cached distinctions, and preferred decompositions that change what is easy to do next. Formally, this means that whatever object plays the role of a distinction policy is iteratively updated so that future instances of a decomposition problem are solvable at lower marginal effort, e.g. by reusing internal structure rather than reconstructing it from scratch. In this frame, "resistance" to a proposed decomposition can be read as an induced cost that persists across time (a kind of inertial term), while "submission" corresponds to a learned alignment in which the same decomposition pathway becomes increasingly low-effort. This is also where the present algebraic notions become temporally textured: weakness and effort will be evaluated not only at a single time slice, but along an updating process, making the relevant quantities explicitly history-dependent.

- **Mind-world correspondence (Section 14 and onward).** "Good models" are those that achieve task adequacy with low effort, i.e. they lie near the Pareto frontier of adequacy vs effort. Weakness provides an algebraic handle for composing such models across contexts, as emphasized in [3]. The Pareto framing is meant to prevent a false dichotomy between "accurate" and "simple": in later sections, adequacy (predictive, explanatory, or control success) and effort (cognitive/work cost under a policy) will be treated as jointly constrained objectives. On this view, a model that is "too complex" is not rejected for having many parts per se, but because its achieved adequacy does not justify its effort relative to available alternatives; conversely, a model that is "too simple" is one whose low effort comes at an avoidable adequacy loss. Weakness enters as a compositional bridge: when moving between contexts or composing submodels, one wants to track how far the composed construction is from an ideal of effortless adequacy, and weakness provides a way to express and bound that deviation without re-deriving everything from first principles each time. This is especially important when the later causality/control layer introduces interventions and control authority: the "effort" budget then includes not only internal computation but also the cost of acquiring leverage over the environment, and the same algebraic bookkeeping is intended to remain applicable.

In short: effort provides the primitive experiential "thermodynamics" of cognition, and simplicity is its observer-relative, compositional shadow. Read this as a methodological constraint as well as a slogan: whenever later layers introduce new entities (patterns, habits, control structures), they should be interpretable as mechanisms for reallocating, reducing, or regularizing effort across tasks and contexts. Correspondingly, "simplicity" is not an intrinsic label attached to an object x in isolation, but a relational statement about how an observer can interact with x under some representational and policy constraints, and about how such interactions compose when x is embedded into larger constructions.

9 Patterns, emergence, properties, and blending

Outline

- Fix a general "description-and-decoding" setup in a context C: entities, a combination operation, a description language, and a cost/effort functional.
- Define *pattern* as a compressive re-description (a representation-as-something-simpler), and define *pattern intensity* as normalized compression gain (optionally p-bit-valued to allow "strong but wrong" patterns).
- Define *properties* as fuzzy sets of patterns (membership = intensity), and define *specific entities* as temporally coherent bundles of patterns (identity-as-a-derived-pattern).
- Define *emergence* for a combination $A*B$ as patterns whose intensity in $A*B$ exceeds a weighted combination of their intensities in A and B.
- Formalize *combination*, *inheritance*, *association*, and *lifting from instances to groups* as operations on pattern/property structures (with quantale-style aggregation as a unifying tool).
- Define *blends* in property-set terms (large overlap of properties), and present a categorical blend construction (pushout/colimit with weakness/effort ranking).
- Define *combinatorial-categorical patterns* (patterns that appear after category-theoretic substitutions), and define *combination systems*, *interpreted combination systems*, and *combinational dynamical causal models*.

Summary and Hyperseed concepts covered

Hyperseed's "pattern layer" is the pivot from phenomenological primitives and effort/simplicity to structured cognition. The core move is operational: a *pattern* in x is a way to represent x as something simpler (lower effort / lower description cost) in a given observer/context. Once pattern intensity is available, one can define properties (as fuzzy sets of patterns), emergence (as patterns whose intensity is amplified by combination), and blending (as property overlap). This section also supplies formal counterparts of Hyperseed's auxiliary constructs that are needed to make patterns interact with computation and dynamics: combination systems, interpreters, substitution-lifted (combinatorial-categorical) patterns, and combination-preserving representations of dynamical causality.

The intended reading is that the "observer/context" C fixes not only what counts as a valid description, but also what resources are salient: the same underlying entity can exhibit different patterns under different description languages, different decoders, different noise models, or different effort functionals. In particular, the cost/effort functional should be understood broadly: it may be a code length, a runtime/space budget, an energy expenditure, a statistical risk, or any proxy for what the context treats as "simplicity." This is what makes patterns comparable and "intensity" meaningful: intensity is not an intrinsic property of the entity alone, but a context-indexed degree of compressive advantage.

The phrase "representation-as-something-simpler" is meant to cover both exact and lossy re-descriptions. An exact pattern corresponds to a shorter description that still decodes to the same target (up to the equivalence notion induced by the decoder), whereas a lossy pattern permits a controlled mismatch when the context does not distinguish the difference. Allowing p-bit-valued intensity is a way to explicitly represent the case where a description is highly compressive yet systematically incorrect: such a pattern can be strong as a proposal while being wrong as a reconstruction, which becomes important when modeling biased or partial observers, adversarial settings, or situations where the decoder is itself fallible. In that sense, intensity is not merely "how present a pattern is," but how much the pattern functions as an economical explanatory handle within the context.

Defining properties as fuzzy sets of patterns makes the ontology "pattern-first" rather than "predicate-first." A property is not an atomic label attached to entities; it is a distribution of pattern intensities, so that property membership is graded and decomposable. This supports a notion of similarity as overlap of property-sets (equivalently, similarity of pattern profiles), and it also supports compositional updates: changing context C changes which patterns are cheap, thereby changing property membership without requiring a separate re-axiomatization of predicates. The notion of a "collective-property-set" then captures the idea that a group or aggregate can carry properties that are not merely pointwise averages of its members' properties, but are properties arising from aggregation of pattern evidence under the chosen combination operator.

Similarly, defining specific entities as temporally coherent bundles of patterns makes identity a derived, dynamical construct. What persists through time is not a metaphysically primitive "thing," but a stable configuration of patterns whose intensities remain coherent under a temporal update rule (the temporal coherence algebra). This lets the framework treat tracking, object permanence, and re-identification as instances of pattern maintenance under resource constraints, rather than as separate primitives. It also clarifies why boundaries of entities can be context-sensitive: what counts as "the same" entity can depend on which patterns are cheap enough to enforce over time.

The emergence criterion for $A * B$ is intended to separate three cases: (i) mere inheritance of patterns already intense in A or B, (ii) dilution or interference where intensities decrease upon combination, and (iii) genuinely emergent amplification where the combined object supports a pattern more strongly than expected from its parts. The weighted comparison baseline makes this precise without forcing linearity: the weights can encode asymmetry of contributions, attention, or relevance, and the aggregation can be tuned to match the semantics of the combination operator $*$. In particular, emergence here is not a mysterious ontological surplus; it is a detectable departure in pattern intensity relative to a specified compositional expectation.

The operations listed (combination, inheritance, association, and lifting) are included to make pattern/property structures usable as algebraic objects rather than mere annotations. Quantale-style aggregation is singled out because it provides a unified way to combine graded evidence (intensities), compose relational links (associations), and transport structure between levels (from instances to groups) while preserving monotonicity and resource-sensitivity. This is the sense in which the pattern layer serves as infrastructure: it supplies the algebra needed to manipulate intensional content in a way that is stable under composition and aggregation.

Blending is presented in two complementary ways: as a high-overlap relation on property-sets and as a categorical construction. The property-overlap view captures an intuitively geometric notion of conceptual mixture: two entities (or two concepts) blend when they share a large portion of their salient properties, with "large" measured relative to the chosen intensity aggregation and any relevance weighting. The categorical pushout/colimit view then captures the constructive side: a blend is not only a comparison between two sources but an explicit amalgam built by identifying shared structure. The mention of weakness/effort ranking indicates that there may be multiple candidate pushouts or colimits, and the framework chooses among them by preferring lower-effort identifications, thereby keeping the construction aligned with the underlying description-cost semantics.

Finally, combinatorial-categorical patterns, interpreted combination systems, and combinational dynamical causal models are included to connect patterns to computation and dynamics. The key point is that new patterns can become visible only after a systematic change of representation (a substitution or functorial re-encoding), so the framework must account for patterns that are invariant or salient under such transformations. A combination system provides the abstract algebra of how entities compose; an interpreted combination system adds a semantics that links abstract compositions to concrete decoded entities and their costs; and a combinational dynamical causal model adds time and causality in a way that is compatible with combination. Together, these notions ensure that patterns are not merely descriptive snapshots but can be propagated, compared, and preserved under dynamical evolution and under the computational processes that implement decoding and substitution.

Hyperseed concepts covered.

- Pattern; pattern intensity.
- Emergence.
- Property; property-set; collective-property-set.
- Specific entity (as a derived pattern with a temporal coherence algebra).
- Blend.
- Combination; inheritance; association; lifting from instances to groups.
- Combinatorial-categorical pattern.
- Combination system; interpreted combination system.

- Combinational dynamical causal model.

9.1 Setup: entities, contexts, descriptions, and effort

We assume the effort/simplicity layer from Section 8 provides, for each context (or observer-relative aspect) C, a universe of entities $\mathcal{E}_C$ together with:

- a (possibly partial) *combination* operation

$$*_C : \mathcal{E}_C \times \mathcal{E}_C \rightharpoonup \mathcal{E}_C,$$

  intended to model "putting things together" in the sense relevant to C;

- a *description system* (syntax) $\mathcal{L}_C$ and an *interpreter/decoder*

$$\mathrm{Dec}_C : \mathcal{L}_C \to \mathcal{E}_C,$$

  intended to model how the observer encodes/constructs entities; and

- an *effort or description cost* functional

$$\mathrm{cost}_C : \mathcal{L}_C \to \mathbb{R}_{\geq 0} \cup \{\infty\}.$$

Here "context" should be read broadly: C may represent a sensory modality, a measurement apparatus, a scientific modeling stance, a downstream task, or a cognitive "view" that determines which distinctions are salient. Accordingly, $\mathcal{E}_C$ is not assumed to be a context-independent ontology; rather, it is the space of *entities as individuated by* C. For example, for a text-processing context C, $\mathcal{E}_C$ might be strings; for a vision context, $\mathcal{E}_C$ might be images up to some equivalence; and for an engineering context, $\mathcal{E}_C$ might be structured designs equipped with tolerances.

The partiality of $*_C$ is deliberate: some pairs of entities may be non-composable (e.g., their interfaces do not match, their physical constraints are incompatible, or the context has no rule for combining them). No global algebraic laws (associativity, commutativity, identities) are assumed unless explicitly stated later; different applications may impose such laws, or may instead treat them as approximate regularities that can themselves be learned or encoded by descriptions. Intuitively, $x *_C y$ captures the *context-specific* notion of composing x and y (e.g., concatenation of strings, overlaying images, wiring components, forming a conjunction of properties, or bundling features into a composite representation).

The role of $\mathcal{L}_C$ is to make explicit that "having an entity" is operationally mediated by representational resources. The map Dec_C then specifies how a description ℓ is interpreted as an entity. Although written as a total function, one can fold ill-formedness or decoding failure into this framework by allowing $\mathrm{cost}_C(\ell) = \infty$ for descriptions that are syntactically valid but semantically unusable in C, or by treating $\mathcal{L}_C$ as already restricted to well-formed, decodable descriptions. The cost functional cost_C can represent many things (bits, time, memory, energy, cognitive effort, or a weighted mixture), and it may incorporate both fixed overheads (e.g., calling a subroutine, invoking a concept) and variable costs (e.g., specifying parameters at a given precision). Allowing ∞ is important: it makes room for hard constraints (some descriptions are forbidden or unattainable), and it ensures the infimum below behaves sensibly even when some candidates are inadmissible.

The *(contextual) simplicity/complexity* of an entity is then the minimal effort required to describe it:

Definition 88 (Contextual description complexity)**.** *For $x \in \mathcal{E}_C$, define*

$$s_C(x) := \inf\{\mathrm{cost}_C(\ell) \ : \ \ell \in \mathcal{L}_C, \ \mathrm{Dec}_C(\ell) = x\}.$$

We interpret lower $s_C(x)$ as "simpler for C" (less representational effort).

The use of inf (rather than min) accommodates description languages with arbitrarily fine approximations or parameterizations: one may be able to describe x increasingly cheaply while approaching it in a limiting sense, or there may be no single cheapest description even though costs can be driven down to a greatest lower bound. In many discrete settings (finite strings, finite programs with integer-valued costs), the infimum is attained and $s_C(x)$ is a true minimum. If there is no ℓ with $\mathrm{Dec}_C(\ell) = x$, the set in the infimum is empty and one may take $s_C(x) = \infty$, expressing that x is indescribable (or not individuated) within the representational resources of context C.

It is also useful to keep in mind that s_C is *relative* in two ways: it depends on what counts as a description (the choice of $\mathcal{L}_C$) and on how descriptions are interpreted (the choice of Dec_C). Thus, changes in measurement conventions, available primitives, background knowledge, or permissible abstractions are all legitimately represented as changes in C (and hence changes in s_C).

Remark 402. *One can equivalently define s_C via compositional simplicity recursion (as in Hyperseed's informal definition) by choosing a grammar for building entities and taking $s_C(x)$ to be the least total effort of any parse tree yielding x, including glue/interaction overheads. The description-based definition above is the most portable because it separates* (i) *the space of possible representations from* (ii) *the evaluator/decoder.*

Concretely, the "parse tree" viewpoint treats a description as an explicit construction plan: internal nodes correspond to applications of combination rules (often modeled by $*_C$ or by a family of typed composition operators), while leaves correspond to primitives (atomic symbols, stored concepts, measurements, or retrieved exemplars). In that view, glue/interaction overheads capture the costs of making parts compatible: specifying alignment, resolving interfaces, setting boundary conditions, or adding correction terms needed for the composite to decode to the intended entity. The description-based formulation packages all of these choices into $\mathcal{L}_C$, Dec_C, and cost_C, which is why it can be transported across domains even when the natural "parts" and "composition" operations differ dramatically.

To connect to the formal core (Section 3), it is often useful to allow the system to store not only scalar costs but also p-bit-valued evidence about whether a putative description actually matches its target. This is optional, but it is exactly where paraconsistency becomes practically relevant: many cognitively useful "patterns" are compressive but partly wrong.

One motivation is that, in practice, an observer often deploys short descriptions that intentionally ignore exceptions (e.g., "birds fly", "objects are rigid", "noise is Gaussian"). Such descriptions can be excellent compression devices (low cost) even when they conflict with some data (nonzero mismatch). Separating "how cheap is the description?" from "how well does it fit?" allows us to model the common situation where a representation is preferred because it is simple *and* informative, not because it is perfectly accurate.

Definition 89 (p-bit-valued mismatch evidence)**.** *Fix a context C. A* mismatch evidence map *is any function*

$$\mathrm{mis}_C : \mathcal{L}_C \times \mathcal{E}_C \to [0,1]^2$$

where $\mathrm{mis}_C(\ell, x) = (m^+, m^-)$ is interpreted as (positive, negative) evidence that ℓ fails to match x in context C.

The two coordinates in $\mathrm{mis}_C(\ell, x) = (m^+, m^-)$ are intended to support paraconsistent situations in which evidence can accumulate on both sides: m^+ can be high because there are clear counterexamples to the description, while m^- can simultaneously be high because there are strong confirmations (or because the context provides reasons the mismatch diagnosis is unreliable). In particular, the framework does not require that "evidence for mismatch" and "evidence against mismatch" sum to 1; allowing both to be nontrivial is what lets the system represent partial, conflicting, or heterogeneous fit in a controlled way.

Operationally, one can use mis_C in several (compatible) ways without fixing a single choice here: as a feasibility filter (only accept descriptions with m^+ below a threshold), as an additive penalty term combined with cost_C (trading off simplicity and mismatch), or as a record used downstream to decide which aspects of a description are trustworthy. In applications where a single scalar is desired, one may derive a mismatch score from the pair (e.g., by a context-dependent aggregation), but keeping the pair explicit preserves information about conflict and uncertainty that would otherwise be collapsed.

9.2 Combination, inheritance, and association as pattern-level notions

Hyperseed distinguishes *dynamic* combination (co-becoming in time) from *static* combination (property union/blend). The present section focuses on the static side (the dynamic side is reconstructed via proto-time and event/process calculi in Section 7). In particular, "static" should be read as "evaluated at a fixed descriptive moment": we intentionally ignore the micro-history of how a compound came about, and only keep the resulting blend of relevant traits. This separation is methodological: the same pair of entities may admit both a temporally detailed story of co-formation (dynamic combination) and a temporally collapsed account in which only the resulting pattern profile matters (static combination).

Definition 90 (Static combination in a context)**.** *A* static combination system *in context C is a pair $(\mathcal{E}_C, *_C)$ where $*_C$ is a partial binary operation on $\mathcal{E}_C$. We write $A *_C B$ when the combination is defined.*

The explicit dependence on C is essential: which combinations are meaningful, admissible, or even nameable depends on the background ontology and the representational resources assumed in that context. Thus $\mathcal{E}_C$ should be read as "the entity-kinds currently in play," and $*_C$ as the rule by which the context permits us to form composites/blends at the static (property-level) description scale. The partiality of $*_C$ is not merely a technical convenience: it encodes the idea that some pairs do not have a well-formed blend in the chosen descriptive scheme, or that a purported blend would require introducing new entity-types not available in $\mathcal{E}_C$. No algebraic laws (such as commutativity or associativity) are assumed a priori; when such laws hold in a given application, they should be stated as additional structure on $(\mathcal{E}_C, *_C)$ rather than taken for granted.

Remark 403. *Many important cases are naturally typed or multi-sorted: $*_C$ is only defined on compatible pairs. This is not a defect; it is exactly what makes combination systems suitable as ontologies.*

Concretely, "compatible" may mean sharing an interface (e.g. two modules with matching ports), belonging to the same sort (e.g. two color swatches that can be mixed), or satisfying a constraint (e.g. two roles that can co-occupy a narrative position without contradiction). In such cases one can think of $*_C$ as implicitly carrying a typing judgment: only when the judgment succeeds do we get a combined entity in $\mathcal{E}_C$. When combination is undefined, that is informative: it marks a boundary of what the context treats as a coherent object of discourse, rather than forcing an artificial "junk" element to stand for incoherence.

Inheritance and association are also most naturally defined using patterns and properties, but we give early "pre-definitions" now (and tighten them after properties are defined). The intent is that these notions operate at the level of pattern-roles (how an entity behaves in typical constructions) rather than at the level of internal constitution: inheritance concerns what can stand in for what, while association concerns what tends to co-appear or co-fit within the same descriptive frame.

Definition 91 (Inheritance as substitutability (preorder form))**.** *Fix a context C. A relation $\preceq_C$ on $\mathcal{E}_C$ is an* inheritance preorder *if $A \preceq_C B$ means "A can substitute for B in many C-relevant contexts without increasing representational effort or breaking too many patterns."*

The phrase "preorder form" signals that, in typical instantiations, $\preceq_C$ is intended to be at least reflexive and transitive (while not necessarily antisymmetric): distinct entities may be mutually substitutable at the granularity that C cares about, yielding equivalence classes of "effectively the same role". The qualifier "many C-relevant contexts" is also deliberate: substitutability is rarely absolute, so $\preceq_C$ should be understood as summarizing a stability of use across a sufficiently rich family of pattern-instances judged important in C. Likewise, "representational effort" is meant to capture the cost of accommodating the substitute (e.g. extra clauses, exceptions, or ad hoc repairs), so inheritance becomes a notion tied to the economy of pattern-description rather than mere set inclusion.

Remark 404. *Later we instantiate $\preceq_C$ by comparing property-sets (Definition 98) or by requiring existence of low-effort rewrite maps in a combination system.*

In property-set terms, the guiding picture is that $A \preceq_C B$ holds when A carries (most of) the properties that make B usable in the patterns of interest, possibly together with additional properties that do not interfere too often. In rewrite-map terms, the idea is that there is a systematic way to translate occurrences of B into occurrences of A with small overhead, so that pattern-instances remain largely valid after substitution. Both readings emphasize that inheritance is not simply a static taxonomic claim, but a claim about preservation of pattern-function under controlled replacement.

Definition 92 (Association (static version))**.** *A (static)* association score *in context C is a symmetric map*

$$\mathrm{assoc}_C : \mathcal{E}_C \times \mathcal{E}_C \to [0, 1]$$

intended to measure "how much A and B tend to occur together" or "how many properties/patterns they share."

The symmetry requirement reflects the intended reading as co-occurrence or overlap rather than directional implication. No further axioms are imposed here: depending on the application, one might want $\mathrm{assoc}_C(A, A) = 1$, or monotonicity with respect to inheritance, or triangle-type constraints, but these should be added only when justified by the chosen construction. The codomain $[0, 1]$ should be interpreted as a normalization convention: association is meant to be comparable across pairs in the same context, even when raw counts or unnormalized overlaps would be scale-dependent. When association is later implemented via property-sets, typical examples include normalized overlap coefficients (such as Jaccard similarity) or weighted variants in which some properties contribute more heavily because they anchor more central patterns in C.

Dynamic notions of association (via short chains of becoming, or temporal co-focusing) are treated in Sections 7 and 12. Here we will implement association in terms of overlap between property-sets (Definition 101). This implementation is meant to make explicit the bridge between "co-occurs" and "co-describes": if two entities share many of the properties that matter to the context, then they will tend to appear together in pattern-instances and will also be easy to group, compare, or blend without introducing exceptional-case bookkeeping.

9.3 Patterns and pattern intensity

We now formalize Hyperseed's key operational definition:

> A pattern is a representation as something simpler.

There are two complementary ways to say this rigorously: *(i)* the description-theoretic way (a code ℓ for x with lower effort than baseline), and *(ii)* the compositional way (a factorization of x into simpler components with bounded glue cost). In practice, these two views are often intertranslatable: a compositional factorization can be encoded as a structured description (e.g. a parse tree), while a good description typically implies some latent factorization (e.g. reuse of subroutines, shared parameters, or repeated motifs). The point of stating both is that different applications make different primitives more natural: for a string, a description is immediate; for a physical or semantic object, an explicit "parts + interaction" picture can be the clearer witness.

9.3.1 Patterns as compressive descriptions

Definition 93 (Pattern witness (description form))**.** *Fix a context C. A* pattern witness *for $x \in \mathcal{E}_C$ is any $\ell \in \mathcal{L}_C$ with* $\mathrm{Dec}_C(\ell) = x$*. Its* description cost *is* $\mathrm{cost}_C(\ell)$*.*

The role of $\mathcal{L}_C$, Dec_C, and cost_C is to make explicit what counts as an admissible representation and what "effort" means for the observer in context C. For example, cost_C might be literal bit-length, runtime, description length under a grammar, MDL-style codelength (data plus model), or an experimentally grounded cognitive effort proxy. Allowing such flexibility is essential later when the same underlying entity is judged by different observers or under different resource constraints.

In this raw form, every entity has infinitely many "patterns" (by trivial re-encoding). The nontrivial content comes from *relative simplicity.* Concretely, without a reference point, one can always define a baroque coding language in which a particular x has a one-token name, thereby making it "simple" by fiat. The baseline mechanism below is what prevents such vacuity: it forces simplicity to be measured relative to a fixed default scheme rather than an adversarially chosen code.

Definition 94 (Baseline description and compression gain)**.** *Fix a context C. Choose a baseline description scheme for entities, represented by a function* $\mathrm{base}_C : \mathcal{E}_C \to \mathcal{L}_C$ *with* $\mathrm{Dec}_C(\mathrm{base}_C(x)) = x$*. Define the baseline cost*

$$s_C^{\mathrm{base}}(x) := \mathrm{cost}_C(\mathrm{base}_C(x)).$$

Given any witness ℓ of x, define the (raw) compression gain

$$\Delta_C(\ell; x) := s_C^{\mathrm{base}}(x) - \mathrm{cost}_C(\ell).$$

The quantity $\Delta_C(\ell; x)$ is positive exactly when ℓ improves on the baseline, and negative when ℓ is a worse-than-default way to represent x. Keeping Δ_C in "absolute units" (whatever units cost_C uses) is convenient for aggregating costs across compositions; later, the normalized intensity I_C will rescale this gain into a unit interval.

Remark 405. *The baseline is part of the observer model: different observers have different "default" ways of representing the same thing, so they will see different patterns. This is not optional; it is Hyperseed's observer-relativity made explicit. A useful way to read $s_C^{\mathrm{base}}(x)$ is "how hard x is* before *I notice any structure"; then a pattern witness is precisely a certificate that the observer can exploit some structure to do better.*

It is often helpful to distinguish the baseline cost $s_C^{\mathrm{base}}(x)$ from any other intrinsic or task-dependent simplicity measure $s_C(x)$ used elsewhere in the paper. Here, the baseline is deliberately operational: it is defined by a concrete encoding choice base_C, so that "compression" is not merely metaphorical but literally an improvement over what the observer would otherwise do by default.

9.3.2 Patterns as compositional factorization

To mirror Hyperseed's (y, z)-pattern picture, we represent patterns as explicit decompositions. Intuitively, $x = y *_C z$ asserts that x can be assembled from parts y and z using the context's composition operator, while t accounts for the additional coordination or interaction cost not already paid for by describing y and z separately. This makes the notion of a "pattern" align with common scientific and engineering practice: a system is understood by specifying components plus a (hopefully small) interaction law.

Definition 95 (Compositional pattern witness)**.** *Fix a context C. A* compositional pattern witness *for $x \in \mathcal{E}_C$ is a tuple*

$$P = (y, z, t)$$

such that $y, z \in \mathcal{E}_C$, $x = y *_C z$, and $t \in \mathbb{R}_{\geq 0}$ is an explicit glue/interaction overhead *intended to upper bound the extra effort needed to assemble the composite from its parts in context C.*

Define the composite cost

$$h_C(P) := s_C(y) + s_C(z) + t.$$

The requirement $t \geq 0$ encodes the idea that composition is never "free" in the accounting: even when the parts are known, there is at least the bookkeeping cost of specifying how they are combined. At the same time, by allowing t to vary by witness, this framework can represent both clean modular decompositions (small t) and strongly entangled composites (large t), which will later be relevant for distinguishing mere aggregation from genuine emergent interaction.

Remark 406. *If one has a direct syntactic representation ℓ for the composite (e.g. a parse tree), t can be derived from the overhead terms in the interpreter; in algorithmic settings t is often a "model class" penalty (e.g. number of parameters, constraint complexity). In MDL terms, one may think of $s_C(y) + s_C(z)$ as the cost of stating the components, and t as the cost of stating the linking hypothesis (alignment, coupling constants, wiring diagram, interface spec, etc.).*

Note that $h_C(P)$ is written using $s_C(y)$ and $s_C(z)$ rather than $s_C^{\mathrm{base}}(y)$ and $s_C^{\mathrm{base}}(z)$. This is intentional: a compositional witness is meant to exploit whatever simplicity notion s_C the context provides for parts, while still being judged against the baseline for the *whole* x when we compute intensity. This matches the informal picture "a pattern is worthwhile if it makes the whole cheaper than my default way of describing the whole," even if the parts themselves are described using specialized (non-baseline) codes.

9.3.3 Pattern intensity

Hyperseed defines pattern intensity as normalized improvement over baseline (in the compositional case, improvement of h_C over the baseline $s_C(x)$). We adopt that, with two small refinements: *(i)* we clamp at 0 so that "non-patterns" have intensity 0, and *(ii)* we optionally add a p-bit negative component to record mismatch evidence.

The normalization by $s_C^{\text{base}}(x)$ makes intensity comparable across entities of different absolute sizes: saving 10 units of cost is a bigger deal when the baseline is 20 than when it is 2000. Clamping at 0 ensures that "actively worse" representations do not create misleading negative intensities; instead, they simply fail to count as patterns under the intensity measure, while their costs can still be tracked separately if needed.

Definition 96 (Scalar pattern intensity)**.** *Fix C and $x \in \mathcal{E}_C$ with $s_C^{\text{base}}(x) > 0$. For any description witness ℓ of x, define the scalar intensity*

$$I_C(\ell; x) := \max\left\{0,\ \frac{s_C^{\text{base}}(x) - \text{cost}_C(\ell)}{s_C^{\text{base}}(x)}\right\} \in [0,1].$$

For any compositional witness $P = (y, z, t)$ of x, define

$$I_C(P; x) := \max\left\{0,\ \frac{s_C^{\text{base}}(x) - h_C(P)}{s_C^{\text{base}}(x)}\right\} \in [0,1].$$

If $s_C^{\text{base}}(x) = 0$, set $I_C(\cdot; x) = 0$ by convention.

As a quick calibration: if $\text{cost}_C(\ell) = s_C^{\text{base}}(x)$, then $I_C(\ell; x) = 0$ (no improvement); if $\text{cost}_C(\ell) = \frac{1}{2} s_C^{\text{base}}(x)$, then $I_C(\ell; x) = \frac{1}{2}$; and if $\text{cost}_C(\ell) \geq s_C^{\text{base}}(x)$, the clamping forces $I_C(\ell; x) = 0$ rather than a negative value. Thus, intensities near 1 correspond to dramatic simplifications relative to baseline, and intensities near 0 correspond to either negligible simplification or none at all.

Proposition 7 (Basic sanity properties of intensity)**.** *Fix C and x.*

1. *$0 \leq I_C(P; x) \leq 1$ for all witnesses P of x.*
2. *$I_C(P; x) > 0$ if and only if $h_C(P) < s_C^{\text{base}}(x)$ (strict compression).*
3. *If P and Q are witnesses of x with $h_C(P) \leq h_C(Q)$, then $I_C(P; x) \geq I_C(Q; x)$.*

Proof. All items follow directly from Definition 96: the ratio lies in $(-\infty, 1]$, clamping yields $[0, 1]$, and the map $u \mapsto \max\{0, (s - u)/s\}$ is monotone decreasing in u for fixed $s > 0$. □

One additional consequence (used implicitly later) is that intensity is invariant under uniform rescaling of cost units within a fixed context: if all costs are multiplied by a positive constant, the ratio $\left(s_C^{\text{base}}(x) - \text{cost}_C(\ell)\right)/s_C^{\text{base}}(x)$ is unchanged. What *does* change intensity is any shift in what the observer treats as baseline, which is exactly as intended: intensity measures improvement over what the observer would have done by default.

Now incorporate paraconsistency: the positive component measures compressive strength, while the negative component records evidence of mismatch ("strong but wrong"). This lets us represent the common situation in which a hypothesis yields a compact description but only approximately fits the data (or fits in one regime while failing in another), without forcing the entire representational apparatus to collapse into triviality.

Definition 97 (p-bit pattern intensity). *Fix C and assume a mismatch map* mis_C *(Definition 89). For any description witness ℓ of x, define a* p-bit *intensity*

$$\mathrm{Int}_C(\ell; x) := \big(I_C(\ell; x),\ \mathrm{mis}_C(\ell, x)^+\big) \in [0,1]^2,$$

where $\mathrm{mis}_C(\ell, x)^+$ *is the positive-evidence component that ℓ mismatches x. (Alternative conventions are reasonable; the only requirement for later sections is monotonicity in compression-gain and mismatch evidence.)*

This two-coordinate view separates two axes that are often conflated: how *useful* the pattern is as a compressor versus how *trustworthy* it is as an account of x. For instance, a coarse model might yield high $I_C(\ell; x)$ by exploiting a strong regularity, yet still incur non-negligible mismatch evidence because it ignores boundary effects or rare events; conversely, an exact but cumbersome encoding may have low intensity while having essentially zero mismatch evidence.

Remark 407. *This construction is intentionally permissive: it lets a system retain a compressive pattern even when it is partially false, without forcing triviality. That is precisely the role of paraconsistent logic in the ontology. Operationally, later selection rules can prefer patterns that are simultaneously high-intensity and low-mismatch, but the representation itself does not have to discard a high-intensity idea merely because it is not perfectly accurate.*

9.4 Properties as fuzzy sets of patterns

Hyperseed's property notion is derived: properties are patterns, collected and graded by intensity. Concretely, one begins with whatever family of pattern-detectors $\mathcal{P}_C$ is deemed relevant to a context C (logical predicates, learned features, dynamical motifs, compression primitives, etc.), and then treats an object's "having a property" as nothing more (and nothing less) than exhibiting the corresponding pattern with some graded strength. In this sense, the property vocabulary is not primitive: it is induced by the pattern vocabulary, and any change in $\mathcal{P}_C$ (or in the intensity functional I_C) changes the resulting property semantics. It is also important that C is explicit: the same entity may support very different salient patterns in different contexts, so $\mathrm{Prop}_C(x)$ should be read as a context-indexed description rather than an absolute inventory of intrinsic attributes.

Definition 98 (Property-set). *Fix a context C and a space of candidate patterns $\mathcal{P}_C$. The* property-set *of $x \in \mathcal{E}_C$ is the fuzzy set*

$$\mathrm{Prop}_C(x) : \mathcal{P}_C \to [0,1], \qquad \mathrm{Prop}_C(x)(P) := I_C(P; x).$$

If one uses p-bit *intensity (Definition 97), then* $\mathrm{Prop}_C(x)$ *is* p-bit*-valued instead.*

This is an explicit "feature map" induced by patterns: it sends an entity x to a membership function on $\mathcal{P}_C$. If $\mathcal{P}_C$ is finite, then $\mathrm{Prop}_C(x)$ can be viewed as a vector in $[0,1]^{|\mathcal{P}_C|}$; if $\mathcal{P}_C$ is countable, as a bounded sequence; and if one generalizes further (e.g. measurable pattern families), as a bounded function suitable for integration against weights. The fuzzy-set reading is deliberate: a pattern P is not simply "present" or "absent," but can be present to a degree, matching the idea that real-world regularities are often partial, noisy, or scale-dependent.

When p-bit-valued intensities are used, the codomain changes but the role does not: $\mathrm{Prop}_C(x)(P)$ still represents the strength of evidence (in the particular p-bit sense) that x supports P. One can always recover an $[0,1]$-valued proxy (for instance, by mapping a p-bit value to an expected degree, a probability of detection, or another application-specific scalarization), but keeping p-bit values can be useful when one wants intensities that compose more naturally under operations introduced elsewhere.

Definition 99 (Mass of a property-set (one simple choice))**.** *Assume $\mathcal{P}_C$ is finite or countable. Define the* mass *of the property-set as*

$$\|\mathrm{Prop}_C(x)\|_1 := \sum_{P\in\mathcal{P}_C} \mathrm{Prop}_C(x)(P).$$

This L^1-style mass is the simplest aggregate notion of "how many patterns are present, counting multiplicity by intensity." In particular, it distinguishes the case where x weakly supports many patterns from the case where it strongly supports only a few, while still remaining additive over the pattern index. For a finite $\mathcal{P}_C$, the mass is automatically finite and lies in $[0, |\mathcal{P}_C|]$; for a countably infinite $\mathcal{P}_C$, finiteness becomes a substantive condition and can be enforced by choosing $\mathcal{P}_C$ so that only finitely or summably many patterns have non-negligible intensity on typical entities, or by introducing weights $w(P) \geq 0$ and considering $\sum_P w(P)\mathrm{Prop}_C(x)(P)$ when different patterns carry different saliencies or costs.

Remark 408. *This mass is a pattern-theoretic analogue of "how much structured regularity" is present. More sophisticated variants can correct for overlap between patterns (see the "structural complexity" discussion in Section 8).*

A useful way to interpret the overlap issue is that two distinct patterns $P, Q \in \mathcal{P}_C$ may be systematically co-triggered by the same underlying regularity, so summing their intensities can double-count evidence. Correcting for this can be done by (i) discounting redundancy via similarity/implication relations among patterns, (ii) selecting approximately independent subsets of patterns, or (iii) passing from a raw pattern-family to a factorized or minimal basis (when such a notion is available). The present definition intentionally stays minimal: it supplies a baseline quantity that is easy to compute and easy to replace.

9.4.1 Inheritance and association via properties

We can now instantiate inheritance and association in a canonical way. The guiding idea is that once entities are represented by their pattern-intensity profiles, standard set-theoretic relations and similarities can be lifted to the fuzzy setting, yielding orderings (for "is-a"-like relations) and symmetric scores (for "related-to"-like relations) directly from the same data.

Definition 100 (Inheritance via property inclusion)**.** *Fix C. Define an inheritance preorder on $\mathcal{E}_C$ by*

$$A \preceq_C B \iff \mathrm{Prop}_C(A)(P) \geq \mathrm{Prop}_C(B)(P) \quad \textit{for all } P \in \mathcal{P}_C.$$

Because the condition is pointwise in P, $\preceq_C$ is automatically reflexive and transitive, hence a preorder (antisymmetry may fail if two distinct entities have identical property-sets on $\mathcal{P}_C$). Equivalently, $A \preceq_C B$ means that $\mathrm{Prop}_C(B)$ is a fuzzy subset of $\mathrm{Prop}_C(A)$ under the usual product order on $[0,1]^{\mathcal{P}_C}$. This matches the intuition that A can stand in for B with respect to all pattern-tests in $\mathcal{P}_C$: any pattern that manifests in B manifests no less in A.

Remark 409. *This reads: "A inherits from B" when every pattern/property that characterizes B is present (at least as strongly) in A. This is a direct mathematical rendering of Hyperseed's "substitutability in contexts." In applications, one usually weakens the $\forall P$ requirement to a weighted or thresholded version.*

Two common weakenings, both compatible with the same conceptual picture, are: (i) a slackened inclusion condition such as $\mathrm{Prop}_C(A)(P) \geq \mathrm{Prop}_C(B)(P) - \varepsilon(P)$ for pattern-dependent tolerances $\varepsilon(P) \geq 0$ (useful when intensities are noisy), and (ii) a weighted aggregate condition such as

$$\sum_{P \in \mathcal{P}_C} w(P) \left(\mathrm{Prop}_C(B)(P) - \mathrm{Prop}_C(A)(P)\right)_+ \leq \delta,$$

where $(t)_+ := \max\{t, 0\}$ measures shortfall of A relative to B and $w(P)$ encodes salience. These variants preserve the idea that inheritance is driven by systematic dominance of property intensity, while allowing controlled exceptions or trading off minor deficits against major matches.

Definition 101 (Association from property overlap)**.** *Fix C. Define the (symmetric) association score*

$$\mathrm{assoc}_C(A, B) := \frac{\sum_{P \in \mathcal{P}_C} \min\{\mathrm{Prop}_C(A)(P), \mathrm{Prop}_C(B)(P)\}}{\sum_{P \in \mathcal{P}_C} \max\{\mathrm{Prop}_C(A)(P), \mathrm{Prop}_C(B)(P)\}}$$

with the convention $0/0 := 0$.

This ratio lies in $[0, 1]$ whenever the denominator is nonzero. It equals 1 precisely when the two property-sets agree pointwise (on all patterns that appear in at least one of them), and it approaches 0 when their supports (in the fuzzy sense) are largely disjoint. The $0/0 := 0$ convention corresponds to treating two entities with identically zero intensity on every candidate pattern (i.e. indistinguishable "blank" descriptions relative to $\mathcal{P}_C$) as having no meaningful association signal under this particular score; alternative conventions are possible, but the present one keeps the score conservative in the absence of evidence.

Remark 410. *This is a fuzzy Jaccard similarity. Other similarity measures (inner product, Hellinger distance, Hutchinson metric on induced measures) fit the same role; the later "pattern web" construction (Section 11) can be built from any reasonable choice.*

The choice of similarity is partly a modeling decision about what "overlap" should mean. Jaccard emphasizes shared intensity relative to total exhibited intensity, hence it is naturally scale-sensitive to the union of properties; inner-product-based scores emphasize co-activation but can be dominated by overall mass; and distributional distances (e.g. Hellinger) become particularly natural if one normalizes $\mathrm{Prop}_C(x)$ to a probability distribution over patterns when $\|\mathrm{Prop}_C(x)\|_1 > 0$. All of these remain instances of the same general recipe: represent entities by graded pattern profiles, then apply a similarity/divergence on those profiles to obtain an association primitive suitable for building higher level relational structure.

9.5 Emergence

Hyperseed defines emergence of (A, B) (relative to a combination operation $*$) as the collection of patterns that become more intense in $A * B$ than is explained by A and B separately. Intuitively, the comparison is made pattern-by-pattern: a candidate pattern P is deemed emergent when its measured intensity in the composite exceeds an explicit baseline prediction formed from the intensities of P in each part. The role of the baseline is to distinguish genuinely "interaction-driven" structure from structure that is already present in A or in B alone and would therefore be expected to appear in the composite even without additional organization.

Definition 102 (Weighted baseline for emergence)**.** *Fix C and $A, B \in \mathcal{E}_C$ with $s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B) > 0$. Define weights*

$$w_C(A) := \frac{s_C^{\mathrm{base}}(A)}{s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B)}, \qquad w_C(B) := \frac{s_C^{\mathrm{base}}(B)}{s_C^{\mathrm{base}}(A) + s_C^{\mathrm{base}}(B)}.$$

Remark 411. *Definition 102 produces a convex weighting in the sense that $w_C(A), w_C(B) \geq 0$ and $w_C(A) + w_C(B) = 1$. The condition $s_C^{\text{base}}(A) + s_C^{\text{base}}(B) > 0$ rules out the degenerate case in which neither entity contributes any baseline "mass" for constructing a meaningful prediction. When $s_C^{\text{base}}(A) = 0$ and $s_C^{\text{base}}(B) > 0$ (or vice versa), the baseline reduces to the nonzero contributor, so emergence is measured relative to the part that carries the entire baseline weight in context C.*

Definition 103 (Emergent intensity and emergent set)**.** *Fix C and assume $A *_C B$ is defined. For a pattern candidate $P \in \mathcal{P}_C$, define the* emergent surplus

$$\mathrm{Sur}_C(P; A, B) := I_C(P; A *_C B) - \big(w_C(A)\, I_C(P; A) + w_C(B)\, I_C(P; B)\big).$$

Define the emergent intensity

$$\mathrm{Emer}_C(P; A, B) := \max\{0, \mathrm{Sur}_C(P; A, B)\}.$$

The emergence of (A, B) *is the fuzzy set $P \mapsto \mathrm{Emer}_C(P; A, B)$, or the crisp set $\{P : \mathrm{Emer}_C(P; A, B) > 0\}$ if desired.*

Remark 412. *The surplus $\mathrm{Sur}_C(P; A, B)$ is permitted to be negative: this corresponds to a pattern candidate whose intensity is* suppressed *in the composite relative to the weighted baseline. Definition 103 focuses the notion of emergence on "positive novelty" by clamping negative surplus to 0 via $\max\{0, \cdot\}$. In settings where suppression is also of interest, one can still recover it directly from $\mathrm{Sur}_C(P; A, B)$ without altering the present definition.*

Remark 413. *Because the baseline term is a convex combination of $I_C(P; A)$ and $I_C(P; B)$, the quantity $\mathrm{Emer}_C(P; A, B)$ measures a* relative gain *over what would be expected if the composite carried forward only a weighted mixture of the parts' pattern intensities. In particular, if $I_C(P; \cdot)$ is normalized (for example, $I_C(P; X) \in [0, 1]$ for all $X \in \mathcal{E}_C$), then $\mathrm{Emer}_C(P; A, B)$ inherits corresponding interpretability as a bounded, nonnegative degree of emergence. The definition itself does not require a particular normalization, but it does require that $I_C(P; X)$ be comparable across $X \in \{A, B, A *_C B\}$ within the same context C.*

Proposition 8 (Basic properties of emergent intensity)**.** *Fix C and assume $A *_C B$ is defined. Then for every $P \in \mathcal{P}_C$:*

1. $\mathrm{Emer}_C(P; A, B) \geq 0$.
2. *If $I_C(P; X) \geq 0$ for all $X \in \{A, B, A *_C B\}$, then*
$$\mathrm{Emer}_C(P; A, B) \leq I_C(P; A *_C B).$$
3. $\mathrm{Emer}_C(P; A, B) = 0$ *whenever* $I_C(P; A *_C B) \leq w_C(A)\, I_C(P; A) + w_C(B)\, I_C(P; B)$.

Proof. (1) holds by definition since Emer_C is the maximum of 0 and a real number. For (2), the baseline term $w_C(A)\, I_C(P; A) + w_C(B)\, I_C(P; B)$ is nonnegative under the stated assumption, so

$$\mathrm{Sur}_C(P; A, B) = I_C(P; A *_C B) - (\text{nonnegative}) \leq I_C(P; A *_C B),$$

and clamping cannot increase the quantity beyond $I_C(P; A *_C B)$. Statement (3) is immediate from the definition of Sur_C and the clamping in Emer_C. $\square$

Proposition 9 (Symmetry of emergence under commutative combination)**.** *Fix C and assume $*_C$ is commutative and $A *_C B$ is defined. Then for every $P \in \mathcal{P}_C$,*

$$\mathrm{Emer}_C(P; A, B) = \mathrm{Emer}_C(P; B, A).$$

Proof. If $*_C$ is commutative, then $A *_C B = B *_C A$, hence $I_C(P; A *_C B) = I_C(P; B *_C A)$. The weights in Definition 102 satisfy $w_C(A)$ and $w_C(B)$ swap under exchanging A and B, so the baseline term swaps accordingly. Therefore the surplus and its clamped version agree. □

Remark 414. *Emergence is the formal bridge from "patterns in parts" to "integration". A high density of high-intensity emergent patterns spanning a composite corresponds to the Hyperseed intuition of a system whose organization is not reducible to its components. The weighting by $s_C^{\mathrm{base}}(\cdot)$ makes this bridge sensitive to the relative "amount" of each component in the context: in many applications s_C^{base} can be chosen to track size, mass, duration, or any other baseline contribution that would make a simple additive expectation reasonable before accounting for interactions.*

Definition 104 (Collective-property-set)**.** *Fix C. Given an entity $A \in \mathcal{E}_C$ and a reference class $\mathcal{B} \subseteq \mathcal{E}_C$ of "other entities" relevant to A, define the* collective-property-set *of A relative to $\mathcal{B}$ as*

$$\mathrm{Prop}_C^{\mathrm{coll}}(A)(P) := \sup_{B \in \mathcal{B}} \mathrm{Emer}_C(P; A, B).$$

Remark 415. *Definition 104 turns emergence into a property assignment for A by asking: across all relevant interaction partners $B \in \mathcal{B}$, how strongly can A support the emergence of pattern P? The use of* sup *(rather than* max*) allows $\mathcal{B}$ to be infinite or to admit limiting sequences of partners for which the emergent intensity approaches, but does not necessarily attain, its least upper bound. When $\mathcal{B}$ is finite (or compact under suitable regularity assumptions on Emer_C), the supremum can often be replaced by a maximum.*

Proposition 10 (Monotonicity in the reference class)**.** *Fix C and $A \in \mathcal{E}_C$. If $\mathcal{B}_1 \subseteq \mathcal{B}_2 \subseteq \mathcal{E}_C$, then for all $P \in \mathcal{P}_C$,*

$$\mathrm{Prop}_C^{\mathrm{coll}}(A; \mathcal{B}_1)(P) \le \mathrm{Prop}_C^{\mathrm{coll}}(A; \mathcal{B}_2)(P),$$

where $\mathrm{Prop}_C^{\mathrm{coll}}(A; \mathcal{B})(P)$ denotes the right-hand side of Definition 104 with the chosen reference class $\mathcal{B}$.

Proof. If $\mathcal{B}_1 \subseteq \mathcal{B}_2$, then the set of values $\{\mathrm{Emer}_C(P; A, B) : B \in \mathcal{B}_1\}$ is a subset of $\{\mathrm{Emer}_C(P; A, B) : B \in \mathcal{B}_2\}$, hence its supremum cannot exceed the supremum over the larger set. □

9.6 Blends

Hyperseed's blend concept is property-theoretic: C is a blend of A and B when a significant fraction of C's properties are also properties of A or B. Here "properties" are understood in the same weighted sense used throughout the property semantics: $\mathrm{Prop}_C(X)(P)$ assigns (possibly graded) salience, strength, or evidential mass to the claim that X has property P in context C, so overlap can be partial rather than all-or-nothing.

Definition 105 (Blend score and blend predicate)**.** *Fix C and choose a threshold $\theta \in (0, 1]$. Define the* property overlap mass *of C with (A, B) as*

$$\mathrm{ov}_C(C; A, B) := \sum_{P \in \mathcal{P}_C} \min\Big\{\mathrm{Prop}_C(C)(P),\ \max\big(\mathrm{Prop}_C(A)(P), \mathrm{Prop}_C(B)(P)\big)\Big\}.$$

Define the blend score

$$\mathrm{blendscore}_{\mathcal{C}}(C;A,B) := \begin{cases} \mathrm{ov}_{\mathcal{C}}(C;A,B)/\|\mathrm{Prop}_{\mathcal{C}}(C)\|_1, & \|\mathrm{Prop}_{\mathcal{C}}(C)\|_1 > 0, \\ 0, & \|\mathrm{Prop}_{\mathcal{C}}(C)\|_1 = 0. \end{cases}$$

We say C is a blend of A and B (in context $\mathcal{C}$) *if* $\mathrm{blendscore}_{\mathcal{C}}(C;A,B) \geq \theta$.

The use of $\max(\mathrm{Prop}_{\mathcal{C}}(A)(P), \mathrm{Prop}_{\mathcal{C}}(B)(P))$ treats the sources A and B as an "either-parent" supplier of property mass for P, while the outer $\min\{\cdot,\cdot\}$ enforces that only as much of C's mass on P can be credited as is supported by at least one parent. Thus $\mathrm{ov}_{\mathcal{C}}$ is a fuzzy-set analogue of $|C \cap (A \cup B)|$ when properties are crisp indicators, and $\mathrm{blendscore}_{\mathcal{C}}$ becomes a normalized coverage ratio for how much of C can be explained as inherited from A or B at the property level. In particular, whenever $\|\mathrm{Prop}_{\mathcal{C}}(C)\|_1 > 0$ one has $0 \leq \mathrm{blendscore}_{\mathcal{C}}(C;A,B) \leq 1$, with $\mathrm{blendscore}_{\mathcal{C}}(C;A,B) = 1$ precisely when, for every $P \in \mathcal{P}_{\mathcal{C}}$, $\mathrm{Prop}_{\mathcal{C}}(C)(P) \leq \max(\mathrm{Prop}_{\mathcal{C}}(A)(P), \mathrm{Prop}_{\mathcal{C}}(B)(P))$.

Because the normalization uses $\|\mathrm{Prop}_{\mathcal{C}}(C)\|_1$, the score measures the fraction of C's own asserted property mass that is supported by A or B; properties that are salient for A or B but not salient for C do not inflate the score. This keeps the predicate focused on explaining C rather than on measuring generic similarity between A and B. The special case $\|\mathrm{Prop}_{\mathcal{C}}(C)\|_1 = 0$ corresponds to a context where C has no active property mass (e.g. missing data, a fully uncommitted representation, or an explicitly "null" property profile), in which case the conservative convention sets the score to 0.

Remark 416. *This definition is intentionally parametric: the threshold θ and the mass functional can be chosen based on application. In cognitive modeling, blends are typically context-sensitive; the present definition makes that explicit. A higher θ demands that most of what is asserted about C be attributable to at least one parent, whereas a lower θ allows C to introduce more novel or emergent properties not present in A or B. Likewise, replacing* max *by another pooling operator (e.g. a t-conorm, a softmax, or an additive rule with a cap) changes whether joint support from both parents can strengthen the accounting for a property.*

For intuition, consider the crisp/unweighted limit where $\mathrm{Prop}_{\mathcal{C}}(X)(P) \in \{0,1\}$ and $\|\mathrm{Prop}_{\mathcal{C}}(C)\|_1 = |\{P : \mathrm{Prop}_{\mathcal{C}}(C)(P) = 1\}|$. Then $\mathrm{ov}_{\mathcal{C}}(C;A,B)$ counts the number of properties that C has and that at least one of A or B also has, and $\mathrm{blendscore}_{\mathcal{C}}(C;A,B)$ is the fraction of C's properties covered by $A \cup B$. In the graded case, the same picture holds but with fractional contributions: if C partially satisfies P to degree 0.6 while the stronger parent support is 0.4, then only 0.4 counts as overlap and the remaining 0.2 of C's mass on P is treated as not inherited from either parent.

9.6.1 Categorical blend construction (pushout intuition)

A more structural notion of blend is useful when entities are themselves compositional objects (e.g. graphs, terms, enriched presheaves). In that case, a blend is naturally modeled by a colimit that glues two objects along a shared substructure, with a weakness/effort bias to prefer minimal glue. This captures the common cognitive intuition that blending reuses a matched subpattern and then merges the remaining structure around it, rather than arbitrarily combining the entirety of A and B.

Definition 106 (Blend as colimit with weak-glue preference (sketch))**.** *Fix a category (or enriched category) $\mathcal{C}$ of entity-structures appropriate to the domain. Given $A, B \in \mathrm{Ob}(\mathcal{C})$, a* blend diagram *is a span*

$$S \xrightarrow{i_A} A, \qquad S \xrightarrow{i_B} B$$

where S is an extracted "shared subpattern." A categorical blend *is a choice of pushout (or more generally colimit)*

$$A \xleftarrow{i_A} S \xrightarrow{i_B} B \quad \rightsquigarrow \quad A \to \mathrm{Blend}(A, B; S) \leftarrow B,$$

together with a ranking functional (effort/weakness) that prefers spans S yielding lower glue overhead.

Operationally, S represents the alignment hypothesis: it specifies which parts of A and B are to be treated as "the same" for the purpose of blending, and the pushout performs the minimal identification consistent with that hypothesis. The effort/weakness preference then plays a role analogous to regularization: among many possible spans S (and many possible ways to extract them from data), one favors those that explain the perceived commonality while introducing as few identifications, coercions, or ad hoc repairs as possible. In concrete categories (e.g. graphs), the glue overhead can be understood as the size or complexity of the interface S relative to A and B, the number of forced identifications, or the amount of additional structure required to make the span commute in the chosen modeling formalism.

Remark 417. *In practice, one rarely needs literal pushouts; approximate colimits in a quantale-enriched setting often match cognition better (multiple partial shared subpatterns, conflicting identifications, etc.). Paraconsistency enters here in a controlled way: one can glue while retaining evidence against some identifications. From the property-theoretic perspective, such "approximate gluing" corresponds to allowing the blend to inherit some properties strongly while keeping other candidate inheritances tentative or contested, which then manifests as intermediate masses in* $\mathrm{Prop}_C(\mathrm{Blend}(\cdot))$ *rather than hard yes/no attributions.*

9.7 Lifting from instances to groups

Hyperseed notes that once a relation is defined for instances, there are multiple sensible ways to lift it to groupings of instances. We formalize three common lifts (average-like, $\forall\exists$-like, and $\exists\forall$-like) in a form that generalizes well.

Definition 107 (Three lifts of an instance relation)**.** *Let $C(\cdot, \cdot) : X \times Y \to [0, 1]$ be any graded instance-level relation. For finite nonempty $A \subseteq X$ and $B \subseteq Y$, define:*

$$\begin{aligned} C_{\mathrm{avg}}(A, B) &:= \frac{1}{|A||B|} \sum_{a \in A} \sum_{b \in B} C(a, b), \\ C_{\forall\exists}(A, B) &:= \min_{a \in A} \max_{b \in B} C(a, b), \\ C_{\exists\forall}(A, B) &:= \max_{b \in B} \min_{a \in A} C(a, b). \end{aligned}$$

Remark 418. *These correspond (respectively) to "on average", "for most a there exists some b", and "there exists some b that works for most a", in a graded sense. The same pattern works in quantale-valued settings by replacing* $(\min, \max)$ *with meet/join and the average with a chosen aggregation functional.*

Remark 419. *The nonemptiness of A, B ensures each lift is well-defined without additional conventions. In applications where empty groups may arise (e.g., sparse clustering outputs), one can extend the definitions by selecting neutral elements (e.g.,* 1 *for "vacuously true" lifts,* 0 *for "no evidence") or by explicitly carrying an "undefined" value; the present formalization keeps the core algebra clean.*

Remark 420. *When C is crisp, i.e. $C(a,b) \in \{0,1\}$, the second and third lifts reduce to familiar quantifier patterns:*

$$C_{\forall\exists}(A,B) = 1 \iff \forall a \in A\, \exists b \in B : \; C(a,b) = 1, \qquad C_{\exists\forall}(A,B) = 1 \iff \exists b \in B\, \forall a \in A : \; C(a,b) = 1.$$

Thus, in the Boolean case, $C_{\forall\exists}$ behaves like an "every a can be matched" score, while $C_{\exists\forall}$ behaves like a "single prototype b covers all a" score.

Remark 421. *Basic bounds and order-theoretic behavior are immediate from the definitions. Writing*

$$C_{\min}(A,B) := \min_{a\in A,\, b\in B} C(a,b), \qquad C_{\max}(A,B) := \max_{a\in A,\, b\in B} C(a,b),$$

one always has $C_{\min}(A,B) \le C_{\forall\exists}(A,B) \le C_{\max}(A,B)$ and $C_{\min}(A,B) \le C_{\exists\forall}(A,B) \le C_{\max}(A,B)$, and the minimax inequality gives

$$C_{\exists\forall}(A,B) \;\le\; C_{\forall\exists}(A,B).$$

In particular, $C_{\exists\forall}$ is the more "demanding" lift: it asks for one element of B that uniformly scores well against all of A, whereas $C_{\forall\exists}$ allows the best witness in B to depend on a.

Remark 422. *If C is interpreted as a similarity or compatibility, then C_{avg} measures overall affinity between two clouds, $C_{\forall\exists}$ measures whether each point in A is well-covered by some point in B (a directed "coverage" score), and $C_{\exists\forall}$ measures whether B contains a single representative that fits all of A (a directed "prototype" score). These readings often align with empirical choices in clustering, retrieval, and exemplar-based modeling.*

This is the generic mechanism behind lifting reference, association, and even emergence-like relations from episodes to categories.

9.8 Combinatorial-categorical patterns

Hyperseed introduces "combinatorial-categorical patterns" as patterns that become visible only after running a category-theoretic substitution/relabeling process. We formalize this as: apply a rule system that assigns category labels to instances, producing a derived structure in which ordinary patterns can be mined.

Definition 108 (Category domain and membership state)**.** *Fix a finite set of categories (types) W. A* membership state *on a set of instances S is a map*

$$m : S \to 2^W.$$

Remark 423. *Equivalently, a membership state can be seen as a binary relation $R_m \subseteq S \times W$ via $(s,w) \in R_m \Leftrightarrow w \in m(s)$, or as a $|S| \times |W|$ incidence matrix. This viewpoint makes the subsequent closure operation look like a monotone update of a relation by rules.*

Definition 109 (Combinatorial-categorical theory)**.** *Fix a set of instances S and a category domain W. A* combinatorial-categorical theory *T is a finite set of rules of the form*

$$(x \in A) \;\wedge\; (y \in B) \implies (z \in C),$$

where $x, y, z \in S$ and $A, B, C \in W$.

Remark 424. *Syntactically, these are Horn-style implication rules over the atomic predicates "$s \in w$" (read: the instance s has category label w). The restriction to conjunctions in the antecedent ensures that the associated operator on membership states is monotone under set inclusion, which is what makes least-fixed-point semantics natural and robust.*

Definition 110 (Substitution output / closure)**.** *Given an initial membership state $m_0 : S \to 2^W$ and a theory T, define the closure m_T as the least fixed point (under set inclusion) obtained by repeatedly applying the rules of T: start from m_0 and whenever a rule's antecedent holds under the current m, add C to $m(z)$. Let*

$$\mathrm{sub}(T, S, m_0) := (S, m_T)$$

denote the resulting labeled structure.

Remark 425. *Because S and W are finite and rules only add labels, the iterative forward-chaining process must terminate after at most $|S| \cdot |W|$ successful additions, independent of rule order. Moreover, the least-fixed-point characterization implies confluence: any fair rule-application schedule yields the same m_T, so* $\mathrm{sub}(T, S, m_0)$ *is well-defined without committing to an operational order.*

Remark 426. *It is often useful to name the associated closure operator explicitly: define F_T on membership states by adding, for each rule $(x \in A) \wedge (y \in B) \Rightarrow (z \in C)$, the label C to z whenever $A \in m(x)$ and $B \in m(y)$. Then m_T is the least fixed point of F_T above m_0 (i.e. the least $m \supseteq m_0$ with $F_T(m) = m$). This makes clear that* sub *is monotone in m_0 and in T (adding initial labels or rules can only add, never remove, derived labels).*

Definition 111 (Combinatorial-categorical pattern)**.** *Fix a context C and assume a pattern mining scheme has been defined on labeled structures. A pattern candidate P is a* combinatorial-categorical pattern *in S relative to T and m_0 if P is a (standard) pattern in the derived structure* $\mathrm{sub}(T, S, m_0)$.

Remark 427. *Concretely, one can take the "labeled structure" to be the multiset $\{m_T(s) : s \in S\}$ and apply any off-the-shelf pattern formalism (frequent itemsets, association rules, MDL-based codes, subgraph motifs after encoding m_T as a bipartite graph, etc.). The key is that patterns are not searched for in the raw instance space, but in the feature space induced by closure under T.*

Remark 428. *This construction cleanly separates two kinds of inductive bias. The theory T determines which composite categories are even expressible (a kind of "feature generation"), while the mining scheme determines which regularities count as salient (frequency, compressibility, predictive utility,* etc.*). In this sense, "combinatorial-categorical patterns" are ordinary patterns, but in a theory-generated representation.*

Remark 429. *This is a clean formal docking port to "pattern theory" constructions: T generates a derived feature space (categories as features), after which one mines compressive structures (patterns) over that space.*

9.9 Combination systems, interpreters, and combinational dynamical causal models

We now formalize the computational and dynamical notions Hyperseed attaches to combinations. The intent of this subsection is to keep the algebraic structure minimal (a set equipped with a not-necessarily-total binary operation), while still being expressive enough to cover common cases such as term concatenation, multiset union, function composition, event interaction, and process coupling. In particular, the partiality of the operator is used to encode compatibility constraints: some pairs of objects simply do not combine (or are not allowed to combine) under the rules of a given model.

Definition 112 (Combination system)**.** *A* combination system *is a pair* $(S, *)$ *where* S *is a set and* $* : S \times S \rightharpoonup S$ *is a partial binary operation.*

The use of a partial operation $*\colon S \times S \rightharpoonup S$ means that there may exist $x, y \in S$ for which $x * y$ is undefined. This can be read either operationally (the system refuses to execute that composition) or semantically (there is no meaningful composite object in the chosen ontology). No associativity, commutativity, identity, or inverses are assumed unless explicitly added later; this allows the same template to describe both highly structured algebraic settings and ad hoc gluing rules that arise in modeling and representation.

Definition 113 (Interpreted combination system)**.** *An* interpreted combination system *is a triple* $(S, *, \mathrm{Dec})$ *where* $(S, *)$ *is a combination system,* $\mathcal{L}$ *is a syntactic language of expressions, and* $\mathrm{Dec} : \mathcal{L} \to S$ *is an interpreter such that whenever* $\ell_1 \cdot \ell_2$ *denotes a syntactic composition corresponding to* $*$*, one has*

$$\mathrm{Dec}(\ell_1 \cdot \ell_2) = \mathrm{Dec}(\ell_1) * \mathrm{Dec}(\ell_2)$$

whenever the right-hand side is defined.

Here $\mathcal{L}$ may be thought of as a grammar-generated set of expressions, while $\cdot$ is the syntactic constructor for putting two expressions together in whatever way is appropriate (concatenation, application, pairing, sequencing, etc.). The condition

$$\mathrm{Dec}(\ell_1 \cdot \ell_2) = \mathrm{Dec}(\ell_1) * \mathrm{Dec}(\ell_2)$$

is a compositionality requirement: decoding a composite expression agrees with composing the decoded parts, whenever that semantic composition exists. Equivalently, Dec behaves like a homomorphism from the syntactic combination (where defined as a constructor) into the semantic combination system (where defined as a partial operation), and undefinedness on the semantic side signals that the syntactic composite has no coherent meaning under the intended interpretation.

Remark 430. *This is the formal core of "a computational model is an interpreted combination system": syntax plus an evaluation map into semantic objects equipped with composition.*

One can also view $(S, *)$ as the model's semantic workspace, and Dec as the mechanism that embeds symbolic expressions into that workspace. The definition deliberately does not constrain $\mathcal{L}$ to be closed under $\cdot$ for all pairs: even at the syntactic level there may be formation rules, and at the semantic level there may be compatibility conditions. When $\mathcal{L}$ *is* closed under $\cdot$ but $*$ is partial, then some well-formed syntactic composites may decode to undefined semantic composites, which captures the common situation where an expression is grammatical but ill-typed or semantically incoherent.

Next, a combination-preserving representational mapping allows a system to talk about a dynamical domain using a symbolic combination system. The central idea is that the same combinational structure appears on two sides: in the world-domain of processes/events and in the representational-domain of symbols. A map that preserves combination is the minimal requirement for symbols to track how interactions in the domain assemble into larger composite processes.

Definition 114 (Combination-preserving representational mapping)**.** *Let* $(D, **)$ *be a domain of processes or events with a (possibly partial) interaction/combination operator* $**$*. Let* $(S, *)$ *be a combination system of symbols. A map* $f : D \to S$ *is* combination-preserving *if*

$$f(a * *b) = f(a) * f(b)$$

whenever $a * *b$ *and* $f(a) * f(b)$ *are defined.*

This condition can be read as a consistency constraint between what happens in the dynamical domain and how we name it in the symbol system. Because both $**$ and $*$ may be partial, the definition only enforces equality on the intersection of their defined regions: if an interaction $a ** b$ exists and the corresponding symbolic combination $f(a) * f(b)$ is also meaningful, then the symbol for the interaction must agree with the combination of the symbols. In modeling terms, this is precisely the requirement that representation respect the compositional granularity of the domain. When f is not injective, it intentionally collapses distinct domain elements into the same symbol; the later validity condition for causal attribution is designed to ensure that causal claims are invariant under such representational collapse.

Finally, Hyperseed's "combinational dynamical causal model" is a graded causal attribution for triples. The triple (a, b, c) is intended to capture a two-input interaction resulting in (or contributing to) an outcome. The range $[0, 1]$ supports soft or probabilistic attributions, and it is compatible with both deterministic and statistical readings depending on how Γ is instantiated.

Definition 115 (Combinational dynamical causal model)**.** *Let $(D, **)$ be a dynamical process domain. A* combinational dynamical causal model *is a function*

$$\Gamma : D \times D \times D \to [0, 1]$$

where $\Gamma(a, b, c)$ is interpreted as the degree to which "interaction of a and b caused c."

Given a combination-preserving representational mapping $f : D \to S$ into a symbol system $(S, *)$, we say Γ is valid relative to f *if*

$$f(a) = f(a'),\ f(b) = f(b'),\ f(c) = f(c') \quad \Longrightarrow \quad \Gamma(a, b, c) = \Gamma(a', b', c')$$

for all $a, b, c, a', b', c' \in D$.

The valid relative to f condition can be understood as invariance under the equivalence relation induced by the representation. If we define $x \sim_f y$ to mean $f(x) = f(y)$, then validity requires Γ to be constant on $\sim_f$-equivalence classes in each argument simultaneously. Equivalently, Γ factors through the quotient induced by f: there exists a well-defined function $\widetilde{\Gamma}$ on the level of symbols/classes such that $\Gamma(a, b, c)$ depends only on $(f(a), f(b), f(c))$. This makes explicit that the causal scores are not absolute facts about D alone, but are constrained to be compatible with the descriptive alphabet provided by f.

Remark 431. *Validity means the causal model "respects the symbols": it does not distinguish processes that the representation identifies. This is the causal analogue of observer-relativity: causality is computed relative to a representational alphabet (and thus relative to an ontology).*

In particular, if f merges multiple micro-level processes into a single macro-symbol (e.g., many distinct trajectories mapped to one coarse label), then validity forces Γ to assign the same causal degree to any two triples that are indistinguishable at that macro level. This ensures that causal attributions are stable under re-description: once an ontology has decided what counts as the same process, the causal model cannot re-introduce distinctions that the ontology has explicitly discarded. Conversely, if a proposed Γ violates validity, then either the representation f is too coarse for the causal distinctions being made, or the causal model is implicitly using additional latent features not present in $(S, *)$.

9.10 Specific entities as temporally coherent patterns

Hyperseed treats "specific entities" (ordinary objects, persons, institutions) as complex derived constructions rather than primitives. The key observation is that specific-entity identity behaves like a pattern with a temporal algebra. In particular, what is being modeled is not an additional metaphysical glue beyond the entities already available in $\mathcal{E}_C$, but a rule-governed way of *tracking* a coherent thread through time-slices: the stream provides the candidate trajectory, while the coherence rule $\mathcal{R}$ fixes which kinds of variation count as "the same" within the intended resolution of the context C. This makes explicit that persistence is always relative to (i) the granularity of proto-time, (ii) the measurement/description vocabulary encoded by the properties used in assoc_C, and (iii) the tolerance encoded by $\mathcal{R}$.

Definition 116 (Occurrence stream)**.** *Fix a context C with proto-time ordering (Section 7). An* occurrence stream *is a family $\{x_t\}_{t\in T}$ of entities $x_t \in \mathcal{E}_C$ indexed by times (or time-slices) t in a partially ordered set $(T, \leq)$.*

The choice of $(T, \leq)$ as a partially ordered set, rather than assuming a total order, is intentional: it allows proto-time to represent branching, concurrency, or causal precedence structures (e.g. distributed records, parallel sub-processes, or partially ordered observations), without forcing a single linear history. In this setting, an occurrence stream may be *partial*: for some $t \in T$ there need not be an x_t at all, reflecting missing observations, gaps in memory, or times at which the entity is simply not represented in $\mathcal{E}_C$. The phrase "if … both occur" in the coherence conditions is meant to accommodate such partiality.

Definition 117 (Specific entity (pattern-theoretic criterion))**.** *A* specific entity *in context C is specified by an occurrence stream $\{x_t\}_{t\in T}$ together with a coherence rule $\mathcal{R}$ such that:*

1. *(Same-time identity) If $t = t'$ and both x_t and $x_{t'}$ occur, then they are identified: $x_t = x_{t'}$.*

2. *(Near-time similarity) If t and t' are close in proto-time, then the association $\mathrm{assoc}_C(x_t, x_{t'})$ is high (Definition 101), or equivalently the property-sets overlap strongly.*

The strength of "being the same specific entity" is graded by how well the stream satisfies these rules.

Condition (1) should be read as a determinacy constraint internal to the representation: within a fixed time-slice, the stream does not bifurcate into multiple candidates that are *simultaneously* treated as distinct occurrences of the same tracked entity. This is a minimal consistency requirement for a tracking convention, and it separates questions of "co-reference at a time" from questions of persistence across time. Condition (2) provides the persistence signal: if proto-time steps are small, then large discontinuities in properties are penalized (low assoc_C), while small variations are tolerated. The coherence rule $\mathcal{R}$ can be taken to parameterize what counts as "close" in proto-time (e.g. adjacent steps, bounded distance in the order, or neighborhood relations induced by the context) and what counts as "high" association (e.g. a threshold, a soft score, or a weighted overlap depending on which properties are privileged in C). Thus, even when the same underlying object is being discussed informally, different contexts C (legal, biological, physical, social) can yield different specific-entity criteria because they select different property vocabularies and tolerances.

The graded reading in the final sentence is crucial: rather than producing a binary verdict, the framework supports *degrees of identity* driven by the quality of temporal coherence. For example, a heavily repaired artifact (a "Ship of Theseus" trajectory) can yield a stream where local similarity remains high even though long-range similarity between distant times is low; the framework then naturally supports the common phenomenon that identity feels secure locally but disputable globally. Likewise, institutional entities (companies, governments) are often stable under large personnel changes, so $\mathcal{R}$ in such contexts would weight organizational roles, charters, or registries more than physical continuity; by contrast, for biological organisms $\mathcal{R}$ would privilege different properties (e.g. bodily continuity, metabolic functioning).

Remark 432. *This captures the intended Hyperseed idea: "specific entity" is a pattern (a temporally stable bundle of properties) with conventional default rules, but those rules can be violated in exotic scenarios (yielding graded/ambiguous identity rather than forcing contradiction).*

A further consequence is that identity questions can be reframed as optimization or inference problems: given a set of candidate occurrences in $\mathcal{E}_C$ at various times, one seeks streams that maximize coherence under $\mathcal{R}$ (high near-time association, minimal violations of same-time determinacy), possibly subject to additional constraints coming from the context. This aligns the informal practice of "tracking an object/person" with a precise, context-sensitive criterion: the best-supported stream is the one that forms the most temporally coherent pattern. In cases with competing high-coherence streams (e.g. fission, duplication, imperfect records), the model predicts *plural* partially supported identifications rather than a forced all-or-nothing answer.

9.11 Worked micro-example (optional but useful)

Example 9 (A minimal pattern and emergent pattern)**.** *Let C be a context with a combination operator $*$ and baseline costs s_C^{base}. Suppose $x = y * z$ and $s_C^{\text{base}}(x) = 10$, $s_C(y) = 3$, $s_C(z) = 4$, and glue overhead $t = 1$. Then $h_C(P) = 3 + 4 + 1 = 8$ so*

$$I_C(P; x) = \max\left\{0, \frac{10 - 8}{10}\right\} = 0.2.$$

Thus (y, z, t) is a pattern in x of intensity 0.2. Here $h_C(P)$ is the hypothesized cost of "explaining" or "reconstructing" x via the structured description provided by the pattern P (namely, reuse y and z and pay the additional glue overhead t to combine them in the appropriate way). The baseline $s_C^{\text{base}}(x)$ is the cost of representing x without exploiting any special structure, so the numerator $10-8$ measures the absolute savings attributable to recognizing P inside x. Dividing by 10 normalizes this savings, making the resulting intensity scale-free relative to the baseline size of x in context C. The outer $\max\{0, \cdot\}$ enforces that an alleged pattern cannot have negative intensity: if the hypothesized description is no cheaper than baseline (i.e., if $h_C(P) \geq s_C^{\text{base}}(x)$), then the correct conclusion is simply that P provides no compression advantage in x (intensity 0) rather than treating it as "anti-pattern" evidence.

Now suppose also that $A *_C B$ exists and a pattern P has intensities $I_C(P; A) = 0.1$, $I_C(P; B) = 0.1$, but $I_C(P; A *_C B) = 0.5$. If $s_C^{\text{base}}(A) = s_C^{\text{base}}(B)$ then $w_C(A) = w_C(B) = 1/2$ and

$$\mathrm{Sur}_C(P; A, B) = 0.5 - (0.5 \cdot 0.1 + 0.5 \cdot 0.1) = 0.4,$$

so P is emergent in $A *_C B$ with emergent intensity 0.4. The point of this second computation is that emergence is assessed relative to what one would "expect" from the parts when combined, where that expectation is a weighted average of part-wise intensities. In this symmetric case, equal baseline sizes lead to equal weights, so the predicted intensity absent interaction effects is just the simple average of 0.1 and 0.1, namely 0.1. The surplus $\mathrm{Sur}_C(P; A, B) = 0.4$ quantifies the genuinely interaction-dependent gain: the pattern becomes much more detectable (or much more cost-saving) in the composite than one would anticipate from its weak presence in each component *alone. Equivalently, this example isolates a situation where the combined object $A *_C B$ supports a strong structural shortcut described by P that is not available, or not salient enough to be valuable, when considering A and B in isolation.*

Remark 433. *This example is numerically trivial, but it is exactly the formal shape of the Hyperseed definitions. In later sections, the toy resonance model (Section 5) and the habit dynamics (Section 12) will turn these static notions into time-evolving structures. One should read the numbers here as placeholders for whatever cost model is supplied by the context C: for instance, costs may encode description length, energy, inference effort, or any other resource that the agent tracks. Likewise, the "glue overhead" t is the minimal place where contextual idiosyncrasy can enter: even if y and z are individually cheap, composing them may require additional bookkeeping, alignment, interface matching, or constraints to be satisfied, all of which are abstracted into t. The emergent calculation is also intentionally schematic: it highlights that emergence is not merely "having high intensity," but rather "having higher intensity than predicted from the parts under the chosen weighting scheme." Consequently, changing s_C^{base} (and hence the weights w_C) can change the quantitative emergent intensity, reflecting the fact that what counts as "surprising" depends on how the context measures and compares the relative contribution of the components.*

10 Information, uncertainty, and ineffability

10.1 Motivation: information as observer-indexed bookkeeping

Hyperseed treats *distinction* as primitive and observer-relative (Hyperseed-Concept 98). As soon as we take this stance seriously, "information" and "uncertainty" can no longer be treated as absolute scalars attached to a world-state; they must be indexed by a *context* (or observer) (Hyperseed-Concept **??**, Hyperseed-Concept 195; see also [1]). This section provides a small formal layer that lets us: (i) speak about probabilistic belief (Hyperseed-Concept 139); (ii) relate classical Shannon information to distinction-based measures (logical entropy and graphtropy) (Hyperseed-Concept 105, Hyperseed-Concept **??**; [17]); (iii) make "ineffability" precise as a representational limitation (Hyperseed-Concept **??**); and (iv) clarify what "potential infinity" and "infinitesimals" can mean in a resource-sensitive ontology (Hyperseed-Concept **??**, Hyperseed-Concept **??**).

Throughout, let X denote a (typically finite) set of "world items" (entities, events, situations) and let O denote an observer/context. The basic data carried by O are: (a) a family of distinctions it can make about X; and (b) a belief state over those distinctions.

In this framing, X should be read as a domain of discourse relative to a modeling task: it might be a set of perceptual episodes, candidate hypotheses, experimental outcomes, or coarse-grained situations that are treated "as if" they were atomic for current purposes. The parenthetical "typically finite" is not merely a convenience: in Hyperseed the finiteness (or boundedness) of X often stands in for resource limits on attention, memory, time, and representational capacity, while still allowing limits to be taken when discussing "potential" infinities.

Item (a) can be made concrete in multiple equivalent ways, depending on which mathematical lens is most appropriate. For example, a distinction-making capacity can be encoded as a partition of X into equivalence classes (items that O cannot tell apart), or as a set of binary questions of the form "does x have property P?", or (more generally) as a σ-algebra of subsets of X specifying which events are *measurable* for O. Each representation emphasizes a different intuition: partitions emphasize *indistinguishability*, question-sets emphasize *interrogability*, and σ-algebras emphasize closure properties needed for consistent probability assignments. In particular, once distinctions are taken as primary, it becomes natural to treat two items $x, y \in X$ as observationally equivalent for O when no available distinction separates them; the "world-state" relative to O is then more faithfully represented by the cell of a partition (or, dually, by the truth-values of all questions in the algebra) than by a bare element of X.

Item (b) is then the observer's weighting over the distinguishable alternatives. Operationally, one may think of O as assigning probabilities to the events it can express (e.g., to the cells of a partition, or to measurable subsets), which is why a probability measure naturally appears alongside the distinction structure. This is intentionally broad: it includes Bayesian degrees of belief, empirical frequencies within a data stream, and hybrid or imprecise credal assignments, so long as they respect the representational constraints imposed by (a). The key point is that probabilities are not assigned to an unstructured "reality" but to *recognizable* possibilities—hence even a numerically identical probability vector may correspond to different informational situations if the underlying distinctions differ.

Remark 434. *The philosophical point is modest but consequential: an "information measure" is never purely a property of* the world*; it is a property of a world* as carved *by some scheme of recognition, and as weighted by some state of belief. Russell would say that the definitions below are not metaphysical proclamations about Being, but carefully chosen bookkeeping devices; Peirce would add that this bookkeeping is itself a habit of interpretation, hence belongs as much to the interpreter as to the interpreted. Formally, the bookkeeping will appear as (i) a σ-algebra encoding what can be asked, and (ii) a probability measure encoding how strongly the observer leans toward different answers.*

A useful way to read the remark is as a constraint on what it could even *mean* to compare information across observers. If two contexts O_1, O_2 carve X differently, then an expression like "O_1 has more information than O_2" is not automatically well-defined until one specifies a translation between their distinction structures (e.g., refinement/coarsening maps between partitions, or homomorphisms between σ-algebras). When such a translation exists, many familiar monotonicity intuitions reappear (finer distinctions can support lower uncertainty, higher potential information gain), but these become theorems about relationships between algebras/partitions rather than metaphysical claims about a single observer-independent quantity.

This observer-indexed bookkeeping also motivates why distinction-based measures (logical entropy, graphtropy) are not merely alternative "formulas" for the same idea. Shannon entropy presumes a fixed alphabet of outcomes and measures expected code length relative to that alphabet; logical entropy directly counts (in expectation) how often two draws fall into *different* distinguishability classes, making the role of distinctions explicit. Graphtropy generalizes the same intuition from partitions to graphs of indistinguishability or comparability relations on X, which is often closer to how real cognitive and computational systems represent "can/cannot tell apart" in a graded or relational manner. Thus, the formal layer introduced here is meant to keep the distinction structure visible, so that later statements about uncertainty reduction, learning, and ineffability remain tethered to what the observer can actually represent.

Finally, the promised link to ineffability can be previewed already at this introductory stage: something is "ineffable for O" not because it is mystical, but because it cannot be stably encoded within O's distinction system and the associated algebra of questions. On this view, ineffability is an internal, structural limitation: there may be facts about X that exist in some richer meta-description, yet are not measurable (or not finitely describable) in the σ-algebra available to O, or cannot be assigned coherent probabilities without extending O's representational resources. This is also where resource-sensitive readings of infinity and infinitesimals enter: what looks like an "infinitary" refinement may be treated as a limit of finite refinements that an observer can only ever approximate, and "infinitesimal" differences may correspond to distinctions that are in principle definable but in practice unresolvable at the observer's current granularity.

10.2 Observer-indexed probability spaces

Definition 118 (Observable events)**.** *Fix an observer/context O. An* event observable to O *is a predicate on X whose truth value is determined at the resolution of O. Formally, we model the collection of O-observable events as a sigma-algebra $\Sigma_O \subseteq 2^X$. A* probability model for O *is a probability measure*

$$P_O : \Sigma_O \to [0, 1].$$

The triple (X, Σ_O, P_O) is the observer-indexed probability space.

Remark 435. ***Notation/conventions.*** *Here 2^X denotes the power set of X (all subsets of X); $\Sigma_O \subseteq 2^X$ is a σ-algebra, meaning it is closed under complements and countable unions (in the finite case, this reduces to closure under complements and finite unions). The probability measure P_O assigns to each observable event $A \in \Sigma_O$ a number in $[0, 1]$ with $P_O(X) = 1$ and countable additivity on disjoint unions. It is also standard that $P_O(\varnothing) = 0$ and that (by additivity) $P_O(A^c) = 1 - P_O(A)$ whenever $A \in \Sigma_O$; these identities emphasize that P_O is defined only on the observer's event-language Σ_O rather than on arbitrary subsets of X. When X is large or continuous, the restriction to Σ_O is not only philosophical but technically necessary: many subsets of X are not measurably well-behaved, and σ-algebras are precisely the minimal structure needed to make probability assignments coherent.*

Intuition. *Σ_O is the mathematical shadow of the observer's* question-set*: it lists precisely which yes/no questions about X are meaningful at O's resolution. If $A \notin \Sigma_O$, it is not that A is false; it is that A is* not a well-formed observable event *for O. Once the observer has a question-set, P_O encodes the observer's uncertainty over answers. In this sense, an "observer" O can be read broadly: a physical sensor suite, an agent with finite memory and categories, a modeling choice about which variables are tracked, or even a scientific community that has stabilized a repertoire of admissible experimental distinctions.*

Example. *Let X be the set of microstates of a gas. A coarse observer might only measure temperature and pressure, so Σ_O is generated by macroscopic equivalence classes (microstates with the same macro-observables). A finer observer might distinguish many more subsets, having a much larger Σ_O. This is the formal version of saying: different observers inhabit different informational worlds even when they speak about the same underlying X. Equivalently, one can think of the coarse observer as having access only to a map $f_O : X \to Y_O$ of microstates into macrostates, so that Σ_O is the pullback of the power set (or Borel σ-algebra) on Y_O; in that view, P_O is the pushforward of whatever uncertainty the observer implicitly has over X into the observer's accessible variables.*

Remark 436 (Coarse-graining as "loss of distinction")**.** *If Σ_O is generated by a partition π_O of X, then the observer does not represent individual elements of X but only the block in π_O that contains them. The move from 2^X to Σ_O is a formal encoding of "failure to make distinctions." In particular, any two microstates $x, x' \in X$ that lie in the same block of π_O are observationally interchangeable for O: no event in Σ_O can separate them. This makes explicit that "coarse-graining" is not merely a lossy summary of a distribution, but a restriction on the very predicates that can be formed and evaluated.*

Remark 437. *A partition-induced σ-algebra is the simplest case, and it corresponds to crisp in-distinction: O treats two items as the same iff they fall in the same block. Later we generalize* *this to graded and even asymmetric indistinction (via indistinction graphs), which is closer to how cognition behaves in practice (cf. the pattern-based picture in [5]). In the Hyperseed vocabulary this is an instance of treating* distinctions *as primary structure (Hyperseed-Concept 98). It is useful to note that "finer" and "coarser" observers can be compared directly at the level of σ-algebras: if $\Sigma_{O_1} \subseteq \Sigma_{O_2}$, then O_2 can express every question O_1 can (and possibly more), so O_2 is informationally at least as fine as O_1. This inclusion relation is a precise, order-theoretic version of "one observer refines another," and it will later support principled ways to relate models across levels (e.g. restricting a finer model to a coarser question-set, or lifting a coarse belief to a family of compatible fine beliefs).*

Definition 119 (Paraconsistent evidence annotations)**.** *To connect to the paraconsistent core (Section 3), we may annotate events with a* p-bit evidence value

$$E_O(A) = (E_O^+(A), E_O^-(A)) \in [0,1]^2 \qquad (A \in \Sigma_O),$$

where $E_O^+(A)$ is degree of positive evidence and $E_O^-(A)$ is degree of negative evidence. No consistency constraint is imposed: it is allowed that $E_O^+(A) + E_O^-(A) > 1$. In particular, E_O is not assumed to be a probability measure, nor is it assumed that $E_O^-(A)$ equals $E_O^+(A^c)$; the point is to retain two channels of support that need not be reducible to a single additive calculus.

Remark 438. ***Intuition.*** *Ordinary probability tries to compress all epistemic nuance into one scalar $P_O(A)$. Paraconsistent annotation instead records two partially independent intensities: reasons* for *A and reasons* against *A. Allowing $E_O^+(A)+E_O^-(A) > 1$ is not a bug but a formal admission that real epistemic agents can be pulled strongly in incompatible directions at once (e.g. contradictory testimonies, model mismatch, sensor conflict). This connects directly to paraconsistent logics such as Constructible Duality Logic [23] and to resonance-style dynamics studied in [24]. One can read $E_O^{\pm}$ operationally as aggregating heterogeneous sources that are not forced to "cancel" into a net score; the annotation thereby separates* amount of support *from* degree of resolution*, and it allows an agent to represent "I have strong reasons on both sides" without collapsing that state into a near-*1/2 *probability. At a technical level, this is a way of preserving informational structure that would otherwise be lost under a single-number summary.*

Examples. *If $E_O(A) = (0.9, 0.1)$ the observer has strong support for A with little counterpressure. If $E_O(A) = (0.9, 0.9)$ the observer has a deep conflict: A is simultaneously strongly supported and strongly opposed, reflecting a state closer to dissonance than ignorance. If $E_O(A) = (0.1, 0.1)$, by contrast, the agent has little evidence either way; this can be interpreted as genuine informational poverty rather than a balanced clash of considerations.*

Usefulness. *This annotation is not meant to replace probability, but to complement it when the observer's representational regime allows mutually incompatible local inferences. Later, when habit dynamics and resonance/dissonance are modeled as update rules on graded supports (Section 12), the possibility of conflict becomes structurally central. In particular, keeping P_O alongside E_O allows one to distinguish (i) the agent's betting-odds or action-guiding summary from (ii) the internal tension profile that may drive future reorganization of distinctions, attention, or model class.*

Remark 439 (Two kinds of "uncertainty")**.** *The pair (P_O, E_O) supports two distinct phenomena:*

- Ignorance*: probabilities near $1/2$ and/or low total evidence.*
- Conflict*: simultaneous strong positive and strong negative evidence.*

In Hyperseed terms, ignorance is "not enough distinction-making power or data," whereas conflict is "incompatible distinction-making pressures that are both locally supported." Later (Section 12) we will connect conflict to resonance/dissonance dynamics. It is often useful to treat these as empirically and behaviorally different regimes: ignorance tends to invite exploration or refinement of sensing (seek more data or sharper distinctions), whereas conflict tends to invite adjudication (seek error sources, reconcile models, or split contexts so that incompatible pressures are not forced into the same representational frame).

Remark 440. *When comparing observers O_1 and O_2, two further distinctions are helpful. First, if $\Sigma_{O_1} \subseteq \Sigma_{O_2}$ and P_{O_2} is given, then P_{O_2} restricts to a probability measure on Σ_{O_1}; this corresponds to "forgetting" distinctions while keeping coherent odds on the coarser questions. Second, even when $\Sigma_{O_1} = \Sigma_{O_2}$, different P_O (or different E_O) can represent differences in priors, training histories, or sensor reliabilities: the observer-indexing is therefore not only about* what can be asked, *but also about* how uncertainty is distributed *over what can be asked. These two axes (expressivity via Σ_O and credence via P_O and E_O) will matter later when we separate changes in "world-model resolution" from changes in "belief within a fixed resolution."*

10.3 Shannon information, coding, and divergence

Assume X is finite and $\Sigma_O = 2^X$ (or that we have reduced to the finite set of blocks of a partition). Write $p_O(x) := P_O(\{x\})$.

Remark 441. ***Notation/conventions.*** *Because X is finite, a probability measure P_O is equivalent to its point-mass function $p_O : X \to [0, 1]$ with $\sum_{x \in X} p_O(x) = 1$. The expression $p_O(x) := P_O(\{x\})$ is this identification. When we write $H(X)$ later, we mean the Shannon entropy of the distribution of the random variable X, i.e. the entropy of $p(x)$ on its finite support.*

Definition 120 (Entropy and surprise)**.** *The* surprisal *of an outcome x is*

$$s_O(x) := -\log p_O(x),$$

where log *denotes the natural logarithm. The* Shannon entropy *of P_O (in nats) is*

$$H(P_O) := \sum_{x \in X} p_O(x)\, s_O(x) \;=\; -\sum_{x \in X} p_O(x) \log p_O(x).$$

Define also the entropy in bits as

$$H_{\text{bits}}(P_O) := \frac{H(P_O)}{\log 2}.$$

Remark 442. ***Intuition.*** *Surprisal $s_O(x)$ is high when x was deemed unlikely by O; entropy $H(P_O)$ is the average surprisal under the observer's own expectations. One may read this as the expected amount of* conceptual work *needed to accommodate an observation, provided that "work" is measured in logarithmic units.*

Examples. *If p_O is uniform on $|X| = N$, then $H(P_O) = \log N$ (maximal uncertainty). If p_O concentrates on one point, entropy is 0 (no uncertainty). A biased coin with $p(heads) = 0.9$ has lower entropy than a fair coin, because the observer is rarely surprised.*

Usefulness in this document. *Entropy is a bridge from belief to description length: if an observer believes outcomes are distributed according to p, then optimal codes have expected length about $H_{\text{bits}}(p)$. This will later be tied to effort-based simplicity (Section 8) and pattern intensity (Section 9), and it parallels the algorithmic viewpoint on description length emphasized in [16].*

Definition 121 (Cross-entropy and KL divergence)**.** *Given two distributions p and q on X with $q(x) > 0$ whenever $p(x) > 0$, the* cross-entropy *and* Kullback–Leibler divergence *are*

$$H(p,q) := -\sum_{x\in X} p(x)\log q(x), \qquad D_{\mathrm{KL}}(p\|q) := \sum_{x\in X} p(x)\log\frac{p(x)}{q(x)}.$$

Remark 443. ***Notation/conventions.*** *The condition $q(x) > 0$ whenever $p(x) > 0$ ensures $\log\frac{p(x)}{q(x)}$ is well-defined wherever it is weighted by $p(x)$. $D_{\mathrm{KL}}(p\|q)$ is not symmetric in (p,q) and is not a metric; it is an information-theoretic divergence.*

Intuition. *Cross-entropy $H(p,q)$ is the expected code length (in nats) if the world is distributed as p but you encode using a code optimized for q. KL divergence is the penalty for that mismatch: $D_{\mathrm{KL}}(p\|q) = H(p,q) - H(p)$.*

Usefulness. *Later, when we define fidelity and effability, we effectively compare a target item x with a reconstructed distribution $q = \mathrm{dec}_O(d)$. KL divergence is a canonical way to measure such mismatches; we do not enforce it as the unique notion of error here, but the reader should recognize it as a standard candidate.*

Proposition 11 (Entropy as optimal expected code length)**.** *Let p be a distribution on a finite alphabet X. Among all prefix-free binary codes with codeword lengths $\ell(x) \in \mathbb{N}$, the optimal expected length*

$$L^*(p) := \inf_{\ell} \sum_{x\in X} p(x)\,\ell(x)$$

obeys

$$H_{\mathrm{bits}}(p) \le L^*(p) < H_{\mathrm{bits}}(p) + 1.$$

Remark 444. ***What the proposition says (plainly).*** *If an observer believes outcomes follow p, then there exists an essentially optimal way to encode outcomes in binary so that the* average *number of bits used is about the entropy of p. One cannot beat $H_{\mathrm{bits}}(p)$ on average (lower bound), but one can get within 1 bit of it with an explicit construction (upper bound).*

Why it matters. *This is the classical theorem that makes entropy operational: it is not merely a numerical ornament on a probability distribution; it is the best achievable average compression rate under an ideal coding scheme. In the Hyperseed framing, this is one key bridge from* belief *to* effort*: shorter codes mean less representational work, and longer codes mean more (cf. the effort/simplicity lens in Section 8 and the coding/description lens in [16]).*

Connection to later sections. *Patterns (Section 9) are defined by compressive re-description; the inequality above is one of the classical reasons compression and probability models are inseparable. When we later speak of observer-relative "simplicity" or "weakness" as an optimization principle, this proposition is a basic exemplar of how such minima arise.*

Proof. (Lower bound.) For any prefix-free code, Kraft's inequality gives $\sum_x 2^{-\ell(x)} \le 1$. Let $K := \sum_x 2^{-\ell(x)}$ and define $q(x) := 2^{-\ell(x)}/K$. Then q is a probability distribution, and

$$0 \le D_{\mathrm{KL}}(p\|q) = \sum_x p(x)\log\frac{p(x)}{q(x)}.$$

Rearranging yields

$$-\sum_x p(x)\log p(x) \le -\sum_x p(x)\log q(x) = \log K + (\log 2)\sum_x p(x)\ell(x).$$

Since $K \leq 1$ we have $\log K \leq 0$, hence $H(p) \leq (\log 2) \sum_x p(x)\ell(x)$. Dividing by $\log 2$ gives $H_{\text{bits}}(p) \leq \sum_x p(x)\ell(x)$. Taking an infimum over codes proves the lower bound.

(Upper bound.) Define candidate lengths by

$$\ell(x) := \lceil -\log_2 p(x) \rceil \in \mathbb{N}.$$

Then $2^{-\ell(x)} \leq 2^{\log_2 p(x)} = p(x)$, hence $\sum_x 2^{-\ell(x)} \leq \sum_x p(x) = 1$. By Kraft's inequality, there exists a prefix-free binary code whose codeword lengths are exactly these $\ell(x)$ (for instance, via a Shannon–Fano construction, or by building a binary tree whose leaf depths match ℓ).

For this code,

$$\sum_x p(x)\ell(x) \;\leq\; \sum_x p(x)\bigl(-\log_2 p(x) + 1\bigr) \;=\; H_{\text{bits}}(p) + 1.$$

Taking an infimum over all codes yields $L^*(p) \leq H_{\text{bits}}(p) + 1$, and since the bound is strict at the level of $L^*(p)$ (because an integer-length constraint cannot in general achieve the real-valued optimum exactly), we obtain $L^*(p) < H_{\text{bits}}(p) + 1$ as stated. ☐

Remark 445. ***On the*** $+1$ ***slack.*** *The additive* 1 *bit arises from the integrality of* $\ell(x)$ *and the ceiling operation. If one allows idealized non-integer code lengths (or, operationally, block coding over long sequences and arithmetic coding), the achievable average length can be made arbitrarily close to* $H_{\text{bits}}(p)$*. Equivalently: the entropy is the fundamental rate, while the* $+1$ *term is a single-symbol overhead due to discretizing lengths.*

KL divergence as a coding penalty. *The proof of the lower bound already contains a more general statement: if a prefix-free code induces an implicit distribution* $q(x) \propto 2^{-\ell(x)}$*, then the expected length satisfies*

$$\sum_x p(x)\ell(x) \;=\; H_{\text{bits}}(p) + \frac{1}{\log 2} D_{\text{KL}}(p\|q) - \frac{1}{\log 2} \log K,$$

with $K = \sum_x 2^{-\ell(x)} \leq 1$*. Thus, mismatch between the "true"* p *and the code-implied* q *shows up as a nonnegative penalty term (the KL divergence), mirroring the earlier identity* $H(p,q) = H(p) + D_{\text{KL}}(p\|q)$ *in coding form.*

Observer-relativity. *In the present document, it is often* p_O *(the observer's model) rather than an objective distribution that matters. The same theorem applies with* p *replaced by* p_O*: if the observer's beliefs are wrong, the code that is optimal under* p_O *need not be optimal under the world's distribution, but it is still optimal relative to the observer's own representational commitments.*

Remark 446 (Why this matters for Hyperseed)**.** *In Hyperseed, "simplicity" is grounded in representational effort. The proposition formalizes one standard bridge: a probability model induces an optimal expected description length. Later sections connect description length to weakness and to pattern intensity.*

Additional detail on the "one checks" step. The feasibility claim for $\ell(x) = \lceil -\log_2 p(x) \rceil$ is the concrete place where discretization (integer lengths) meets the continuous ideal $-\log_2 p(x)$. Since $\ell(x) \geq -\log_2 p(x)$, we have

$$2^{-\ell(x)} \leq 2^{-(-\log_2 p(x))} = p(x),$$

and therefore $\sum_x 2^{-\ell(x)} \leq \sum_x p(x) = 1$. This is exactly Kraft's inequality for a binary prefix code, so the length assignment is not merely formal: it is realizable by an actual prefix-free set of codewords (equivalently, by a pruned binary tree whose leaves occur at depths $\ell(x)$).

Where the strict inequality comes from. For any real number r, the ceiling satisfies $\lceil r \rceil < r+1$. Applying this pointwise to $r = -\log_2 p(x)$ gives $\ell(x) < -\log_2 p(x) + 1$, hence

$$\sum_x p(x)\ell(x) < \sum_x p(x)\big(-\log_2 p(x) + 1\big) = \sum_x p(x)\big(-\log_2 p(x)\big) + \sum_x p(x) = H_{\text{bits}}(p) + 1,$$

making explicit that the sole source of slack is integer rounding. In particular, when all probabilities are dyadic (i.e. $p(x) = 2^{-k_x}$ for integers k_x), the ideal lengths are already integers and the rounding loss vanishes, so the upper bound can meet $H_{\text{bits}}(p)$ exactly.

More explicit link between coding and D_{KL}. Given any prefix lengths $\ell(x)$ satisfying Kraft, the unnormalized weights $2^{-\ell(x)}$ form a sub-probability mass function; normalizing by $Z := \sum_x 2^{-\ell(x)} \leq 1$ yields

$$q(x) = \frac{2^{-\ell(x)}}{Z}.$$

Then $\ell(x) = -\log_2 q(x) - \log_2 Z$, so taking expectation under p gives

$$\mathbb{E}_p[\ell(X)] = \mathbb{E}_p[-\log_2 q(X)] - \log_2 Z.$$

Because $Z \leq 1$, we have $-\log_2 Z \geq 0$, so $\mathbb{E}_p[\ell(X)] \geq \mathbb{E}_p[-\log_2 q(X)]$. Finally,

$$\mathbb{E}_p[-\log_2 q(X)] - H_{\text{bits}}(p) = \sum_x p(x) \log_2 \frac{p(x)}{q(x)} = D_{\text{KL}}(p\|q) \quad \text{(in bits)},$$

so $D_{\text{KL}}(p\|q) \geq 0$ implies $\mathbb{E}_p[\ell(X)] \geq H_{\text{bits}}(p)$. This makes concrete the interpretation that a code induces a model q, and the penalty for using the "wrong" model is precisely a KL divergence term.

Units and interpretation. The notation $H_{\text{bits}}(p)$ emphasizes that the logarithm base is 2, so entropy is measured in bits and code lengths are measured in binary digits. If one instead uses natural logarithms, the same statements hold with lengths measured in nats and with the conversion factor $\log_2 t = (\log t)/(\log 2)$ accounting for the change of units.

Tightness and algorithmic realizations. The $+1$ in the upper bound is a worst-case guarantee for single-symbol (one-shot) coding with integer lengths. In practice, Huffman coding achieves an expected length within 1 bit of the entropy and is optimal among prefix codes for a fixed alphabet. Moreover, by coding blocks of n symbols from the product distribution $p^{\otimes n}$, the per-symbol overhead can be driven to 0 as $n \to \infty$, reflecting that the discreteness penalty is not fundamental but a finite-length artifact.

Further connection to the Hyperseed framing. In settings where a system maintains an internal predictive distribution q while the world follows p, the expected description length under q decomposes into $H_{\text{bits}}(p)$ plus a mismatch cost $D_{\text{KL}}(p\|q)$. Thus, "simplicity" (short expected code length) can be read simultaneously as (i) compressibility of observations under the true law and (ii) adequacy of the internal model. This dual view is often useful when later notions (e.g. weakness, pattern intensity) depend not only on how much structure is present in p but also on how well an agent-like representation aligns with it.

10.4 Mutual and interaction information

Let (X, Y) be a pair of random variables on finite sets with joint distribution $p(x, y)$. In this finite setting all entropies and divergences below are well-defined (possibly taking value $+\infty$ only if one allows zero-probability events in ways that make the KL divergence diverge), and $I(X;Y)$ can be read as an *average* quantity over outcomes rather than a pointwise guarantee about any particular sample.

Definition 122 (Mutual information)**.** *The* mutual information *between X and Y is*

$$I(X;Y) := H(X) + H(Y) - H(X,Y).$$

Equivalently, $I(X;Y) = D_{\mathrm{KL}}(p(x,y)\|p(x)p(y))$. In particular, $I(X;Y) \geq 0$, with equality if and only if $p(x,y) = p(x)p(y)$ (independence).

Remark 447. ***Intuition.*** *Mutual information measures how much knowing X reduces uncertainty about Y (and symmetrically, knowing Y reduces uncertainty about X). The KL expression says: it is the divergence between the true joint distribution and the distribution you would get if you falsely assumed X and Y were independent. Equivalently, it is the expected log-likelihood ratio*

$$I(X;Y) = \mathbb{E}_{(X,Y)\sim p}\left[\log \frac{p(X,Y)}{p(X)p(Y)}\right],$$

so it quantifies the average extent to which joint observations look "surprising" relative to an independence model. A useful identity that often clarifies the "uncertainty reduction" reading is

$$I(X;Y) = H(Y) - H(Y \mid X) = H(X) - H(X \mid Y),$$

so it is literally the drop in entropy of one variable after conditioning on the other. From this, one sees immediately the bounds $0 \leq I(X;Y) \leq \min\{H(X), H(Y)\}$: no channel can convey more information about Y than the total uncertainty that was present in Y to begin with.

Example. *If $Y = X$ (perfect copying), mutual information equals $H(X)$: observing Y tells you everything about X. If X and Y are independent, then $I(X;Y) = 0$. More generally, if Y is a noisy copy of X through some stochastic channel, then $I(X;Y)$ decreases as noise increases; in this sense it is a quantitative measure of "fidelity" that is independent of any particular decoding rule.*

Usefulness. *In a Hyperseed setting, $I(X;Y)$ is a clean numerical proxy for "how many distinctions about Y are made available by access to X," i.e. how one representational channel supports another. This will reappear when discussing pattern webs and dependency-like relations between representational units (Sections 11 and 12). A further practical reason it is favored is its invariance under bijective reparameterizations of X or Y: relabeling symbols does not change $I(X;Y)$, so it depends on the structure of dependence rather than the names of states.*

Chain rules and conditioning. *For later use it is convenient to recall the chain rule*

$$I(X;Y,Z) = I(X;Y) + I(X;Z \mid Y),$$

which formalizes the idea that information provided by a compound representation (Y,Z) decomposes into the part already provided by Y plus the additional part provided by Z once Y is known. Here $I(X;Z \mid Y)$ is the conditional mutual information*, defined by*

$$I(X;Z \mid Y) = H(X \mid Y) - H(X \mid Y,Z) = H(Z \mid Y) - H(Z \mid X,Y),$$

and it is always nonnegative as well.

Definition 123 (Interaction information)**.** *For three random variables (X,Y,Z), the* interaction information *is*

$$I(X;Y;Z) := I(X;Y) - I(X;Y \mid Z).$$

This quantity may be positive or negative, reflecting synergy or redundancy. It can also be written symmetrically in entropies as

$$I(X;Y;Z) = H(X) + H(Y) + H(Z) - H(X,Y) - H(X,Z) - H(Y,Z) + H(X,Y,Z),$$

so it is invariant under permutation of X, Y, Z despite being defined using $I(X;Y \mid Z)$.

Remark 448. ***Intuition.*** *Interaction information asks whether the relationship between X and Y becomes* more *or* less *informative once Z is known. If Z explains away the dependence between X and Y, the quantity tends to be negative (redundancy). If Z unlocks a dependence that is not visible marginally, it may be positive (synergy). One way to read the sign is:*

$$I(X;Y;Z) > 0 \iff I(X;Y \mid Z) < I(X;Y),$$

so conditioning on Z reduces the apparent X–Y association (suggesting that what X and Y "share" is, in part, already present in Z), whereas

$$I(X;Y;Z) < 0 \iff I(X;Y \mid Z) > I(X;Y),$$

so learning Z reveals dependence between X and Y that was not apparent marginally. The possibility of negative values is not a paradox: it does not *contradict nonnegativity of mutual information, because interaction information is a* difference *of two nonnegative quantities.*

Example. *In the classical XOR example, X and Y are independent fair bits and $Z = X \oplus Y$. Then $I(X;Y) = 0$ but conditioning on Z makes X and Y perfectly dependent, leading to a positive interaction information: information is present only in the* triad. *Conversely, if Z is a common cause that copies into both X and Y (e.g. $X = Z$ and $Y = Z$), then $I(X;Y)$ is large but $I(X;Y \mid Z) = 0$, yielding negative interaction information: the apparent X–Y dependence is explained by the shared variable. These two extremes motivate the informal language of "synergy" versus "redundancy," while also hinting that any single scalar can only be a coarse summary of multi-way dependence.*

Usefulness. *Hyperseed frequently emphasizes that cognition is not purely additive: wholes can carry relations not present in parts. Interaction information is one standard quantitative hint of such non-additivity, and it resonates with emergence-style notions introduced later in the pattern section (Section 9). It is also a warning label against naive "Venn diagram" interpretations of information: although the symmetric entropy formula resembles inclusion–exclusion, the sign changes show that multivariate dependence does not behave like ordinary set overlap.*

Remark 449 (Observer-relative "second law" reading)**.** *Entropy-like quantities depend on which variables are being tracked. If O changes its representational partition (coarse-grains or refines), then the induced random variables change and so do H and I. Thus, statements that resemble a "second law" (monotone entropy increase under typical dynamics) should always be read as:* for the chosen coarse variables, under the chosen effective dynamics, typical trajectories move toward larger macro-uncertainty. *This matches Hyperseed's perspectivism: "the same world" can have different entropic arrows at different resolutions. A concrete way to see this is that coarse-graining typically reduces the maximum achievable mutual information between a microscopic state and a macro-description: when distinctions are merged, there is (by design) less that can be learned from the coarse variable about fine structure. Dually, refining a partition can create apparent information flows that were previously invisible, simply because the representational vocabulary has changed.*

Remark 450. *This remark is a formal caution against turning a contextual regularity into a metaphysical absolute. The second law (Hyperseed-Concept 164) is robust in physics, but its informational analogs are always indexed by (i) what we count as a macrostate and (ii) what we treat as the effective dynamics. Hyperseed's insistence on observer-indexing is, in this sense, a reminder that entropy is a measure of* description *as much as a measure of* disorder*. In particular, when one says "entropy increases," what is usually meant is that the distribution over the tracked variables spreads out under the chosen dynamics and constraints; but changing the tracked variables* *changes the sample space, the constraint set, and the induced notion of "spread." The same underlying micro-dynamics can therefore support multiple, seemingly competing, informational narratives depending on which distinctions are treated as salient.*

10.5 Logical entropy and graphtropy from distinction structure

Logical entropy (also called "Gini impurity" in some applied contexts) measures the probability that two independent draws fall into different "distinction classes." In Hyperseed terms, it measures the fraction of distinctions that are actually made.

Definition 124 (Logical entropy of a partition)**.** *Let $\pi = \{B_1, \ldots, B_k\}$ be a partition of X. Given a distribution p on X, define the block masses*

$$p_i := \sum_{x \in B_i} p(x).$$

The logical entropy *of (π, p) is*

$$h(\pi, p) := 1 - \sum_{i=1}^{k} p_i^2.$$

Remark 451. ***Intuition.*** *Where Shannon entropy measures expected code length under optimal compression, logical entropy measures expected* distinguishability *under the partition π. It does not ask: "How many bits to encode?" but rather: "How often do two random observations fall into different blocks?" This makes it an especially direct companion to Hyperseed's primitive of distinction (Hyperseed-Concept 98) and aligns with Ellerman's development of logical entropy [17].*

Example. *If π is the discrete partition into singletons, then $p_i = p(x)$ and $h(\pi, p) = 1 - \sum_x p(x)^2$. If π is the trivial one-block partition, then $h(\pi, p) = 0$ (no distinctions are made).*

Why useful. *Logical entropy is quadratic in p, hence behaves differently from Shannon entropy under fine-graining; in many cognitive settings, quadratic forms correspond naturally to "pairwise comparison" processes (e.g. sampling two items and checking whether they are treated as the same). Graphtropy will generalize this beyond partitions, preserving this pairwise-comparison intuition.*

Remark 452. *The quantity $\sum_i p_i^2$ is the probability that two iid draws fall in the* same *block. Hence $h(\pi, p)$ is the probability that two iid draws fall in* different *blocks, i.e. that the partition makes a distinction between them.*

Definition 125 (Distinction graphs and graphtropy)**.** *Let G be a (possibly directed) graph on vertex set X. We interpret an edge $x \to y$ as "O does* not *distinguish x from y" (an* indistinction*). Let $\iota_G(x, y) \in [0, 1]$ be a weight encoding degree of indistinction, with $\iota_G(x, y) = 1$ meaning "fully indistinct" and $\iota_G(x, y) = 0$ meaning "fully distinct." Given a probability distribution p on X, define the* graphtropy *as*

$$\mathrm{GT}(G, p) := 1 - \sum_{x \in X} \sum_{y \in X} p(x)p(y)\, \iota_G(x, y).$$

Remark 453. ***Notation/conventions.*** *$\iota_G : X \times X \to [0, 1]$ is an* indistinction weight *rather than an adjacency matrix in the usual graph-theoretic sense. The double sum $\sum_x \sum_y p(x)p(y)\, \iota_G(x, y)$ is an expectation over two independent draws $X_1, X_2 \sim p$ of the indistinction degree $\iota_G(X_1, X_2)$.*

Intuition. *Graphtropy asks: if I sample two items according to p, how indistinguishable are they on average? Then it flips the answer by taking $1-$, so that higher graphtropy means "more* *expected distinction". This makes graphtropy a direct numerical shadow of an observer's distinction structure, even when that structure is graded, context-dependent, and not transitive.*

Examples. *If* $\iota_G(x,y) = \mathbf{1}[x = y]$ *(only identical items are treated as indistinct), then* $\mathrm{GT}(G,p) = 1 - \sum_x p(x)^2$. *If* $\iota_G(x,y) = 1$ *for all pairs (everything indistinct), then* $\mathrm{GT}(G,p) = 0$.

Why useful. *Partitions (equivalence relations) are often too rigid for cognitive modeling. A mind can treat* x *as indistinct from* y *in one direction but not the other (asymmetry), and can treat* $x \approx y$ *and* $y \approx z$ *without treating* $x \approx z$ *(non-transitivity). Graphtropy keeps the core idea—distinction measured by pairwise sampling—without demanding equivalence-relation structure (Hyperseed-Concept* **??***).*

Remark 454 (Fuzzy and asymmetric cases)**.** *If* ι_G *is crisp and symmetric and transitive (an equivalence relation), then* G *encodes a partition and graphtropy reduces to logical entropy. If* ι_G *is fuzzy and/or asymmetric, then graphtropy measures "expected distinguishability" without requiring a partition. This extra generality is important for modeling minds, which often treat "x indistinguishable from y" as context-sensitive, graded, and non-transitive.*

Proposition 12 (Reduction to logical entropy)**.** *Let* π *be a partition of* X*, and define* $\iota_\pi(x,y) = 1$ *iff* x *and* y *lie in the same block, and* 0 *otherwise. Let* G_π *be the induced indistinction graph. Then*

$$\mathrm{GT}(G_\pi, p) = h(\pi, p).$$

Remark 455. ***What the proposition says.*** *Graphtropy is not a competing definition but a strict generalization: in the special case where indistinction really is a partition (crisp equivalence classes), graphtropy collapses exactly to logical entropy.*

Why it matters. *This justifies graphtropy as a conservative extension. We gain the ability to represent graded/non-transitive indistinction without losing compatibility with classical partition-based measures such as logical entropy [17].*

Connection to the rest of the document. *Earlier we treated distinctions as policies (Section 8); graphtropy is a canonical way to turn such a policy into a scalar measure of how "finely" the observer is carving* X *under a distribution* p*. This scalar will later be useful when comparing distinction regimes in the definition of effability and in discussions of resolution changes.*

Proof. Two iid draws (X_1, X_2) from p fall in the same block with probability $\sum_i p_i^2$, which equals $\sum_{x,y} p(x)p(y)\,\iota_\pi(x,y)$. Here $\iota_\pi(x,y)$ is the (0–1) indistinction indicator for the partition π, so the right-hand side is simply the probability (under independent sampling) of the event "X_1 and X_2 land in the same block": independence gives $\Pr[X_1 = x, X_2 = y] = p(x)p(y)$, and the indicator $\iota_\pi(x,y)$ selects exactly those pairs (x,y) that are in a common block. Equivalently, one may write

$$\sum_{x,y} p(x)p(y)\,\iota_\pi(x,y) = \sum_i \sum_{x\in B_i} \sum_{y\in B_i} p(x)p(y) = \sum_i \Big(\sum_{x\in B_i} p(x)\Big)\Big(\sum_{y\in B_i} p(y)\Big) = \sum_i p_i^2,$$

which makes explicit how the pairwise sum "collapses" onto block masses. Taking $1-$ of both sides yields the claim. ☐

Remark 456. ***Proof sketch.*** *Compute the same probability in two ways: (i) by summing block masses squared, and (ii) by summing over pairs* (x,y) *with an indicator that they lie in the same block. Since graphtropy is defined as* $1-$ *that pairwise indistinction probability, it matches logical entropy.*

Key step. *The identity* $\sum_{x,y} p(x)p(y)\,\iota_\pi(x,y) = \sum_i p_i^2$ *is simply the law of total probability applied to blocks: it groups the pairwise sum by which block both elements fall into. Another way* *to say this is that the indicator ι_π is block-constant in the sense that it is* 1 *exactly on the union of the Cartesian products $B_i \times B_i$, and* 0 *off that union; summing against $p(x)p(y)$ therefore sums the total $p \otimes p$-mass of those diagonal block rectangles.*

Visual intuition. *Imagine drawing two balls from an urn labeled by blocks. The chance that both draws land in the same block is the sum over blocks of (chance of landing in that block)^2. If one instead thinks in terms of ordered pairs, the same probability is obtained by summing the probability of each ordered pair (x, y) and then discarding (via ι_π) all pairs that straddle two different blocks; graphtropy/logical entropy is precisely the complement of this "pair-collision" event.*

Proposition 13 (Monotonicity under loss of distinction)**.** *Let G and G' be two indistinction graphs on X with weights satisfying $\iota_G(x, y) \le \iota_{G'}(x, y)$ for all x, y. Then for every distribution p,*

$$\mathrm{GT}(G, p) \ge \mathrm{GT}(G', p).$$

In particular, adding more indistinction edges (or strengthening indistinction weights) cannot increase graphtropy.

Remark 457. ***What the proposition says.*** *If an observer becomes* less discriminating *(treats more pairs as indistinct, or treats them as more strongly indistinct), then the expected distinguishability cannot go up.*

Why it matters. *This is the formal monotonicity property one expects from any sensible "distinction content" measure. It lets us reason order-theoretically about resolution changes: coarsening is an order move, and graphtropy moves monotonically with it. This will be echoed later when effability is shown to be monotone in the indistinction regime. Concretely, if G' is obtained from G by declaring additional pairs (x, y) to be indistinct (changing $\iota_G(x, y)$ from* 0 *toward* 1*) or by increasing their indistinction weight in a fuzzy model, then G' represents a genuine loss of discriminative power, and* GT *registers that loss by decreasing (or staying equal) for every p.*

Connection. *Notice the parallel between this proposition and Proposition 14 below: both say that making fewer demands on distinctions expands what is achievable/expressible. In both cases, the underlying mechanism is order preservation: increasing indistinction enlarges the set of "identified" pairs, which increases the expected indistinction and thereby reduces the complement quantity (graphtropy) that counts distinctions.*

Proof. Immediate from the definition of $\mathrm{GT}(G, p)$ as $1-$ a weighted average of ι_G. More explicitly, if $\mathrm{GT}(G, p) = 1 - \sum_{x,y} p(x)p(y)\iota_G(x, y)$ (or the corresponding normalized variant used in the surrounding text), then pointwise $\iota_G \le \iota_{G'}$ implies

$$\sum_{x,y} p(x)p(y)\iota_G(x, y) \;\le\; \sum_{x,y} p(x)p(y)\iota_{G'}(x, y),$$

and subtracting from 1 reverses nothing (it is an order-preserving affine transformation), yielding $\mathrm{GT}(G, p) \ge \mathrm{GT}(G', p)$. □

Remark 458. ***Proof sketch.*** *The quantity subtracted from* 1 *is an expectation of $\iota_G(X_1, X_2)$ under independent sampling from p. If $\iota_G \le \iota_{G'}$ pointwise, then the expectation under G is no larger than under G', hence $1-$ that expectation is no smaller. Said differently,* $\mathrm{GT}(G, p)$ *is the expectation of the complementary "distinction indicator" $1 - \iota_G(X_1, X_2)$, and if ι_G increases pointwise then $1 - \iota_G$ decreases pointwise, so its expectation cannot increase.*

Geometric intuition. *Think of ι_G as a "blur kernel" over $X \times X$. Increasing blur reduces contrast; graphtropy measures contrast, so it decreases. In the crisp (0–1) case, adding indistinction* *edges literally increases the region in $X \times X$ on which the kernel equals 1, so the $p \otimes p$-mass of indistinct pairs grows and the complementary mass of distinct pairs shrinks.*

Theorem 10 (Shannon entropy lower-bounds quadratic/logical distinguishability)**.** *Let p be a distribution on a finite set X and define*

$$S_2(p) := \sum_{x \in X} p(x)^2, \qquad H_2(p) := -\log S_2(p).$$

Then

$$H(p) \geq H_2(p) = -\log S_2(p).$$

If π is a partition of X and p_i are the block masses, then

$$H(\pi) := -\sum_i p_i \log p_i \geq -\log \sum_i p_i^2 = -\log(1 - h(\pi, p)).$$

Remark 459. ***What the theorem says (plainly).*** *Shannon entropy is always at least the order-2 Rényi entropy H_2 (sometimes called "collision entropy" because it depends on $\sum p(x)^2$, the collision probability). So if an observer's belief distribution is highly uncertain in the Shannon (coding) sense, then it is also uncertain in this quadratic (pairwise-collision) sense.*

Why this is important here. *Logical entropy and graphtropy are built from quadratic pairwise expressions. This theorem links the coding-theoretic world (Shannon) to the distinction/pairwise world (logical entropy/graphtropy). It is, in effect, a compatibility guarantee: the different notions of "uncertainty" discussed in this section are not unrelated numbers but are constrained by inequalities. In particular, whenever one uses $S_2(p)$ (or its complement $1 - S_2(p)$) as a proxy for uncertainty/heterogeneity, the theorem bounds how far that proxy can drift from Shannon's coding interpretation.*

Connection to earlier/later material. *Earlier we motivated information as observer-indexed; this theorem remains valid under that indexing, because it is a statement about any finite distribution p_O the observer might hold. Later, in pattern and habit sections, we will move between coding-like and distinction-like quantities; having such monotone bridges makes those translations principled rather than merely metaphorical. One can also view this as a special case of a more general monotonicity phenomenon for Rényi entropies: as the order α increases, H_α decreases, so $H = H_1$ sits above H_2; the present proof gives a direct inequality tailored to the quadratic quantity that appears in graphtropy.*

Proof. Define $r(x) := p(x)^2/S_2(p)$, which is a probability distribution on X. Nonnegativity of KL divergence gives

$$0 \leq D_{\mathrm{KL}}(p\|r) = \sum_x p(x) \log \frac{p(x)}{r(x)}.$$

Substituting $r(x) = p(x)^2/S_2(p)$ yields

$$D_{\mathrm{KL}}(p\|r) = \sum_x p(x) \log \frac{p(x)}{p(x)^2/S_2(p)} = \sum_x p(x) \log \frac{S_2(p)}{p(x)}.$$

Hence

$$0 \leq \log S_2(p) - \sum_x p(x) \log p(x) = \log S_2(p) + H(p),$$

which rearranges to $H(p) \geq -\log S_2(p) = H_2(p)$. The partition statement follows by applying the same argument to the block distribution (p_i). Note that no special cases are needed for $p(x) = 0$ (or $p_i = 0$): the conventional interpretation $0 \log 0 := 0$ makes all displayed sums well-defined, and KL divergence remains nonnegative as long as $r(x) > 0$ whenever $p(x) > 0$, which holds here because $r(x) \propto p(x)^2$. $\square$

Remark 460. ***Proof sketch.*** *Construct an auxiliary distribution r proportional to p^2, then apply the universal inequality $D_{\mathrm{KL}}(p\|r) \geq 0$ to derive an inequality between $\sum p \log p$ and $\log \sum p^2$.*

Key step. *The choice $r(x) \propto p(x)^2$ is not arbitrary: it is exactly the distribution that turns $\log S_2(p)$ into a normalization constant inside the KL divergence. Once that substitution is made, the inequality becomes algebraic. One can also read the algebra as comparing the average of $-\log p(x)$ under p (which is $H(p)$) to the log of an L^2-type quantity $S_2(p)$; the KL step is what guarantees the comparison has the correct direction for all p (not just for nearly uniform distributions).*

Visual intuition. *Shannon entropy is sensitive to the entire distribution shape, while $S_2(p)$ is dominated by larger probabilities (since it squares them). The inequality $H \geq H_2$ expresses that if a distribution is "peaky," its S_2 becomes large (so H_2 becomes small), and Shannon entropy cannot be larger than that quadratic constraint allows. In the common "collision" interpretation, $S_2(p) = \sum_x p(x)^2$ is the probability that two independent draws from p coincide; thus $H_2 = -\log S_2$ measures how difficult it is (in bits) to force a collision. Under this reading, $H \geq H_2$ says that the coding-theoretic uncertainty H cannot undercut the collision-based notion of spread captured by H_2, and it becomes tight (up to support effects) when the distribution is close to uniform over its effective support.*

Remark 461 (Hyperseed reading)**.** *The theorem says: if an observer's distribution is spread out enough to have large Shannon entropy, then it must also have a large "quadratic spread," hence a large logical entropy/graphtropy. In other words, uncertainty in the coding sense lower-bounds the expected rate at which distinctions are encountered. Equivalently, when the observer is forced (by high Shannon uncertainty) to distribute probability mass broadly, the probability that two independent samples fall into the* same *indistinction class drops, so the complement quantity (logical entropy / graphtropy) rises. This is one way to connect the "uncertainty" modality (coding/inference spread) to the "distinction" modality (how often the observer can separate states): the former constrains the latter because concentrated mass simultaneously increases collision probability and reduces the expected number of effective distinctions available to the observer.*

10.6 Uncertainty and ineffability as observer-relative modalities

Hyperseed uses "ineffable" in a practical sense: something may exist and matter to a mind, yet remain resistant to being stably and communicably represented. We formalize this by combining (i) a cost model for representations and (ii) a fidelity predicate that depends on the observer's distinctions. The key point is that both ingredients are explicitly indexed by the observer/context O, so "ineffability" is not an absolute metaphysical label but a relative statement about what can be encoded *given* a representational interface and a limited budget.

Definition 126 (Observer representational resources)**.** *An observer/context O is equipped with:*

- *a description space (language) $\mathcal{D}_O$;*
- *a cost/effort function $\sigma_O : \mathcal{D}_O \to [0, \infty)$;*

- *a decoding map* $\mathrm{dec}_O : \mathcal{D}_O \to \Delta(X)$*, where* $\Delta(X)$ *is the set of probability distributions on* X*.*

Given $d \in \mathcal{D}_O$*, the distribution* $\mathrm{dec}_O(d)$ *is interpreted as the observer's best reconstruction of the target in* X *from description* d*.*

Remark 462. ***Notation/conventions.*** $\mathcal{D}_O$ *is a set of descriptions (strings, programs, structured messages, etc.).* $\sigma_O(d)$ *is the effort/cost of using description* d*; it plays the same formal role as description length or resource use, but we do not insist it be literal bit-length.* $\Delta(X)$ *denotes the simplex of probability distributions on* X*.*

Intuition. *A description* d *is not required to point to a single* $x \in X$*; instead it may decode to a distribution, reflecting that a finite description can determine only a region of possibilities. This is a deliberately observer-friendly model: what the observer can* say *need not uniquely identify what the world* is*.*

Example. *If* X *is a set of images and* $\mathcal{D}_O$ *is a natural-language vocabulary, then* $\mathrm{dec}_O(d)$ *is the distribution over images compatible with the phrase* d *(e.g. "a red apple on a table"). If* X *is microstates and* $\mathcal{D}_O$ *is macroscopic parameters, then* $\mathrm{dec}_O(d)$ *is a macrocanonical distribution over microstates.*

Why useful. *This definition provides the scaffold needed to define effability/ineffability as a resource-bounded property, aligning with Hyperseed's emphasis that what can be expressed depends on effort and available representational moves (Hyperseed-Concept 100, Hyperseed-Concept* **??***).*

Further clarification. *The map* dec_O *can be read in several compatible ways: (a) as a conventional semantics map (a description denotes a set/region of states, represented here by a distribution), (b) as Bayesian posterior inference given a message* d*, or (c) as a lossy decompressor in a coding system. Allowing* $\mathrm{dec}_O(d)$ *to be a distribution rather than a point makes room for ambiguity, underspecification, and context-dependence, which are precisely the regimes where ineffability is most natural to discuss. Similarly, the cost* σ_O *may measure time, energy, cognitive effort, social negotiation cost, or any other constrained resource, so that "saying more precisely" is not free.*

Definition 127 (Fidelity relative to a distinction structure)**.** *Fix an indistinction weight function* ι_G *on* X*. Given a target* $x \in X$ *and a reconstructed distribution* $q \in \Delta(X)$*, define the* distinction error

$$\mathrm{Err}_G(x, q) := \sum_{y \in X} q(y)\,(1 - \iota_G(x, y)).$$

Define the corresponding distinction fidelity

$$\mathrm{Fid}_G(x, q) := 1 - \mathrm{Err}_G(x, q) = \sum_{y \in X} q(y)\,\iota_G(x, y).$$

Remark 463. ***Intuition.*** $\mathrm{Fid}_G(x, q)$ *is the expected indistinction between the true target* x *and a random draw* $y \sim q$*. So fidelity is high when* q *puts most of its mass on states* y *that the observer would treat as indistinct from* x*. This makes fidelity explicitly dependent on the observer's distinction policy.*

Example. *If* ι_G *is induced by a partition into categories (say, "cat" vs. "dog"), then fidelity measures whether your reconstruction distribution stays within the correct category. A description might be "good enough" even if it cannot identify the exact microstate, as long as it lands in the right coarse class.*

Why useful. *This is the technical move that makes ineffability meaningful rather than mystical: we can say precisely which aspects of* x *the observer fails to capture, because the failure is* *measured by the observer's own indistinction structure. It also anticipates the later use of graded relations/quantales to represent cognition (Sections 11 and 12).*

Basic properties. *When $\iota_G(x,y) \in [0,1]$ for all x,y, one has $\mathrm{Err}_G(x,q) \in [0,1]$ and $\mathrm{Fid}_G(x,q) \in [0,1]$. Moreover, $\mathrm{Fid}_G(x,q)$ is linear in q, so mixing reconstructions mixes fidelities in the obvious way. At the extremes: if $\iota_G(x,y) = \mathbf{1}_{x=y}$ (perfect distinction of microstates), then $\mathrm{Fid}_G(x,q) = q(x)$ is just the probability that q hits the correct state exactly; if $\iota_G(x,y) \equiv 1$ (no distinctions at all), then $\mathrm{Fid}_G(x,q) \equiv 1$ and everything is trivially "perfectly faithful" in this coarse sense.*

Remark 464. *If ι_G encodes a partition, then $\mathrm{Fid}_G(x,q)$ is exactly the probability mass that q assigns to the block of x. Thus Fid_G measures whether the reconstruction lands in the "right distinction class." For fuzzy ι_G, it becomes a graded correctness criterion. In particular, when ι_G is derived from a weighted graph (or similarity kernel), $\mathrm{Fid}_G(x,q)$ can be read as the expected similarity between x and a q-sample, so the same formalism covers both crisp categorization and graded perceptual similarity.*

Definition 128 ((ϵ, K)-effability and ineffability)**.** *Fix thresholds $\epsilon \in (0,1)$ and $K \in (0,\infty)$. An element $x \in X$ is* (ϵ, K)-effable for O (relative to G) *if there exists a description $d \in \mathcal{D}_O$ such that*

$$\sigma_O(d) \le K \quad \textit{and} \quad \mathrm{Fid}_G\big(x, \mathrm{dec}_O(d)\big) \ge 1-\epsilon.$$

Otherwise x is (ϵ, K)-ineffable for O (relative to G). *We write $\mathrm{Eff}_O(\epsilon, K; G) \subseteq X$ and $\mathrm{Ineff}_O(\epsilon, K; G) := X \setminus \mathrm{Eff}_O(\epsilon, K; G)$.*

Remark 465. *Intuition.* *Effability is a two-threshold notion:*

- *K limits how much representational effort the observer may spend;*
- *ϵ limits how much distinction error the observer is willing to tolerate.*

An item is ineffable if every description cheap enough fails the fidelity test.

Examples. *A detailed inner sensation might be ineffable for an observer with a coarse language (small $\mathcal{D}_O$) or small budget K. A high-dimensional physical state may be ineffable relative to a coarse distinction structure G if the observer demands fine fidelity (tiny ϵ) but lacks resources.*

Monotonicity and limiting cases. *Holding O and G fixed, $\mathrm{Eff}_O(\epsilon, K; G)$ is monotone increasing in both parameters: if $K' \ge K$, then any description feasible under K is feasible under K', and if $\epsilon' \ge \epsilon$, then any reconstruction meeting the stricter fidelity target $1-\epsilon$ also meets the weaker target $1-\epsilon'$. Thus ineffability is most stringent at small K and small ϵ, matching the informal idea that "hard to say" can mean either "too expensive to say precisely" or "no available description hits the demanded granularity." At the opposite extreme, if $\mathcal{D}_O$ contains arbitrarily long descriptions and dec_O can represent point masses δ_x (perfectly specific reconstructions), then every x becomes (ϵ, K)-effable for sufficiently large K and sufficiently small ϵ; the interesting regime is where either the language cannot express such pinpoint reconstructions or the budget K forbids them.*

Relation to lossy coding. *Formally, the condition $\mathrm{Fid}_G(x, \mathrm{dec}_O(d)) \ge 1-\epsilon$ parallels a distortion constraint in rate–distortion theory, with $(1-\iota_G)$ acting as an observer-relative distortion measure. The novelty here is that distortion is not imposed externally but induced by the observer's distinction structure, so "what counts as an acceptable lossy description" is itself observer-relative.*

Remark 466. *Why this is useful.* *This definition separates three sources of "ineffability" that are often conflated: (i) lack of resources (small K), (ii) lack of expressive language (restricted $\mathcal{D}_O$*

and dec_O*), and (iii) demanding too fine a notion of correctness (too discriminating an* ι_G *or too small* ϵ*). In Hyperseed terms, it makes ineffability a modality indexed by* effort *and* distinction regime*, rather than an absolute metaphysical boundary (Hyperseed-Concept* **??***). Equivalently, the question "is x ineffable?" is replaced by the operational question "for which budgets* K*, tolerances* ϵ*, and regimes* G *does* x *fall outside the reachable set of reconstructions?". This shift matters because it lets one diagnose* which knob *(capacity, vocabulary/decoding, or resolution) is responsible for the failure, rather than treating all failures as the same phenomenon. It also clarifies that "ineffability" can arise even in a fully deterministic world: it is about limits of mediation and evaluation, not about indeterminacy in the target.*

Proposition 14 (Monotonicity in resources and resolution)**.** *If* $K' \geq K$ *then* $\mathrm{Eff}_O(\epsilon, K; G) \subseteq \mathrm{Eff}_O(\epsilon, K'; G)$*. If* G' *is coarser than* G *in the sense that* $\iota_G(x,y) \leq \iota_{G'}(x,y)$ *for all* x, y *(more indistinction), then*

$$\mathrm{Eff}_O(\epsilon, K; G) \subseteq \mathrm{Eff}_O(\epsilon, K; G').$$

Remark 467. ***What the proposition says.*** *Two monotonicities hold:*

- *More resource budget* ($K' \geq K$) *cannot make previously sayable things unsayable.*
- *Coarser resolution (more indistinction) cannot make previously acceptable reconstructions unacceptable.*

Here "resource budget" is whatever complexity/cost measure is encoded in the definition of $\mathrm{Eff}_O(\epsilon, K; G)$ *(e.g., description length, time, energy, sample size, or any composite bound), so the first monotonicity is a statement about feasibility under constraint relaxation. Likewise, "coarser" is not an informal metaphor but the pointwise order* $\iota_G \leq \iota_{G'}$*, which guarantees that every pair* (x, y) *is judged at least as "similar" (or at least as "indistinct") in* G' *as it was in* G*.*

Why it matters. *This is the minimal sanity condition for an effability notion: adding capacity should not reduce what you can express, and relaxing your standards of distinction should not reduce what you can count as successfully expressed. It also gives a clean formal handle on developmental/cultural claims: as a community gains representational resources or shifts its distinction regime, the boundary between effable and ineffable moves monotonically. In particular, if one thinks of* ϵ *as a tolerance parameter for "good enough" reconstruction, then this proposition isolates two other monotone directions (in* K *and in* G*) that move the boundary without changing* ϵ*. This is useful when comparing observers: two agents can agree on* ϵ *but still differ radically in effability because they differ in budget* K *or in the similarity structure* ι_G *they implicitly apply.*

Connection. *Compare with Proposition 13: graphtropy decreases under coarsening, while effability increases under coarsening. Together they express a trade: fewer distinctions encountered means more targets count as representable. One can read this as a duality between (i) the "complexity of the world as cut" (how many distinctions are treated as real) and (ii) the "complexity of a message needed to succeed" (how hard it is to meet the fidelity test). When* G *is made coarser, the observer is, in effect, permitted to ignore more microstructure, so many different underlying states can share a single acceptable description.*

Proof. The first inclusion is immediate: any description of cost at most K is also of cost at most K'. Concretely, if $d \in \mathcal{D}_O$ is feasible under K (i.e., it belongs to the allowed-cost subset of descriptions), then it remains feasible under any larger bound K', and the corresponding decoded reconstruction $\mathrm{dec}_O(d)$ does not change; only the admissible set of d expands. For the second, if $\iota_G \leq \iota_{G'}$ then for any $q \in \Delta(X)$ we have

$$\mathrm{Fid}_{G'}(x, q) = \sum_y q(y)\, \iota_{G'}(x, y) \geq \sum_y q(y)\, \iota_G(x, y) = \mathrm{Fid}_G(x, q).$$

A coarser G' makes the fidelity test easier to satisfy, so the effable set can only expand. Equivalently, for each fixed x and each candidate reconstruction q, the set of regimes under which q is ϵ-acceptable is upward closed in the pointwise order on ι; taking an existential quantifier over descriptions preserves this monotonicity. □

Remark 468. ***Proof sketch.*** *The first part is pure set inclusion under a relaxed constraint: enlarging the allowed-cost set enlarges the feasible descriptions. The second part is an inequality under a pointwise domination $\iota_G \leq \iota_{G'}$, which transfers directly through the expectation defining fidelity. What is doing the work is that $\mathrm{Fid}_G(x, q)$ depends on G only through $\iota_G(x, \cdot)$, so comparing regimes reduces to comparing two functions pointwise and then averaging.*

Key step. *Fidelity is linear in ι_G (it is an average of $\iota_G(x, y)$ under q), so pointwise ordering of ι implies ordering of fidelities. In particular, no additional regularity assumptions (convexity, continuity, etc.) are needed: the argument is purely order-theoretic.*

Intuition. *If you blur your distinctions, you become easier to satisfy: many reconstructions that were previously "wrong in the details" become "close enough" in the new regime. Conversely, sharpening distinctions (moving from G' to a finer G) can render previously adequate summaries inadequate, not because the agent "lost" expressive power, but because the scoring rule became stricter.*

Remark 469 (Ineffability versus unknowability)**.** *Ineffability is not the same as (absolute) unknowability. Even if x is ineffable to O at some (ϵ, K), it may become effable after: (i) increasing resources (larger K); (ii) changing the representational language $\mathcal{D}_O$; or (iii) changing the distinction regime (a different G). Hyperseed's point is that such changes are common in development and culture: a concept can become sayable once a community learns to carve the world differently. Said differently, ineffability here is indexed by an* interface*: a particular coding/decoding practice together with a particular way of scoring similarity. Under that interpretation, an "ineffable" x is often better described as "not currently compressible into the observer's available description forms without exceeding the tolerated error". This also prevents a common equivocation: a fact may be perfectly learnable in principle (there exists some richer observer O' or some larger K for which it is effable) while being practically unsayable for a given agent in a given context.*

Remark 470. *In Peircean terms, ineffability is not a statement about the absence of a Third (law/representation), but about the current poverty of mediating habits available to the agent or community. In Whiteheadian terms, it is a limitation in the available forms of "prehension" and their integration, not a denial that the occasion exists (cf. [14, 15] for the broader metaphysical framing). The present formalism simply makes those philosophical diagnoses testable against parameters: one can ask whether the obstacle is primarily one of habit/mediation (modeled by $\mathcal{D}_O$ and dec_O), one of effort (modeled by K), or one of discriminatory stance (modeled by G and ϵ). On that reading, a "new concept" in a community can be seen as simultaneously (a) an expansion of $\mathcal{D}_O$ (new symbols, new grammars, new practices of description) and (b) a reconfiguration of ι_G (new similarities taken as salient), either of which can move items from the ineffable to the effable region without changing the underlying target space.*

10.7 Potential infinity and infinitesimals as "limit objects"

Hyperseed frequently speaks about "potentially infinite" or "potentially infinitesimal" quantities. Rather than invoke full nonstandard analysis, it is often enough to work with a constructive surrogate: *germs of sequences at infinity.* In this subsection, "limit object" should be read in an informal operational sense: we take a potentially unbounded or potentially refining process (a sequence), and then identify processes that differ only by a finite amount of "startup behavior." What remains is a stable tail-pattern that functions like an idealized object for asymptotic reasoning.

Definition 129 (Eventual equality and germs)**.** *Let $\mathbb{R}^{\mathbb{N}}$ be the set of real sequences. Define an equivalence relation $\sim$ on $\mathbb{R}^{\mathbb{N}}$ by*

$$a \sim b \quad \iff \quad \exists N \in \mathbb{N}\, \forall n \geq N: \; a_n = b_n.$$

The quotient

$$\mathbb{R}_\infty := \mathbb{R}^{\mathbb{N}}/\sim$$

is called the set of germs at infinity*. We write $[a]$ for the germ of the sequence a. Addition and multiplication are defined pointwise on representatives.*

Remark 471. ***Well-definedness and algebra.*** *Because $\sim$ is compatible with pointwise addition and multiplication (if two pairs of sequences agree eventually, then so do their pointwise sums and products), the operations "defined pointwise on representatives" do not depend on which representative of a germ one chooses. Thus $\mathbb{R}_\infty$ is naturally a commutative ring. It is not a field in general: a germ can fail to have a multiplicative inverse, e.g. if a representative has infinitely many zero terms (so that no pointwise reciprocal sequence exists beyond any finite stage).*

Embedding of standard reals. *There is a canonical map $\mathbb{R} \hookrightarrow \mathbb{R}_\infty$ sending a real number c to the germ of the constant sequence $(c, c, c, \dots)$. This makes it precise to compare a germ to an ordinary real "benchmark" without leaving the germ language. In what follows, inequalities such as $\varepsilon <_\infty c$ implicitly use this embedding.*

Notation/conventions. *$\mathbb{R}^{\mathbb{N}}$ is the set of sequences $(a_0, a_1, a_2, \dots)$ with real entries. The relation $a \sim b$ means "a and b are eventually the same," i.e. they may differ at finitely many initial indices but coincide from some point onward. $[a]$ denotes the equivalence class (germ) of a.*

Intuition. *A germ forgets finite beginnings and remembers only tail behavior. This captures the idea of "potential" processes: what matters is not having an actually completed infinity, but having a rule whose behavior stabilizes beyond any finite horizon. Equivalently, a germ is a bookkeeping device for statements of the form "for all sufficiently large n," which will recur whenever one reasons about limits, asymptotics, or tolerances.*

Examples. *The sequences $(0, 1, 2, 3, \dots)$ and $(5, 1, 2, 3, \dots)$ define the same germ: they differ only at the first entry. The sequences $(1, 1, 1, \dots)$ and $(1, 1, 1, 0, 1, 1, \dots)$ do* not *define the same germ if they differ infinitely often. Similarly, the sequences (n) and $(n+1000)$ define the same germ difference as a constant shift: $[n + 1000] = [n] + [1000]$, so the "potential infinity" is insensitive to finite offsets in starting point.*

Why this is useful. *Resource-sensitive ontology often wants to say "can be made arbitrarily large" or "arbitrarily small" without committing to completed infinities. Germs provide a minimal algebraic language for such talk, compatible with an operational view of approximation. They also separate two kinds of information that often get conflated: the finite transient behavior of a process (which can be idiosyncratic or context-specific) and its eventual regime (which is what asymptotic comparison and "limit" talk typically tracks).*

Definition 130 (Eventual order)**.** *For germs $[a], [b] \in \mathbb{R}_\infty$ define*

$$[a] \leq_\infty [b] \quad \iff \quad \exists N \in \mathbb{N}\, \forall n \geq N: \; a_n \leq b_n.$$

This is a partial order compatible with addition and multiplication by nonnegative germs.

Remark 472. ***Basic properties.*** *The relation $\leq_\infty$ is reflexive and transitive, and it is antisymmetric in the sense appropriate for a quotient: if $[a] \leq_\infty [b]$ and $[b] \leq_\infty [a]$, then $a_n = b_n$ eventually, hence $[a] = [b]$. It is generally not a total order: there may be incomparable germs whose representatives cross infinitely often.*

Intuition. *$[a] \leq_\infty [b]$ means: after some finite stage, a_n never exceeds b_n. So the order compares asymptotic tail behavior and ignores finitely many initial anomalies. This is exactly the quantifier pattern used in many "limit" arguments: the tail is constrained uniformly beyond some cutoff.*

Example. *If $a_n = n$ and $b_n = n^2$, then $[a] \leq_\infty [b]$ since eventually $n \leq n^2$. But $[a] \leq_\infty [c]$ and $[c] \leq_\infty [a]$ can both fail if the sequences oscillate forever. For instance, if $c_n = (-1)^n n$, then neither $[c] \leq_\infty [0]$ nor $[0] \leq_\infty [c]$ holds: the sign keeps flipping, so no single tail bound of one by the other stabilizes.*

Why useful. *The eventual order lets us define "infinitely large" and "infinitesimal" elements as order-theoretic comparisons with constants, matching Hyperseed's use of potential infinity/infinitesimals (Hyperseed-Concept **??**, Hyperseed-Concept **??**). Concretely, a germ x is "(potentially) infinite" if it eventually exceeds every constant, and it is "(potentially) infinitesimal" if it is eventually positive yet eventually below every fixed positive constant.*

Example 10 (A potentially infinite and a potentially infinitesimal element)**.** *Let $\omega := [n]$ where $n \mapsto n$. Then ω dominates every standard constant: for any $c \in \mathbb{R}$, eventually $n > c$. Let $\varepsilon := [1/n]$. Then ε is positive but smaller than any fixed positive constant in the eventual order.*

Remark 473. *This example is the operational core: ω stands for an unbounded growth process, while ε stands for a decay process that can be made smaller than any fixed tolerance by going far enough along the sequence. Neither requires a completed infinite magnitude; both require only the ability to continue the process as needed. In particular, the germ formalism explicitly tolerates the fact that real computations have "initial conditions": changing finitely many initial values of n or $1/n$ does not change the potential object.*

A useful consistency check is that these two limit objects interact as expected under multiplication:

$$\omega \cdot \varepsilon \;=\; [n] \cdot [1/n] \;=\; [\, n \cdot (1/n)\,] \;=\; [1],$$

since $n \cdot (1/n) = 1$ for all $n \geq 1$, i.e. the product is eventually the constant 1. This illustrates how the germ quotient encodes the idea that "after a finite warm-up," scaling up and scaling down can cancel in a stable way.

Lemma 2 (Infinitesimal property in the germ order)**.** *Let $\varepsilon = [1/n] \in \mathbb{R}_\infty$. Then $0 <_\infty \varepsilon$ and for every standard $c > 0$ we have $\varepsilon <_\infty c$.*

Remark 474. ***What the lemma says.*** *The germ of $1/n$ behaves exactly as one informally expects of an infinitesimal: it is eventually positive, yet eventually smaller than any fixed positive real constant.*

Relation to "limit" language. *In ordinary analysis one writes $\lim_{n\to\infty} 1/n = 0$. Here, instead of collapsing* $1/n$ to *the value* 0, *we keep the whole tail-behavior as an object ε that remains distinguishable from 0 but is dominated by every positive constant. This is precisely the kind of "nonzero but negligible" quantity that potential-infinitesimal talk is aiming at.*

Why it matters. *This provides a precise, lightweight sense in which we can talk about "arbitrarily weak couplings" or "arbitrarily small errors" inside a framework that treats infinity as potential rather than completed. Such language is later useful when describing diminishing influences* *across increasingly remote contexts (e.g. in resonance-style stories), where one wants "nonzero but negligible" rather than exactly zero. In particular, the lemma justifies replacing a family of tolerance statements "for every $c > 0$ there exists a stage after which the error is $< c$" with a single order-theoretic comparison against all constants.*

Proof. For $n \geq 1$, $1/n > 0$, so $\varepsilon >_\infty 0$. Given $c > 0$, choose $N > 1/c$. Then for all $n \geq N$, $1/n < c$, so $\varepsilon <_\infty c$. □

Remark 475. ***Proof sketch.*** *Both claims follow by choosing a sufficiently large index N. Positivity is immediate because all terms $1/n$ are positive; smallness follows because $1/n$ eventually falls below any fixed threshold c.*

Key step. *The eventual order bakes "there exists an N such that for all $n \geq N$" into the definition, so asymptotic estimates translate directly into order relations. This is the same quantifier structure that appears in ε–δ reasoning; germs package it into algebraic objects so that one can reason about tails without constantly reintroducing quantifiers.*

Visual intuition. *Plot $1/n$ against n; the curve descends toward 0. The lemma is simply the statement that any horizontal line at height $c > 0$ is eventually above the curve.*

Interpretive note. *Although ε is "smaller than any fixed constant," it is not* equal *to 0 in $\mathbb{R}_\infty$: the sequence $1/n$ is never eventually the zero sequence. This distinction is exactly what makes ε a useful "limit object" rather than merely a limit value.*

Remark 476 (Conceptual role)**.** *Germs provide a lightweight way to talk about "approaching infinity" or "approaching zero" without assuming that a mind must represent completed infinite objects. In this sense, a germ functions as a stable* direction of refinement*: it records what remains invariant as one continues to sharpen a description (for example, by increasing resolution, adding measurement time, or enlarging a comparison class), while refusing to reify the unattainable endpoint as a finished entity. This is the intended "limit object" reading: not an actually-given limit, but a disciplined placeholder for an indefinitely extensible process of approximation.*

In the ontology, this supports statements like: "the distinction granularity can be refined without bound" (potential infinity) and "a coupling can be arbitrarily weak" (potential infinitesimal). Here "without bound" should be read as a modal claim about available refinements (there is always a further distinction regime available in principle), rather than as a claim that an infinite set of distinctions is ever simultaneously present to an observer. Likewise, "arbitrarily weak" emphasizes a comparative ordering of couplings under refinement: for any operational threshold fixed by an observer, one can consider contexts in which the coupling falls below that threshold, even if no absolute "zero-coupling" state is ever asserted.

When we later discuss morphic resonance across increasingly remote contexts, it can be useful to treat resonance strength as an infinitesimal germ rather than as exactly zero. This avoids a sharp discontinuity between "no influence" and "some influence" that would otherwise be an artifact of representational coarseness: the germ formalizes the idea that influence may persist in a way that is systematically negligible for any fixed finite resource bound, yet not logically excluded. Equivalently, the infinitesimal germ lets us separate two questions that are often conflated: whether a coupling is detectable *at a given resource level, and whether it is* structurally present *in the relational organization being modeled.*

10.8 Section wrap-up

This section supplied three bridges that will be used repeatedly later:

- Shannon information provides the standard coding-theoretic notion of uncertainty. In particular, it supplies a quantitative baseline for how many bits are required, on average, to resolve a choice among alternatives given an assumed probability model, and it supports the usual trade-offs between compression, prediction, and error.
- Logical entropy and graphtropy connect uncertainty to the Hyperseed primitive of distinction. This makes uncertainty explicitly about *separations* (which pairs are distinguished and which are not), so that information measures can be read directly as properties of a distinction graph or partition structure, rather than only as properties of symbol sequences.
- Ineffability becomes a monotone property relative to observer resources and distinction regimes. That is, an object or pattern may be perfectly effable for one observer (or one modeling interface) while remaining ineffable for another, and increasing resources or refining distinctions can only decrease ineffability in the sense that more becomes stably nameable and communicable.

With these in place, we can treat hierarchy and pattern webs (Section 11) and habit dynamics (Section 12) as information-processing structures whose meaning depends explicitly on what is, and is not, distinguished. This dependence is not merely epistemic but structural: changing a distinction regime can change what counts as an entity, a relation, or a causal regularity in the model, thereby shifting which compressions are valid and which predictions are well-posed. Conversely, by keeping the distinction regime explicit, later sections can state claims about organization and dynamics in a way that remains robust under changes of scale, granularity, or observational interface.

11 Hierarchy, heterarchy, and pattern webs

11.1 Motivation: why Hyperseed needs both hierarchies and webs

Patterns (Section 9) do not occur in isolation. Once an observer can represent "P is a pattern in x" with some intensity, it can also represent relationships *between* patterns and *between* patterned entities. This is not an optional embellishment: as soon as patterns are treated as reusable cognitive objects, the observer must be able to compare them, compose them, and propagate information from one to another. In particular, even a minimal pattern-recognizer tends to (a) reuse the same patterns across many inputs and (b) relate those reused patterns via co-occurrence, entailment, explanation, control, abstraction, and part–whole decomposition. Two structural motifs appear immediately:

- *Hierarchy:* some entities are treated as "higher" than others (more valuable, more general, more controlling, more explanatory) and this induces an order-like structure.
- *Heterarchy (web):* most entities have multiple different paths of relationship to other entities, forming loops and multi-path dependence networks rather than trees.

The emphasis on "order-like" versus "network-like" is deliberate: in practice, the same pair of patterns may be related in multiple ways at once (e.g. one pattern may be more general, while the other is more predictive in a restricted domain), and the cognitive model must be able to represent both the comparative directionality (who outranks whom, or who constrains whom) and the lateral connectivity (who interacts with whom, possibly reciprocally). In this section, the word "hierarchy" will be used broadly enough to include not only strict trees but also preorders and partial orders, i.e. structures where many elements may be incomparable, and where "being higher" can mean "being at least as good as" rather than "being the unique parent of."

Remark 477. *The philosophical pressure behind this bifurcation is simple: a mind (or any modeling system) must both (i) compress the world into* comparative priorities *(a ranking of what matters, what explains, what controls), and (ii) keep track of the fact that the world is not a ladder but a tangle, where explanation and influence typically move along many partially redundant and mutually constraining routes. Hierarchy and heterarchy are thus not competing metaphors; they are complementary projections of the same cognitive act, seen from the angles of order and connectivity (Hyperseed-Concepts* **??** *and* **??***).*

A useful way to read this remark is that hierarchy expresses a kind of *compression* (reduce many degrees of freedom to a comparative relation), while heterarchy expresses a kind of *closure under interaction* (allow many routes of influence and evidential support, including feedback). A cognitive system that only ranks without interconnection becomes brittle (it cannot represent mutual constraint, circular causation, or context sensitivity), while a cognitive system that only connects without ranking becomes diffuse (it cannot decide what to attend to, what to optimize, or what to treat as explanatory leverage). Thus, the two motifs show up not merely as descriptive metaphors but as recurring representational necessities.

Hyperseed uses these motifs in several places: subpattern hierarchy (patterns within patterns), control/perceptual hierarchies, self-hierarchies, and the "pattern web" picture of cognition. Here "subpattern hierarchy" points to part–whole and compositional structure (a pattern may be built from constituent patterns), whereas "control/perceptual hierarchies" point to layered organization in action and inference (e.g. high-level goals constraining lower-level controllers, and higher-level interpretations organizing lower-level percepts). "Self-hierarchies" similarly reflect that an agent can maintain multiple self-models with differing levels of generality, authority, or temporal scale. Meanwhile, the "pattern web" picture emphasizes that these hierarchical decompositions are embedded in a larger network: patterns participate in many overlapping decompositions and predictive/explanatory links, and any given pattern typically inherits constraints from many sources at once.

The mathematical point of this section is that all of these can be treated as special cases of *quantale-enriched structure* (Section 3): the same formal machinery that represents "how related" two entities are (possibly with degrees, costs, or truth-values) can specialize to order-theoretic hierarchy, metric-like connectivity, and more general graded relations. Concretely, enrichment replaces the crisp statement "there is a relation from a to b" with a value that can encode intensity, confidence, cost, or compatibility, and it equips these values with a notion of composition. When applied to patterns, this means we can model not only whether one pattern subsumes or controls another, but also *to what extent* and *through which chains of intermediate patterns* that relationship holds.

- A crisp hierarchy is enrichment in the Boolean quantale $\{0, 1\}$.
- A metric heterarchy is enrichment in the Lawvere quantale $([0, \infty], \geq, +, 0)$.
- A paraconsistent, graded hierarchy is enrichment in a p-bit quantale (Section 3.4).

To unpack the intuition: Boolean enrichment yields relations valued in $\{0, 1\}$, so composition reduces to logical conjunction and the structure behaves like a preorder (and, with suitable antisymmetry, a partial order), matching the usual mathematical abstraction of "hierarchy." Lawvere enrichment replaces "true/false relatedness" with extended nonnegative "distance" or "cost," where composing paths adds costs; this naturally captures web-like multi-path structure because indirect connections compete with direct ones via triangle-inequality-style constraints. Finally, p-bit enrichment allows relationship-values that can represent graded support and graded conflict simultaneously (paraconsistency), which is important when the same pair of patterns can be connected by evidence that points in different directions, or when an agent maintains multiple partially incompatible models without immediate collapse into triviality.

Remark 478. *The "pattern web" framing is central in Hyperseed's earlier presentations and related work on patterns, emergence, and cognitive network structure [1, 5]. The present section is deliberately modest: it does not add new metaphysics; it supplies a single mathematical dialect in which these recurrent motifs can be spoken without ambiguity.*

In this sense, the goal is methodological: once hierarchies and webs are both expressed as enriched structures, one can translate intuitions and results across domains. For example, "subpattern-of" can be treated as an order-like relation, while "influences" or "predicts" can be treated as graded, directional, and compositional; and in both cases, the formalism makes explicit what it means for indirect relationships to accumulate through intermediate patterns.

We will define the Hyperseed terms (hierarchy, systemic hierarchy, subpattern hierarchy, heterarchy, pattern web) and then show how they fit into the enriched-categorical core.

11.2 Hierarchy as observer-assessed order

Hyperseed treats "hierarchy" as inherently observer-relative: an observer O assesses some entities as higher than others, *in some respect* (importance, generality, desirability, control, explanatory priority). The simplest mathematical representation of "higher than" is a partial order, but we will allow graded and paraconsistent structure. In particular, allowing "graded" comparisons accommodates the common situation where O can compare u and v only weakly or provisionally, while allowing "paraconsistent" comparisons accommodates the situation where O simultaneously carries evidence both for and against the claim that u outranks v without collapsing into triviality. Note also that even in the ungraded case, a hierarchy need not be total: many pairs of entities may remain incomparable, reflecting underspecification, competing criteria, or simply irrelevance under the current respect-of-comparison.

Definition 131 (Order-like relations)**.** *Let U be a set of entities (objects, patterns, processes, roles).*

- *A* preorder *on U is a relation $\preceq \subseteq U \times U$ that is reflexive and transitive.*
- *A* partial order *is a preorder that is also antisymmetric.*
- *A* graded preorder *(relative to a commutative quantale V) is a map*

$$h : U \times U \to V$$

with reflexivity $e \leq h(u, u)$ *and* transitivity

$$h(u, v) \otimes h(v, w) \leq h(u, w) \qquad (u, v, w \in U),$$

where $(V, \leq, \oplus, \otimes, e)$ is as in Section 3.

It is worth stressing what is *not* required by these definitions. A preorder permits ties (distinct $u \neq v$ with $u \preceq v$ and $v \preceq u$), which can be interpreted as observational or pragmatic equivalence under the chosen respect-of-comparison. Antisymmetry upgrades this to a partial order, ruling out such ties except when $u = v$; thus, moving from preorder to partial order amounts to deciding that "mutual outranking" should be treated as identity rather than as a legitimate equivalence class. Conversely, neither preorders nor partial orders require comparability: it can happen that neither $u \preceq v$ nor $v \preceq u$ holds, which is often the appropriate formalization of "O has no basis to rank them (yet)".

Remark 479 (Notation unpacking: what the symbols mean). *The data of a graded preorder live in a commutative quantale $(V, \leq, \oplus, \otimes, e)$ (Section 3). Here:*

- *V is the space of "grades" (truth-strengths, costs, evidences, similarities, etc.).*
- *$\leq$ is the order on grades ("no stronger than").*
- *$\oplus$ is the join/supremum operation (aggregating alternative supports).*
- *$\otimes$ is the monoidal product (aggregating sequential supports, as in composition along a path).*
- *e is the unit grade (the neutral element for $\otimes$), playing the role of identity.*

Thus $h(u, v) \in V$ should be read as "the degree (in V) to which u is at least as high as v" in the hierarchy. The transitivity inequality says: if u is above v and v is above w, then (by composing these two claims) u is above w to at least the composed degree.

One additional interpretive point is that $\oplus$ and $\otimes$ encode two qualitatively different ways of accumulating support for a comparison. Typically, $\otimes$ is used when comparisons are chained (e.g., "u outranks v" and "v outranks w" together provide a route from u to w), while $\oplus$ is used when comparisons arise through multiple alternative routes or arguments (e.g., two different explanatory pathways both suggest that u outranks v). This separation becomes especially important when the same domain U simultaneously participates in multiple interacting structures: a "hierarchy" viewed as an order-like relation can later be combined with other relational webs using the same quantale operations, so that path-composition and route-aggregation are not redefined ad hoc for each application.

Remark 480 (Intuition, examples, and why graded preorders matter). *A crisp preorder answers a yes/no question: "is u above v?" But in cognition and modeling we usually have degrees: we may have strong reasons, weak reasons, or even simultaneous reasons for and against a comparison. A graded preorder is exactly a disciplined way to represent such comparative gradations (Hyperseed-Concept* **??***).*

Two simple examples:

- *If $V = \{0, 1\}$ with $\otimes = \wedge$ and $\oplus = \vee$, then $h(u, v) = 1$ means "$u \preceq v$" in the ordinary preorder sense. Transitivity becomes $(u \preceq v \ \wedge \ v \preceq w) \Rightarrow u \preceq w$.*
- *If $V = [0, 1]$ with $\otimes$ as multiplication and $\oplus$ as maximum, then $h(u, v)$ can be read as "confidence" in the comparison $u \preceq v$. A longer chain of comparisons generally decreases confidence by multiplication, while multiple independent routes can increase it by the maximum.*

The usefulness is structural: once comparisons are V-valued, one can reuse the same algebra both for "hierarchy" and for "web" propagation later in the section, rather than maintaining separate formalisms. This is also where Hyperseed's notion of weakness naturally enters, because weakness is precisely an order-theoretic measure of what distinctions one has collapsed [3, 2] (Hyperseed-Concept 202).

To connect these examples to more applied readings: when $V = [0, 1]$ is interpreted as confidence, the inequality $h(u, v) \otimes h(v, w) \leq h(u, w)$ enforces the idea that indirect support for $u \preceq w$ via v should never exceed what the model assigns directly. If the model later learns a stronger direct comparison for $u \preceq w$, this can be seen as adding a new "route" whose contribution can be combined (via $\oplus$) with the routed support. If instead V represents a cost or penalty scale, then

$\leq$ may be interpreted as "no worse than," and $\otimes$ can be interpreted as accumulating costs along a chain; in that case the same axiom becomes a disciplined form of "taking paths seriously" while still preferring cheaper direct comparisons when available. These shifts of interpretation are exactly why the definition is parameterized by a quantale rather than hard-coding a particular numeric scheme.

Remark 481 (Thin V-categories)**.** *A graded preorder is exactly the same data as a* thin V*-enriched* *category: there is at most one hom-value between any two objects, and composition is encoded by the quantale transitivity inequality. Thus, "hierarchy" is naturally treated as a special case of the enriched-categorical core.*

This thinness perspective also clarifies the difference between "having a hierarchy" and "having a richer relational structure." A thin V-category records only the best available grade $h(u, v)$ of the comparison, not the internal structure of *why* u outranks v (e.g., which intermediate arguments, subcriteria, or evidential sources support it). Later, when we discuss pattern webs, those internal justifications can be represented explicitly as additional nodes and edges, while the induced graded preorder can be recovered as an "overall reachability/strength" summary through the same $(\oplus, \otimes)$ machinery.

Definition 132 (Observer-assessed hierarchy)**.** *Fix an observer/context O. A* hierarchy for O on *a domain U is a graded preorder*

$$h_O : U \times U \to V_O$$

for some quantale V_O chosen to match the observer's representational regime. In the p-bit *case,* $h_O(u, v) = (h^+_O(u, v), h^-_O(u, v))$ *encodes positive and negative evidence for "u is above v."*

The freedom to choose V_O is not merely technical: it expresses that different observers may treat the same underlying signals as probabilities, costs, plausibilities, bipolar evidences, or even multi-criteria vectors. Even for a fixed observer, different respects-of-comparison can justify different codomains: "priority under time pressure" might be naturally cost-like, while "explanatory generality" might be naturally evidence-like. In the p-bit (positive/negative bit) case, allowing both h^+_O and h^-_O to be simultaneously large permits the model to represent genuine tension (e.g., competing heuristics) without forcing an immediate resolution; the graded preorder axioms then constrain how such tensions propagate along chains of comparisons.

Remark 482 (Intuition and simple examples)**.** *This definition bakes in a central Hyperseed stance: hierarchy is not "in the world" as a bare relation, but in the triad (world, observer, respect-of-comparison). Formally, h_O is indexed by O, and even the codomain V_O is chosen to suit O's mode of representation (Hyperseed-Concept 86).*

A simple example is a task-based priority ordering in an intelligent system: U might be a set of goals or subgoals, and $h_O(u, v)$ encodes the degree to which u has priority over v given the current task context (cf. the broader AGI motivation for context-relative prioritization in [19]). Another example is an explanatory hierarchy: U might be hypotheses, and $h_O(u, v)$ measures how strongly u is judged a "higher-level" explanation than v in the sense of compressing more data with fewer assumptions [5]. The utility of this observer-indexed view is that it lets us discuss multiple coexisting hierarchies without contradiction: distinct observers (or the same observer at different times) may impose distinct but internally coherent V_O-orders.

A further consequence of indexing by O is that changes in context can be modeled as changes in h_O itself rather than as inconsistencies in a single absolute hierarchy. For instance, if O shifts from "short-term reward" to "long-term safety" as the respect-of-comparison, the domain U may remain the same while the ranking relation changes substantially; this is naturally expressed by moving to a different h_O (or, equivalently, treating the observer as updated). Similarly, disagreements between observers can be tracked at the level of their chosen quantales and aggregation rules: two observers might share the same underlying comparisons but combine them differently (different $\otimes$), or they might treat alternative supports differently (different $\oplus$), yielding different induced hierarchies even when looking at the same evidence. In this sense, "observer-assessed hierarchy" is a portability layer: it isolates the order-like constraints (reflexivity, transitivity) from the representational conventions by which O encodes and composes comparative judgments.

Remark 483 (Values and "higherness")**.** *Hyperseed's gloss is that entities higher in a hierarchy are "more valuable in some sense." Formally, this can be captured in several equivalent ways:*

- Order-first: *define h_O directly as an order of priority or importance.*
- Value-first: *define a valuation $\nu_O : U \to V$ (or to $\mathbb{R}$) and set $h_O(u, v)$ to be evidence that $\nu_O(u) \geq \nu_O(v)$.*
- Constraint-first: *define h_O as the order induced by a model class (e.g. the simplest causal explanations), so that "higher" means "more explanatory" or "more compressive."*

In later sections, these perspectives will be linked: in a resource-sensitive ontology, "valuable" typically means "valuable for prediction/control under bounded effort," which often correlates with explanatory compression. In particular, the "value-first" stance can be read as a representation theorem in miniature: whenever one has a (possibly graded) comparative judgment of "at least as important as," it is often convenient to embed that judgment into a numerical or lattice-valued score ν_O that makes comparisons mechanically checkable. Conversely, the "order-first" stance emphasizes that the comparison itself is primary: one may know that u outranks v even when no single scalar score captures all the reasons, motivating valuations into richer codomains V (e.g. vectors, intervals, or evidence pairs). The "constraint-first" stance makes explicit that "higher" can be tied to a background standard of adequacy: if two descriptions fit observed behavior equally well, then the one requiring fewer degrees of freedom, fewer exceptions, or fewer ad hoc auxiliary assumptions can be treated as "above" the other because it supports more robust generalization under perturbation or distribution shift.

Remark 484. *The equivalence of these perspectives is not merely a convenience; it expresses a deeper pragmatic unity. In a Whiteheadian idiom, "value" is a mode of selection among processes, while "explanation" is a mode of organization among descriptions; the point of a formalism like a graded preorder is precisely that it allows these to be treated as two views of the same comparative act [15]. One can read the graded preorder as recording a* practice *of preference rather than a discovery of a metaphysical ladder: what counts as "higher" is the result of repeated comparative acts (selection, attention, justification) stabilized into a relation. This also clarifies why "equivalence" here should be taken up to the observer's operational needs: different encodings (order-first vs. value-first) may disagree on fine structure while remaining interchangeable with respect to the tasks that motivated the hierarchy in the first place.*

11.3 Systemic hierarchy via models of a dynamical system

Hyperseed introduces "systemic hierarchy" to emphasize that a hierarchy is often not a primitive of the system, but a structure induced by a *model*. The intended case is: a dynamical system D is mapped into a symbolic domain S equipped with a partial order. In this framing, "systemic" is meant to contrast with purely stipulative taxonomies: the hierarchy is anchored in regularities of D as *captured* by ϕ, even though it is not assumed to be uniquely determined by D without an observer, a language, and a purpose.

Definition 133 (Systemic hierarchy (model-induced))**.** *Let D be a dynamical system (in any sense suitable for the application). Let $\mathrm{Proc}(D)$ denote a set of processes (or process-types) associated with D. A* hierarchical model *of D consists of:*

- *a symbol domain S;*
- *a (possibly partial) order relation $\prec_S$ on (part of) S;*
- *an interpretation map (a model) $\phi : \mathrm{Proc}(D) \to S$.*

We say that D manifests a systemic hierarchy relative to *$(S, \prec_S, \phi)$ if ϕ is sufficiently faithful for the observer's purposes and $\prec_S$ is used to guide prediction, explanation, or control. The qualifier "for the observer's purposes" is doing substantive work: faithfulness may mean predictive adequacy, counterfactual reliability, or control-relevant abstraction rather than isomorphism to an underlying "true" state space. Likewise, allowing $\prec_S$ to be defined only on part of S permits models in which only some symbols participate in the hierarchical comparison (e.g. only those corresponding to actionable options, stable patterns, or salient macrostates).*

Remark 485 (Intuition and examples)**.** *The definition is a reminder that hierarchy often appears* after *representation. The system D unfolds in time; the observer selects a set of processes $\mathrm{Proc}(D)$ to pay attention to; and only then does an ordering $\prec_S$ become meaningful as a cognitive or engineering tool (Hyperseed-Concept 133).*

Example: in control, one may model a robot's dynamics by a set of nested controllers and treat high-level policies as "above" low-level motor primitives. Here S is a symbolic space of controller-states, and $\prec_S$ encodes dominance/override relationships among control modules, used to guide action selection [19]. Example: in explanation, one may map physical micro-processes into a symbolic domain of macro-regularities; then "higher" means "more compressive" or "more predictive" relative to some descriptive cost (echoing the pattern-based compression stance [5]). The usefulness of the definition is that it legitimizes plural hierarchies as plural models: different ϕ and $\prec_S$ can both be "right" insofar as they serve distinct purposes. A helpful way to read ϕ is as a choice of coarse-graining*: many distinct trajectories or micro-events in D may be sent to the same symbol in S, and the induced hierarchy then ranks the* symbols *(i.e. the equivalence classes the observer cares about), not the underlying microstates directly. In the control example, "dominance" may itself be context-sensitive (e.g. safety overrides goal pursuit), so $\prec_S$ can encode normative or design constraints (what* should *happen) as much as empirical regularities (what* does *happen). In the explanation example, "compressive" can be understood relative to an explicit description length, a model class capacity, or an algorithmic resource budget; thus the same D can yield different "higher" macropatterns when the observer changes the allowable explanatory vocabulary.*

Remark 486 (Fuzzy and paraconsistent systemic hierarchy)**.** *In realistic cognitive settings, the order $\prec_S$ may be incomplete (only some pairs are comparable) and may be graded or disputed. This is naturally modeled by taking $\prec_S$ to be a graded preorder $h_S : S \times S \to V$. If $V = [0,1]^2$, then $h_S(s,t) = (h_S^+(s,t), h_S^-(s,t))$ can encode both evidence and counterevidence for "s precedes t" (or "s dominates t"). Such a representation is useful when different data sources, different evaluators, or different time-slices of the same evaluator support incompatible rankings: rather than forcing a premature linearization, one records the support structure and postpones commitment to a single* *crisp order. Operationally, graded comparisons can be used to implement decision procedures such as "prefer s to t when $h_S^+(s,t)$ exceeds a threshold and $h_S^-(s,t)$ remains below a tolerance," making explicit how hierarchy-guided action depends on risk appetite and error costs.*

Remark 487 (Why the model view matters)**.** *The same underlying system D may admit many different hierarchical models depending on:*

- *the observer's values and tasks;*
- *the level of abstraction (which distinctions are ignored);*
- *which variables are treated as controls versus observations;*
- *which explanatory language is chosen.*

Hyperseed treats this plurality as normal. Thus, "systemic hierarchy" is best read as: there exists a useful hierarchy in some modeling space that guides successful interaction with the system*. This perspective also clarifies what it means for two hierarchies to "disagree": they may be ranking different symbolizations of the same processes, or the same symbolization under different loss functions and intervention capabilities. For example, an engineer optimizing reliability may place fault-monitoring processes "above" throughput-optimizing processes, while an economist modeling the same organization may rank activities by revenue contribution; both hierarchies can be faithful in their respective senses, because faithfulness is indexed to what is being predicted, explained, or controlled.*

Remark 488. *In Peircean terms, one may say that a systemic hierarchy is a particular way in which Thirdness (law-like mediation) is projected onto a flux of Seconds (actual interactions) and a field of Firsts (qualities felt as salient) [14]. The formal point remains: the hierarchy is carried by $(S, \prec_S)$ and by the interpretive act ϕ, not by D alone. Equivalently, the hierarchy is a property of a semiotic triad (world, signs, interpreter) rather than a property of the world taken in isolation: change the signs (S), the comparative practice ($\prec_S$), or the interpretive mapping (ϕ), and the resulting "systemic hierarchy" may change even when D does not. This does not trivialize hierarchy; it locates its objectivity in reproducible modeling and successful coordination: if many observers with similar access and aims converge on similar $(S, \prec_S, \phi)$, then the induced hierarchy can be treated as stable for those purposes.*

11.4 Subpattern hierarchy: patterns within patterns

Hyperseed defines a subpattern hierarchy by declaring $y \le x$ when y is a *compositional subpattern* of x. The informal criterion is: y can be combined with something else to form a pattern in x. We formalize this using the combination operation from Section 9.

Definition 134 (Compositional subpattern)**.** *Fix a domain of entities X and a combination operation $* : X \times X \to X$ (not assumed commutative). Let $\mathcal{P}$ be a set of pattern-representers (in simple settings one may take $\mathcal{P} = X$, but we keep it separate). Assume we have a (possibly graded) predicate*

$$\mathrm{Pat}(p; x) \in [0,1]$$

interpreted as "degree to which p is a pattern in x" (e.g. pattern intensity).

For $p, q \in \mathcal{P}$, we say that p is a compositional subpattern of q*, written*

$$p \preceq_{\mathrm{sub}} q,$$

if there exists some $r \in X$ such that $\mathrm{Pat}(p * r; q)$ *is nontrivial (e.g. strictly positive, or above a chosen threshold). In a graded version, define the subpattern strength*

$$h_{\mathrm{sub}}(p, q) := \sup_{r \in X} \mathrm{Pat}(p * r; q).$$

Remark 489 (Intuition, examples, and usefulness)**.** *The guiding intuition is almost embarrassingly concrete: p is a subpattern of q if p can serve as a reusable "piece" in constructing a pattern that fits q (Hyperseed-Concept 182). The quantifier "there exists r" is the formal way to say "p can be completed."*

Example 1 (strings): let X be strings and $*$ be concatenation. Let $\mathrm{Pat}(p; x)$ *be high when p is a compressive description of x (Section 9, cf. [5]). Then $p \preceq_{\mathrm{sub}} q$ says: there is some string r such that the concatenation $p*r$ is itself a strong pattern for q. Example 2 (feature composition): let X be structured feature-bundles, and let $*$ combine feature-sets. Then $p \preceq_{\mathrm{sub}} q$ says: the feature-pattern p can be augmented to yield a pattern adequate for q.*

This definition is useful because it turns the informal "patterns within patterns" idea into an algebraic relation that can be composed and closed (later yielding hierarchy-like structure and, via path closure, a web-like structure).

Remark 490 (Two readings)**.** *The relation $p \preceq_{\mathrm{sub}} q$ can be read in (at least) two complementary ways:*

- Constructive: *q can be built (in part) from p by composition.*
- Explanatory: *p is a reusable regularity that helps compress or predict q.*

The constructive reading matches "patterns within patterns." The explanatory reading matches the idea that higher-level patterns summarize or bundle lower-level ones. Both will be used later (especially in Sections 12 and 13).

Proposition 15 (Subpattern is a preorder under associativity)**.** *Assume $*$ is associative and has an identity element $e \in X$. Assume also that for each $p \in \mathcal{P}$ there is an embedding of p into X (so that $p * e$ is defined) and that* $\mathrm{Pat}(p * e; p)$ *is nontrivial. Then $\preceq_{\mathrm{sub}}$ is a preorder on $\mathcal{P}$.*

Remark 491 (What the proposition says, and why it matters)**.** *The statement is: once "combination" behaves like a monoid operation (associative with identity), the subpattern relation behaves like a genuine order-like comparison: every pattern is a subpattern of itself (reflexivity), and subpatternhood chains (transitivity). This is important because it shows that an apparently heuristic notion ("p is a piece of q") inherits the same formal stability properties as more familiar hierarchies. It also connects this section back to the enriched-order viewpoint above: preorders are precisely the crisp case of V-enriched thin categories.*

Proof. (Reflexivity.) For $p \in \mathcal{P}$, choose $r = e$. By assumption $\mathrm{Pat}(p*e; p)$ is nontrivial, so $p \preceq_{\mathrm{sub}} p$.

(Transitivity.) Assume $p \preceq_{\mathrm{sub}} q$ and $q \preceq_{\mathrm{sub}} s$. Then there exist $r_1, r_2 \in X$ such that $\mathrm{Pat}(p*r_1; q)$ and $\mathrm{Pat}(q*r_2; s)$ are nontrivial. Using associativity, $(p*r_1)*r_2 = p*(r_1*r_2)$. Under the intended compositional semantics of patterns (Section 9), a pattern used to form q can be re-used inside a composite pattern used to form s. Thus $\mathrm{Pat}(p*(r_1*r_2); s)$ is nontrivial (possibly with reduced degree), implying $p \preceq_{\mathrm{sub}} s$. □

Remark 492 (Proof sketch and intuition)**.** Proof sketch. *Reflexivity uses the identity element e: completing p by "doing nothing" yields p again, so p is trivially a component of itself. Transitivity uses associativity: if p can be completed to something that patterns q, and q can be completed to* *something that patterns s, then concatenating the completions yields a completion witnessing that p can be completed to pattern s.* $\square$

The key step is the reassociation $(p * r_1) * r_2 = p * (r_1 * r_2)$, which licenses the informal move "reuse the subpattern inside the larger composition." Geometrically, one can picture p as a reusable module, and r_1, r_2 as successive "adapters"; associativity says that the order of bracketing the assembly does not change the assembled whole, so the module relationship persists through multi-stage construction.

Remark 493 (Antisymmetry and "pattern identity")**.** *To obtain a partial order one needs a notion of when two patterns are "the same." In practice, pattern identity is observer-relative: two patterns may be distinct at one resolution and equivalent at a coarser resolution. Thus, it is often best to treat the subpattern hierarchy as a preorder and then quotient by an equivalence relation appropriate to the observer. This aligns with the general Hyperseed stance that equivalence is a re-description of which distinctions are being ignored (Hyperseed-Concept* **??***). In particular, antisymmetry fails precisely when the observational interface cannot (or chooses not to) distinguish two patterns that are mutually subpatterns of one another: one may have $p \preceq q$ and $q \preceq p$ without wanting to conclude $p = q$ as syntactic objects. The quotient construction makes this explicit by replacing "pattern identity" with an equivalence class $[p]$ of mutually inter-subpattern patterns, so that the resulting relation on classes becomes antisymmetric. Concretely, if $\preceq$ is a preorder on patterns and one defines $p \sim q \iff (p \preceq q \ \wedge \ q \preceq p)$, then $\sim$ captures "indistinguishable for this observer, at this granularity"; different observers (or the same observer under a different coarse-graining map) may choose different $\sim$. One can also read the observer-relative choice of $\sim$ as specifying which internal degrees of freedom are treated as gauge: two patterns are identified when they differ only by transformations that the observer treats as non-informative.*

11.5 Heterarchy: multi-path structure and loops

Hyperseed uses "heterarchy" as the opposite of "tree thinking": multiple distinct paths connect entities, and the network contains loops. In cognition and society this is typical: concepts mutually constrain each other, roles interlock, values conflict, and control is distributed. Formally, the point is not merely that there are many nodes and edges, but that relational structure does not factor through a single spine: there is generally no privileged unique lineage of explanation, delegation, or causation. Accordingly, heterarchy is also a warning against forcing a directed acyclic graph (DAG) model too early: cycles often encode precisely the feedback that makes an organization, a mind, or a culture self-maintaining.

Definition 135 (Heterarchy)**.** *A* heterarchy *on a set of nodes U is a directed graph (or weighted digraph)*

$$G = (U, E, w)$$

with the property that for many pairs (u, v) there exist multiple distinct directed paths from u to v, and G contains directed cycles. If weights live in a quantale V, we interpret $w(u, v) \in V$ as a graded link strength. In this definition "for many pairs" is intentionally informal: heterarchy is meant as a structural regime rather than a sharp graph property, and the relevant notion of "many" is domain- and scale-dependent (e.g. dense conceptual association versus sparse but consequential institutional channels). When V is a quantale, the intended semantics is that path composition aggregates along a route via the monoidal product $\otimes$, while competing routes can be compared or pooled using the join structure (often denoted $\oplus$ or $\bigvee$); the enriched viewpoint below makes this explicit.

Remark 494 (Intuition, examples, and why the definition is phrased this way). *A heterarchy is a formal acknowledgement that influence is rarely a single chain. In a conceptual network, there may be several different reasons why u suggests v; in a social network, several institutional routes by which one role constrains another; in a cognitive architecture, several routes by which perception and action co-determine each other [19]. Such multiplicity is not noise; it is the medium by which robustness and conflict coexist (Hyperseed-Concept* **??**).

Example: let U be concepts, and put an edge $u \to v$ when u reliably predicts v in a dataset; then loops encode mutually reinforcing concept-clusters. Example: let U be agents/roles in an organization, and put an edge $u \to v$ when u can request actions from v; loops encode delegation and feedback. The definition is phrased in terms of multiple paths and cycles because these are precisely the features that distinguish a web from a tree: a tree has unique simple paths and no directed cycles. A further reason to phrase the definition this way is methodological: in most empirical settings, it is easier to detect (i) the existence of distinct routes between two points and (ii) the presence of feedback loops than it is to justify any single total ranking or layered decomposition. Equivalently, cycles and multi-path connectivity are "witnesses" that no single linear explanation (or command chain) can be globally valid without loss. In applications one often refines this intuition by analyzing strongly connected components (SCCs): an SCC is a maximal region of mutual reachability, and the condensation graph of SCCs is a DAG. From this angle, a heterarchy can be seen as a system whose dynamics and semantics live primarily inside (possibly large) SCCs, rather than being well-described by the acyclic skeleton alone.

Remark 495 (Heterarchy as a non-thin enriched category). *A hierarchy is "thin": between any two nodes there is (at most) one order value. A heterarchy is better modeled as a general (possibly non-thin) enriched category, where there may be multiple morphisms between u and v representing different explanatory or causal routes. If one wants to remain in the thin setting, one may collapse multiple routes by taking a join (supremum) over path strengths, yielding a single composite strength. Both options appear in Hyperseed practice. In the enriched reading, a distinct directed path is not merely redundant evidence: it can correspond to a different* type *of entailment (e.g. statistical association versus mechanistic constraint), a different mediator (institutional channel A versus channel B), or a different timescale. Keeping multiple morphisms allows one to track these differences explicitly, while composition encodes how routes concatenate. By contrast, the thin collapse (taking a supremum over routes) yields a convenient "best available" or "dominant" linkage, which is often what one wants for scoring, visualization, or approximate reasoning, but it intentionally forgets the internal pluralism that generated the linkage in the first place.*

Definition 136 (Cycle mass (one simple heterarchy index)). *Let $V = [0, 1]$ with $\otimes$ as multiplication and $\oplus$ as maximum, and let $G = (U, E, w)$ be a weighted digraph. Define the* cycle mass *of G by*

$$\mathrm{Cyc}(G) := \max \Big\{ \prod_{i=1}^{k} w(u_i, u_{i+1}) : (u_1, \ldots, u_k) \text{ is a directed cycle} \Big\},$$

with $u_{k+1} = u_1$. Then $\mathrm{Cyc}(G) > 0$ iff G contains a directed cycle with nonzero weight. If G has no directed cycles, the displayed set is empty; in that case one may take $\mathrm{Cyc}(G) := 0$, consistent with the stated iff condition and with the intuition that an acyclic digraph has no "returning signal" at any positive strength.

Remark 496 (Intuition and a toy example). *If each edge-weight is read as a multiplicative "reinforcement factor," then the product around a cycle measures how strongly a signal can return to its starting point after traversing that loop. For a simple 2-cycle $u \to v \to u$ with weights a and b, the* *cycle mass includes the product ab. If either $a = 0$ or $b = 0$, the loop is broken; if both are near 1, the loop is strong. The usefulness of this (admittedly toy) index is that it anticipates the later dynamical claim: habit-taking is autocatalytic and tends to strengthen existing loops (Section 12), so quantifying "loop strength" matters. One can also view $\mathrm{Cyc}(G)$ as a "best feedback gain" under multiplicative composition: it selects the most self-reinforcing directed cycle, not the average cycle. This is appropriate when a single dominant feedback loop can govern qualitative behavior (e.g. a stable institutional feedback channel, or a self-supporting belief cluster), even if many weaker loops also exist. A mild variant replaces the maximum by another aggregator (e.g. a softmax or a sum over cycles) when one wants a notion of distributed cyclicity rather than dominance.*

Remark 497. *The particular definition of $\mathrm{Cyc}(G)$ is not canonical; it is only a toy measure. In later sections, cycles in pattern webs will matter because habit dynamics (Section 12) are autocatalytic: they preferentially reinforce existing loops. It is also worth noting that even this toy measure depends on modeling choices: using multiplication privileges long cycles by accumulating factors, whereas other semiring/quantale choices (e.g. max–min, or additive log-weights) emphasize bottlenecks or total gain differently. Thus, $\mathrm{Cyc}(G)$ should be read as one concrete instantiation of a broader idea: heterarchy invites quantitative indices that are sensitive to feedback, and different indices correspond to different interpretations of what it means for a loop to be "strong" in the domain at hand.*

11.6 Pattern webs from pattern profiles and pattern-based distances

Hyperseed introduces a "pattern web" as a heterarchical structure derived from patterns. One natural construction is:

1. assign to each entity $x \in X$ its fuzzy set of patterns (a *pattern profile*);
2. define a distance between entities in terms of distances between their pattern profiles;
3. convert the distance into a weighted graph (the pattern web).

We give a general construction that can be instantiated in several ways. In particular, the construction deliberately factors the modeling choices into (i) a pattern vocabulary $\mathcal{P}$, (ii) an intensity assignment I, (iii) a notion of profile distance D, and (iv) a graph-building rule. This separation is useful because each component can be varied independently (e.g. refining $\mathcal{P}$ without changing the graph construction rule, or changing D while keeping I fixed), and because it makes explicit where observer- and task-dependence enters.

Definition 137 (Pattern profile)**.** *Let X be a set of entities and $\mathcal{P}$ a set of patterns. Assume we have a pattern-intensity map*

$$I : \mathcal{P} \times X \to [0,1], \qquad I(p,x) = \text{"intensity of pattern } p \text{ in } x\text{"}.$$

For each $x \in X$ define its pattern profile *(a fuzzy set of patterns)*

$$F_x : \mathcal{P} \to [0,1], \qquad F_x(p) := I(p,x).$$

It is often convenient (though not required) to regard $I(p,x)$ as implicitly relative to a context, observation process, or modeling interface, so that one could write $I_C(p,x)$ when emphasizing contextual dependence. In this reading, two analysts with different contexts or sensors may induce different pattern profiles for the "same" underlying x, and hence different pattern webs, without any contradiction: the web is a structure over the modeled entities as distinguished by the chosen pattern interface.

Remark 498 (Intuition, example, and why the definition is useful). *A pattern profile is simply the "fingerprint" of an entity in the pattern vocabulary: it tells you which patterns occur in x and with what strength (Hyperseed-Concept 130). If $\mathcal{P}$ is a finite set of candidate regularities, then F_x is a vector in $[0,1]^{\mathcal{P}}$.*

Example: suppose $\mathcal{P} = \{p_{\text{round}}, p_{\text{red}}, p_{\text{edible}}\}$ and x is an apple (in some context C). Then $F_x(p_{\text{round}}) \approx 0.8$, $F_x(p_{\text{red}}) \approx 0.6$ (green apples exist), $F_x(p_{\text{edible}}) \approx 0.9$. The utility is that once entities are mapped to profiles, we can speak about similarity, clustering, neighborhood, and network propagation without committing to the raw internal structure of x. This is the formal bridge from "pattern" to "pattern web" emphasized in [5].

A further practical advantage is that profiles support partial comparability: two entities can be compared even when their "internal" representations are heterogeneous, so long as they admit pattern intensities against a shared $\mathcal{P}$. Conversely, if two domains cannot share a useful $\mathcal{P}$ (or cannot be mapped into it by a meaningful I), then the construction makes clear that the limitation lies in the pattern interface rather than in the downstream graph machinery.

Remark 499 (Connection to Hyperseed properties). *In Hyperseed, the* property-set *of x is essentially the fuzzy set of patterns in x, with membership degree equal to pattern intensity. Thus F_x can also be read as a property profile. We keep the term "pattern profile" here to emphasize its role in constructing higher-order structure.*

In applications, one may additionally include pattern weights to encode salience or reliability of patterns (e.g. downweighting noisy detectors, or upweighting rare but informative patterns). Such weights can be folded either into the intensity map I (by rescaling intensities) or into the subsequent choice of D (by using a weighted distance), and the present definitions accommodate both approaches.

Definition 138 (Pattern-based pseudo-metric). *Fix a metric (or pseudo-metric) D on the space of fuzzy subsets $[0,1]^{\mathcal{P}}$. Define*

$$d_P(x, y) := D(F_x, F_y).$$

We call d_P the pattern-based pseudo-metric *on X.*

When $\mathcal{P}$ is infinite (e.g. a very large or even uncountable pattern family), specifying D typically entails additional structure (such as a measure on $\mathcal{P}$, a summability condition, or a choice of feature map into a normed space). For instance, one may replace finite sums by integrals, or restrict attention to patterns with non-negligible intensity, yielding a well-defined comparison even when $\mathcal{P}$ is conceptually open-ended.

Remark 500 (Intuition and conventions). *A pseudo-metric is like a metric except it may assign distance 0 to distinct points; this matches the idea that two distinct entities might be indistinguishable at the pattern-resolution induced by $\mathcal{P}$. The symbol D denotes any chosen distance on profile space; d_P is then the induced distance on entities. This is a clean instance of Hyperseed's broader theme: geometry is observer-relative because the chosen distinctions (here, the chosen pattern vocabulary and intensity map) determine which entities are near or far (Hyperseed-Concept 98).*

From a modeling standpoint, allowing $d_P(x, y) = 0$ for $x \neq y$ is often desirable: it expresses that the pattern vocabulary may be coarse-grained, or that the available evidence cannot separate the entities. One may then treat the induced equivalence relation $x \sim y \iff d_P(x, y) = 0$ as an informational quotient, and view the pattern web as operating on equivalence classes at the chosen pattern-resolution.

Example 11 (Finite-pattern ℓ^1 distance). *If $\mathcal{P}$ is finite, we may define*

$$D(F,G) := \sum_{p\in\mathcal{P}} \big|F(p) - G(p)\big|.$$

Then $d_P(x,y)$ is the total absolute difference in pattern intensities across the pattern vocabulary.

A common variant is a weighted ℓ^1 distance,

$$D_w(F,G) := \sum_{p\in\mathcal{P}} w(p)\,\big|F(p) - G(p)\big|,$$

where $w(p) \geq 0$ encodes the relative importance, confidence, or discriminative value of pattern p. This makes explicit that the induced geometry can prioritize certain pattern dimensions without altering the underlying profile representation.

Remark 501 (A second simple example). *Another common choice (when $\mathcal{P}$ is finite) is the ℓ^2 distance $D(F,G) := \Big(\sum_{p\in\mathcal{P}}(F(p) - G(p))^2\Big)^{1/2}$, which penalizes large deviations more strongly. The formalism does not privilege either; it only insists that whatever notion of similarity one uses should be made explicit as a D.*

Depending on the application, one might prefer distances that compare profiles up to overall "mass" or scale. For example, cosine distance (derived from cosine similarity) emphasizes angular agreement between vectors and can be useful when absolute intensity magnitudes are less meaningful than relative pattern mixtures. Likewise, one can normalize profiles (e.g. by ℓ^1 or ℓ^2 norm when appropriate) prior to computing D, thereby distinguishing "composition" from "quantity" of pattern evidence.

Remark 502 (Hutchinson-style choices). *Hyperseed mentions using standard metrics (such as the Hutchinson metric) to compare fuzzy pattern-sets. The present formalism isolates the key idea: any reasonable choice of D yields a pattern-based geometry on X. The specific choice of metric is application-dependent.*

In the same spirit, if patterns carry an internal geometry or ground space (e.g. patterns are distributions over some base domain, or are themselves structured objects), then D can be chosen to respect that structure (e.g. optimal-transport-type distances, kernel-induced distances, or other task-aligned divergences). The point is not to mandate a particular metric family, but to make the dependency of the resulting web on the comparison principle explicit and inspectable.

Definition 139 (From distance to a weighted pattern web). *Fix a monotone decreasing kernel $\kappa : [0,\infty) \to [0,1]$. Define a similarity weight*

$$s(x,y) := \kappa\big(d_P(x,y)\big).$$

A pattern web *on X is a weighted (undirected or directed) graph*

$$W = (X, E_W, w_W)$$

constructed from $s(x,y)$, for example by:

- threshold graph: *include edge (x,y) iff $s(x,y) \geq \tau$;*

- k-NN graph: *connect each x to its k nearest neighbors under d_P;*
- full graph: *take $E_W = X \times X$ with weights $w_W(x, y) = s(x, y)$.*

If a directed web is desired, one can obtain directionality either by using an inherently asymmetric comparison (e.g. a divergence-like D on profiles, or an inclusion/entailment score between fuzzy sets) or by using an asymmetric graph construction rule (e.g. k-NN edges $x \to y$ when y is among the k nearest to x). Even when D is symmetric, k-NN graphs are typically directed unless symmetrized (e.g. by mutual k-NN), and this choice affects the reachability and propagation properties of the resulting pattern web.

Remark 503 (Intuition, examples, and necessity)**.** *This definition performs a familiar maneuver: convert distance ("far means unrelated") into similarity ("near means connected"). The kernel κ is monotone decreasing so that larger distances yield smaller similarities. Example: $\kappa(t) = e^{-\lambda t}$ (a Gaussian-like choice) makes similarity decay exponentially with distance.*

Why is this useful? Because a graph is the natural substrate for heterarchical reasoning: once we have edges, we can talk about multi-step paths, loops, and propagation of support (Hyperseed-Concept 132). In cognitive terms, the pattern web is the externalized form of the judgment "these things share patterns and thus should inform each other," as in earlier Hyperseed discussions [1, 5].

The kernel scale (e.g. λ above, or an analogous bandwidth) plays the role of a resolution parameter: small changes in bandwidth can turn a sparse web into a dense one, changing the balance between local neighborhoods and long-range connections. Similarly, the choice between thresholding, k-NN, and full graphs reflects a trade-off between interpretability and computational cost: thresholding yields explicit "strong ties," k-NN yields bounded degree (often beneficial for scalability), and the full graph preserves all graded similarities but may be impractical for large X. These are not merely engineering details; they influence which heterarchical pathways exist for multi-step association and which loops can form in the induced structure.

Remark 504 (Pattern web as an enriched space)**.** *There are two closely related enriched-category readings:*

- Metric enrichment: *(X, d_P) is a Lawvere metric space, i.e. a category enriched in the quantale $([0, \infty], \geq, +, 0)$.*
- Similarity enrichment: *(X, w_W) is a $[0, 1]$-enriched (or V-enriched) graph/category, where composition along paths multiplies similarities and joins over alternative paths.*

Both are useful. Metric enrichment emphasizes geometry and neighborhood structure; similarity enrichment emphasizes propagation of support along multiple routes. The formal core (Section 3) was designed to support either viewpoint.

11.7 Pattern webs as free V-categories

Given a weighted directed graph of patterns or entities, there is a standard way to "close" it under compositional reasoning. This is exactly the enriched-category analogue of taking the transitive closure of a relation.

Definition 140 (Path composition in a V-graph)**.** *Let V be a commutative quantale. A* V-graph *is a set U with a weight function*

$$g : U \times U \to V.$$

For a directed path $\pi = (u_0 \to u_1 \to \cdots \to u_n)$ *define its* path weight

$$w(\pi) := g(u_0, u_1) \otimes g(u_1, u_2) \otimes \cdots \otimes g(u_{n-1}, u_n).$$

Define the path-closure hom

$$\widehat{g}(u, v) := \bigoplus_{\pi : u \rightsquigarrow v} w(\pi),$$

where the join ranges over all finite directed paths from u *to* v *(including the empty path).*

Remark 505 (Notation unpacking and intuition)**.** *The symbol* $\pi : u \rightsquigarrow v$ *denotes a directed path starting at* u *and ending at* v*. The "empty path" is the path of length* 0 *from* u *to itself; by convention its weight is* e *(the unit of* $\otimes$*). Thus* $\widehat{g}(u, v)$ *aggregates evidence/support from* all *routes from* u *to* v *by:*

- *composing along a fixed route using* $\otimes$ *(sequential aggregation), and*
- *taking the join* $\oplus$ *over alternative routes (parallel aggregation).*

In the Boolean case this is exactly transitive closure: $\widehat{g}(u, v) = 1$ *iff there exists a path from* u *to* v*. In a graded case, it becomes "best-path" (or "best-aggregate") closure, depending on the quantale operations.*

Remark 506 (A tiny example)**.** *Let* $U = \{a, b, c\}$ *and suppose* $g(a, b) = 0.9$*,* $g(b, c) = 0.8$*,* $g(a, c) = 0.1$ *in* $V = [0, 1]$ *with* $\otimes = \times$ *and* $\oplus = \max$*. Then the path* $a \to b \to c$ *has weight* 0.72*, so* $\widehat{g}(a, c) = \max(0.1, 0.72) = 0.72$*. This captures the heterarchical idea that an indirect route can dominate a direct (but weak) link.*

Theorem 11 (Free V-category on a V-graph)**.** *Let* V *be a commutative quantale and* (U, g) *a* V*-graph. Define* $\widehat{g}$ *by path-closure as above, taking the empty path to have weight* e*. Then* $\widehat{g}$ *defines a* V*-enriched category on object set* U*. In particular:*

- *(identity)* $e \leq \widehat{g}(u, u)$ *for all* u*;*
- *(composition)* $\widehat{g}(u, v) \otimes \widehat{g}(v, w) \leq \widehat{g}(u, w)$ *for all* u, v, w*.*

Remark 507 (What the theorem says in plain language)**.** *Starting from a weighted directed graph, the theorem constructs the "best available" composite connection between any two nodes by looking at all finite paths and aggregating their weights. It then asserts that these composite connections automatically satisfy the axioms of a* V*-enriched category: there are identities (the empty paths), and composing a* $u \to v$ *connection with a* $v \to w$ *connection yields a valid* $u \to w$ *connection. So, path closure is not an ad hoc trick; it is the canonical completion of a graph into a compositional reasoning structure.*

Remark 508 (Why it matters here)**.** *This result is the formal hinge between "web" as a static picture and "web" as an inferential substrate. In a pattern web, one typically wants to propagate support (or inhibition, or relevance) along multi-step routes. The theorem guarantees that once we pick a quantale* V *describing how supports combine, the propagation algebra is coherent by construction. This coherence is exactly what later habit dynamics exploit: repeated updating tends to amplify already-available composite routes (Section 12).*

Proof. Identity holds because the empty path from u to u is included and has weight e, hence $e \le \widehat{g}(u,u)$.

For composition, fix u, v, w. A path from u to w can be formed by concatenating a path $\pi_1 : u \rightsquigarrow v$ and a path $\pi_2 : v \rightsquigarrow w$. The weight of the concatenated path is $w(\pi_1) \otimes w(\pi_2)$ by associativity of $\otimes$. Thus, for each pair of paths (π_1, π_2) we have

$$w(\pi_1) \otimes w(\pi_2) \le \widehat{g}(u,w),$$

because $\widehat{g}(u,w)$ is the join over *all* $u \rightsquigarrow w$ paths. Taking joins over all π_1 and π_2 and using distributivity of $\otimes$ over joins gives

$$\Big(\bigoplus_{\pi_1 : u \rightsquigarrow v} w(\pi_1) \Big) \otimes \Big(\bigoplus_{\pi_2 : v \rightsquigarrow w} w(\pi_2) \Big) \le \widehat{g}(u,w).$$

The left-hand side is $\widehat{g}(u,v) \otimes \widehat{g}(v,w)$. □

Remark 509 (Proof sketch and key-step commentary)**.** Proof sketch. *The strategy is to show that the empty path supplies identities, and that concatenating paths supplies composition. Since $\widehat{g}(u,w)$ is defined as a join over* all *$u \rightsquigarrow w$ paths, every particular concatenated path contributes a lower bound, and distributivity lets us lift from particular paths to joins over all paths.* □

The heart of the argument is the monotonicity encoded by joins: if a value is among the terms joined to make $\widehat{g}(u,w)$, then it is $\le \widehat{g}(u,w)$. Concatenation produces the relevant term, and distributivity is what permits "join of left paths" $\otimes$ "join of right paths" to be bounded by the "join of all concatenations." Visually, one can imagine all paths as threads in a fabric: $\widehat{g}(u,v)$ summarizes all threads from u to v, and composition corresponds to splicing threads at v to create longer threads from u to w.

Remark 510 (Interpretation)**.** *If $g(u,v)$ encodes "u supports/predicts/constructs v", then $\widehat{g}(u,v)$ encodes overall support aggregated across all pathways. This is the mathematical backbone of the "web" picture: multi-path reinforcement is represented by the join over paths. If V is* p-bit*-valued, then the same construction supports paraconsistent webs in which multiple routes can provide both support and counter-support. In particular, when V is a join-semilattice (or more generally a quantale), the hat-construction $\widehat{g}$ can be read as a kind of transitive closure: it aggregates not only direct edges $u \to v$ but also indirect chains $u \to \cdots \to v$ by composing along the chain and then taking the join over all chains. Thus $\widehat{g}(u,v)$ measures the best (or most permissive, depending on V) composite evidence that v is reachable from u through the pattern web. When $V =$* p-bit*, the aggregation by joins can simultaneously retain distinct "positive" and "negative" contributions: different paths can witness different polarities without forcing collapse to a single consistent truth value. This is precisely the sense in which the same path-join formalism can model webs that are tolerant of contradiction: the global value $\widehat{g}(u,v)$ records what the web as a whole supports, rather than demanding that all routes agree.*

11.8 Multi-resolution transforms and weakness

Hierarchies are often produced by *abstraction*: collapsing distinctions and bundling lower-level details into higher-level summaries. Pattern webs, likewise, are usually considered at multiple resolutions. We express this using maps (functors) between pattern spaces. At an informal level, the point is that the same underlying system can be described by many different "alphabets": a fine alphabet with many entity- and pattern-types, and a coarse alphabet in which many fine types are identified. The usefulness of a multi-resolution formalism is that it allows one to compare statements made at different descriptive granularities while keeping track of which claims survive abstraction and which are artifacts of fine detail.

Definition 141 (Resolution maps on entities and patterns)**.** *Let X be an entity set and $\mathcal{P}$ a pattern vocabulary. A* resolution change *from a fine description to a coarse one consists of:*

- *a surjective map $\alpha : X \to X'$ (coarse-graining of entities);*
- *a map $\beta : \mathcal{P} \to \mathcal{P}'$ (coarse-graining of patterns);*
- *a rule for pushing forward intensities $I(p, x)$ to $I'(p', x')$.*

A simple pushforward rule is

$$I'(p', x') := \sup\{I(p, x) : \beta(p) = p',\ \alpha(x) = x'\}.$$

Remark 511 (Intuition and example)**.** *Coarse-graining is the formal act of deciding that many differences do not matter for the present purpose. The maps α and β implement this decision on entities and patterns, respectively. Example: X might be images, X' might be object-categories; α maps an image to its category label. Similarly, $\mathcal{P}$ might contain fine-grained visual motifs while $\mathcal{P}'$ contains coarser semantic patterns.*

The pushforward rule via sup *says: a coarse pattern p' holds of a coarse entity x' if* any *of its fine refinements held strongly in* any *representative fine entity mapping to x'. This matches one common cognitive stance: a coarse label is licensed by the strongest supporting instance. The definition matters because multi-resolution comparison is ubiquitous in transfer and abstraction workflows; it is also a bridge to later frameworks emphasizing structured transfer and abstraction [7]. One can also read the* sup *rule as a left Kan extension–style "best upper approximation" of the fine intensity profile by a coarse one: the coarse description is the least committal (largest) assignment consistent with the existence of a supporting witness downstairs. In settings where intensities live in an ordered domain (e.g. $[0, 1]$, a Boolean algebra, or* p-bit*), the use of* sup *ensures that I' is monotone with respect to adding more fine-grained evidence: enlarging the set of fine representatives for a given (p', x') can only increase (never decrease) the pushed-forward intensity. Surjectivity of α is a convenient way to insist that every coarse entity $x' \in X'$ corresponds to at least one fine representative; if α were not surjective, then some coarse entities would be "empty bins," and one would need a convention for the* sup *over an empty set (often the bottom element of V).*

Remark 512. *The pushforward rule above is "optimistic": it preserves any strong evidence that a coarse pattern holds of a coarse entity. Other rules (averaging, expectation, evidence-weighted pooling) may be more appropriate in specific domains. The key point is that coarse-graining can be treated as a monotone operator on pattern profiles. In particular, if $I \le J$ pointwise (every fine intensity in I is bounded by the corresponding one in J), then the induced coarse profiles satisfy $I' \le J'$ under the* sup *rule, since* sup *is monotone in its arguments. This monotonicity is what makes multi-resolution moves compatible with order-enriched viewpoints: resolution change is not merely a lossy projection, but a structured map that respects the underlying preorder of evidential strength.*

Proposition 16 (Coarse-graining is monotone and increases weakness)**.** *Assume an observer's indistinction relation $H \subseteq X \times X$ is pushed forward along α to an indistinction relation $H' \subseteq X' \times X'$ by declaring*

$$(\alpha(x), \alpha(y)) \in H' \text{ whenever } (x, y) \in H.$$

Then H' collapses at least as many distinctions as H. In particular, for any monotone weakness functional $w(\cdot)$ (Section 3.7),

$$w(H) \leq w(H').$$

Remark 513 (Plain-English meaning and connection to earlier results)**.** *The proposition says: when you merge fine entities into coarse ones, you cannot create new distinctions; you only lose them. Therefore any sensible measure of "weakness" (in Hyperseed's technical sense: degree of collapsed distinction-making power) can only increase. This connects directly to the monotonicity theorem for weakness (Theorem 1) and provides a small formal justification for the intuitive idea that abstraction trades detail for simplicity [3, 2] (Hyperseed-Concept 202). Equivalently, passing from H to H' is an order-preserving move in the lattice of indistinction relations: H' contains at least the images of the indistinguishabilities already present in H, and so represents an observer who is (at best) as discriminating as before. If H were an equivalence relation capturing exact perceptual indistinguishability, then the pushforward along α can be seen as inducing a coarser equivalence on X'; the proposition is then the familiar idea that quotienting (or identifying states) cannot increase information.*

Proof. Every indistinction asserted by H induces an indistinction asserted by H'. Thus the set of undistinguished (coarse) pairs contains the image of the set of undistinguished (fine) pairs. Monotonicity of weakness under adding undistinguished pairs (Theorem 1) yields $w(H) \leq w(H')$. More explicitly: if $(x, y) \in H$, then by definition $(\alpha(x), \alpha(y)) \in H'$, so $\{(\alpha(x), \alpha(y)) : (x, y) \in H\} \subseteq H'$. Hence H' is at least as permissive an indistinction relation on the space of coarse entities as the one induced from H, and any weakness functional that is monotone under enlarging the indistinction set must satisfy the stated inequality. □

Remark 514 (Proof sketch and intuition)**.** Proof sketch. *Pushforward along α maps each "confused pair" in X to a "confused pair" in X'. So the coarse observer cannot distinguish at least the pairs the fine observer could not. Then apply monotonicity of w.* □

The key step is the containment claim: H's indistinction assertions survive (as images) in H'. Geometrically, one can think of α as collapsing points into blobs; any pair of points that were already indistinguishable lie in blobs that are indistinguishable in the quotient. The inequality $w(H) \leq w(H')$ is then the numeric shadow of this collapsing. Another way to visualize the same argument is via fibers of α: each coarse point $x' \in X'$ represents a fiber $\alpha^{-1}(x') \subseteq X$. Indistinguishability at the fine level propagates to indistinguishability between fibers at the coarse level, so the coarse description inherits all the "blind spots" of the fine one and may add new ones due to fiber-merging.

Remark 515 (Why this belongs in the hierarchy section)**.** *A hierarchy is often the* result *of a multi-resolution move: the "higher" nodes are coarse summaries that ignore fine distinctions. The proposition formalizes the directionality: moving upward in an abstraction hierarchy typically increases weakness (simplicity) while reducing detail. Later, wu-wei style dynamics (Section 26) will treat "acting with minimal forcing" as moving along flows that are biased toward such weak (simple) representations [21]. In this sense, the same formal move (pushing forward along α) explains two commonplace observations about hierarchies: (i) higher levels are cheaper to reason about because they track fewer distinctions, and (ii) higher levels may be more robust because they do not depend on unstable fine-grained differences. The weakness increase inequality gives a compact way to state that these benefits come with an intrinsic limitation: any decision rule that relies on fine discriminations must be expected to degrade under repeated coarse-graining.*

11.9 Section wrap-up

This section reconstructed four Hyperseed notions in a uniform mathematical language:

- *Hierarchy/systemic hierarchy* as observer-indexed (graded) order, often model-induced. In particular, the "grade" can be read as an explicit resource parameter (e.g. resolution, budget, attention, or tolerance) that determines which distinctions are available, so that what counts as "above" or "below" is not absolute but arises from a chosen standpoint. The phrase "model-induced" emphasizes that the ordering is frequently an artifact of a representation scheme: change the features, the abstraction map, or the inference rule, and the resulting order can refine, coarsen, or even reorder comparisons.

- *Subpattern hierarchy* as the preorder generated by compositional subpattern relationships. Here "generated" signals a closure process: one starts from primitive subpattern links (e.g. "appears as a component of," "factors through," "can be assembled into"), and then takes the smallest reflexive and transitive relation containing them. The fact that the result is a preorder (rather than necessarily a partial order) is conceptually important: different construction paths can yield mutual reachability without forcing equality, capturing the idea that two patterns may embed into one another under composition while remaining distinct as descriptions or mechanisms.

- *Heterarchy* as multi-path, loop-rich network structure. The emphasis on multiple paths encodes the coexistence of alternative explanations, realizations, or routes of influence; the emphasis on loops encodes feedback, mutual reinforcement, and circular dependence. In this view, "non-tree-like" is not merely a combinatorial complication but a signal that comparative relations are context-sensitive and can be revisited: traversing a loop can accumulate costs, change effective granularity, or expose tensions between competing constraints.

- *Pattern web* as a heterarchy derived from the geometry of pattern profiles. Geometric language is meant literally: patterns are represented by profiles (e.g. vectors, distributions, or enriched morphisms) whose relative position determines adjacency, similarity, and feasible transitions under bounded resources. The resulting web is therefore not an arbitrary graph but one induced by a metric-, order-, or quantale-enriched notion of distance/effort, so edges and path weights reflect how distinctions deform under abstraction, noise, or compression.

Read together, these four reconstructions explain how seemingly different vocabularies—rank, inclusion, feedback, and profile geometry—can be treated as different presentations of the same underlying compositional machinery. In particular, the shift from "hierarchy" to "web" is not a change of topic but a change of emphasis: from single-chain comparability to the coexistence of many compatible (and incompatible) comparison pathways, with explicit accounting of the resources required to traverse them.

Remark 516. *The unifying thread is compositionality: in hierarchies, comparisons compose; in webs, paths compose; in multi-resolution transforms, abstraction composes with indistinction and thereby reshapes weakness. Once these are all placed within the same quantale-enriched idiom, it becomes easier to see why Hyperseed can move fluidly between "order" talk and "network" talk without changing subject: both are presentations of structured distinction-making under resource bounds. Concretely, enrichment supplies a common semantics for "how much" (cost, effort, or uncertainty) accompanies a comparison or transition: composing comparisons adds/aggregates that quantity, while taking meets/joins expresses the presence of multiple competing routes. In this sense, hierarchy is the special case where the web of comparisons is sufficiently rigid (or sufficiently* *observed through a single grading) that it behaves like an ordered scaffold, whereas heterarchy is the generic case in which composition exposes parallelism, feedback, and nontrivial trade-offs between pathways.*

The next section (Section 12) adds time and dynamics: it studies how webs reinforce themselves into habits, how they sometimes reverse, and how morphic resonance couples habit dynamics across contexts. From the perspective of the present section, this amounts to endowing the pattern web with update rules that change edge strengths, accessibility, or effective grades as interactions repeat. The same compositional principles then reappear in temporal form: repeated traversals compose into long-run tendencies, loops become attractors or oscillations, and the resource bounds that shaped static comparison now shape learning rates, persistence, and the conditions under which a previously weak distinction can become stable.

12 Habits, self-weaving webs, and morphic resonance

This section reconstructs the Hyperseed dynamical cluster *tendency to take habits* (Hyperseed-Concept 189), *tendency to reverse habits* (Hyperseed-Concept 188), *self-weaving webs* (Hyperseed-Concept 168), and *morphic resonance/anti-resonance* (Hyperseed-Concept 115, Hyperseed-Concept 114) using the minimal formal core (Section 3) and the pattern-web machinery (Sections 11–9). For the broader Hyperseed framing of these notions, see [1].

The key modeling move is to treat a *pattern web* (Hyperseed-Concept 132) as a V-valued directed graph (equivalently, a V-relation) whose edges encode reinforcement or "flow" of pattern support, and to treat habit formation as a family of order-theoretic update operators on V-valued pattern-support states. Morphic resonance is then a cross-context coupling of these same dynamics, in a way philosophically reminiscent of "habit" as a cosmological tendency in Peirce and process-like propagation in Whitehead [14, 15]. In more concrete terms, one may think of a pattern web as a weighted adjacency structure on a set of pattern-indices, where the weight on an arrow $p \to q$ summarizes "how much" support for p tends to induce, propagate, or transform into support for q. The choice of a quantale V allows these weights and supports to be more expressive than ordinary real-valued probabilities: in particular, V can encode graded truth, graded evidence, multi-aspect valuation, or even paraconsistent combinations of support and counter-support, while still providing a disciplined algebra (join, multiplication, order) for composing influences along paths and aggregating multiple sources of reinforcement.

A central theme in what follows is that the above informal notions can be separated into two interacting ingredients: (i) a *structural* ingredient, namely the pattern web itself as a V-relation capturing potential channels of influence; and (ii) a *dynamical* ingredient, namely the operators that update pattern-support states in response to that structure (and to possible external inputs). The "tendency to take habits" will be modeled by update maps that, in a precise order-theoretic sense, consolidate and amplify frequently traversed channels of support, so that repeated activation makes certain state configurations easier to re-enter. The "tendency to reverse habits" will be modeled by companion updates that weaken, invert, or otherwise reorganize these consolidations under suitable triggers, so that entrenched trajectories can become unstable and alternative trajectories can become accessible. The concept of "self-weaving webs" will be treated as the case where the web is not fixed in advance but is itself an evolving object influenced by the very states whose propagation it shapes, yielding a feedback loop between representation (edges) and activity (support values).

Remark 517 (Notation and reading conventions for this section)**.** *We will repeatedly use function spaces of the form V^P, meaning the set of all functions $s : P \to V$ (pattern-support states). When* *we write inequalities such as $s \leq s'$ for $s, s' \in V^P$, this is always the* pointwise *order: $s \leq s'$ iff $s(p) \leq s'(p)$ for all $p \in P$. Similarly, when we write $\oplus$ between two states (or two inputs) we mean the pointwise join induced by the quantale join in V. It is often useful to keep in mind the two complementary readings of the pointwise order: $s \leq s'$ can mean that s' contains at least as much support as s for every pattern, but it can also be read operationally as "s' is reachable from s by adding support and never removing it" (relative to the chosen order on V). This second reading is especially convenient when we treat habit-formation operators as inflationary or extensive maps on V^P, since then $s \leq H(s)$ expresses that an update H can only accrete (or at least not diminish) support, thereby formalizing a minimal sense in which repeated application stabilizes configurations.*

Throughout this section:

- V denotes a commutative quantale. For the concrete toy instantiations we use the p-bit quantale from Section 3.4. In particular, the commutativity assumption ensures that the "combination" of independent support flows (encoded via the quantale multiplication) does not depend on an arbitrary ordering of factors, which matches the intuition that multiple reinforcing sources can be fused without privileging a sequence.
- A *pattern class* is a set P of pattern-indices (abstract "pattern types"). In applied settings P can be a finite or countable subset of the space of candidate patterns from Section 9 (see also the pattern-web discussion in [5]). The abstraction here is deliberate: we only require that elements of P can be used as coordinates for states and as nodes in a directed V-graph, without committing to whether a "pattern" is a perceptual feature, a symbolic structure, a program, a hypothesis, a dynamical attractor, or some hybrid object.
- A *pattern-support state* is a function $s : P \to V$ assigning each pattern a graded (possibly paraconsistent) support value. In this formalism, a single state s may simultaneously encode multiple interacting kinds of information (e.g. evidence-for and evidence-against, or different modalities of support) as long as these are represented in the chosen quantale; the ensuing update dynamics then become a principled way of turning the "static" valuations in s into a time-evolving propagation process along the edges of the web.

The rest of the section will repeatedly move between three closely related objects: (i) a V-relation on P (the web), (ii) a state $s \in V^P$ (the current distribution of support over patterns), and (iii) a state transformer $H : V^P \to V^P$ (a habit operator). One reason for emphasizing this triad is that each of the Hyperseed notions under discussion can be cast as a constraint on, or a construction from, one of these objects: habit-taking concerns the algebraic and order-theoretic properties of H; self-weaving concerns rules for updating the underlying V-relation using s (and possibly also H); and morphic resonance concerns how multiple such triples (P, V, web) interact via coupling maps that transfer support across contexts. When we later speak of "reinforcement" or "anti-reinforcement," the formal interpretation will be that the relevant update either increases support along certain channels (via joins and multiplicative composition in V) or decreases it relative to other channels (e.g. by redirecting flow, introducing inhibitory edges, or applying an antagonistic coupling), always in a way that can be stated in the language of monotone maps, adjunctions, closure-like operators, or their duals.

12.1 From Hyperseed's probability phrasing to V-valued dynamics

Hyperseed's informal definitions of habit-taking and habit-reversal are stated in terms of probabilities of patterns occurring before versus after times T. To connect this to the paraconsistent core we separate two issues:

1. how to represent "pattern occurs" in a paraconsistent way; and

2. how to extract a scalar "occurrence propensity" from that representation when needed.

Definition 142 (p-bit occurrence evidence and scalarization)**.** *Assume the* p-bit *semantics of Section 3.2. A pattern-support value is* $s(p) = (s^+(p), s^-(p)) \in [0,1]^2$*, where* $s^+(p)$ *is positive evidence for "p occurs" and* $s^-(p)$ *is negative evidence.*

A scalarization *is a function* $\pi : V \to [0,1]$ *used when we want a single number comparable across time. For the* p-bit *quantale we will use one of:*

$$\pi_{\text{pos}}(v^+, v^-) = v^+, \qquad \pi_{\text{net}}(v^+, v^-) = \max(0,\, v^+ - v^-).$$

Remark 518 (Intuition: two-channel evidence and why scalarization is optional)**.** *A* p-bit *value* (v^+, v^-) *should be read as a compact record of two distinct pressures: how much the context is being pushed to affirm occurrence, and how much it is being pushed to deny it. This is the paraconsistent posture: we do not demand that the world (or the observer's record of it) collapse into a single consistent bit. One may view this as a formal version of the practical epistemic condition "I have reasons for and against," without forcing premature reconciliation (cf. the paraconsistent perspective developed in Section 3 and related work such as [23, 24]).*

Scalarization π *is then a* choice of lens*. For example, if* $s(p) = (0.7, 0.6)$ *then* $\pi_{\text{pos}}(s(p)) = 0.7$ *declares "there is strong positive pull," whereas* $\pi_{\text{net}}(s(p)) = 0.1$ *declares "net inclination is weak because conflict is strong." Neither is "the truth"; each is a deliberately chosen compression of a richer state, useful for connecting to probability-style statements about averages over time.*

Remark 519. π_{pos} *matches the simplest reading of Hyperseed's "probability of occurrence."* π_{net} *treats strong contradictory evidence as reducing effective occurrence propensity, which is often convenient when modeling anti-resonance or habit reversal as "net suppression."*

Definition 143 (Observer-indexed occurrence process)**.** *Fix a context/observer* C *and a pattern class* P*. A* (discrete-time) occurrence process *in* C *is a sequence*

$$s_0, s_1, s_2, \dots \quad \textit{with} \quad s_t : P \to V.$$

Given a scalarization π*, define the scalar occurrence propensity*

$$p_t(p) := \pi(s_t(p)) \in [0,1].$$

Remark 520 (Intuition and a minimal example)**.** *The sequence* $(s_t)_{t\geq 0}$ *is simply "how supported is each pattern, at each time, in this context?" For* $P = \{p\}$ *a singleton, this reduces to a one-dimensional time series in* V*; in the* p-bit *case, it is two coupled scalar time series* $(s_t^+(p), s_t^-(p))$*. For instance, repeated exposure might drive* $(s_t^+(p), s_t^-(p))$ *upward in the first coordinate while leaving the second roughly constant, reflecting growing positive evidence without resolving doubt.*

The value of formalizing this as a function $s_t : P \to V$ *is that we can later propagate support through a web (via a* V*-relation) and reason about global properties like monotonicity and fixed points using order theory, rather than relying on ad hoc verbal metaphors.*

Definition 144 (Tendency to take habits and tendency to reverse habits)**.** *Fix a distribution* ν *over a class* P *of patterns, a distribution* τ *over times* $T \in \{0, 1, 2, \dots\}$*, and a scalarization* π*. Define, for each* $p \in P$ *and time* T*,*

$$\mathrm{Pre}_T(p) := \mathbb{E}[\, p_t(p) \mid t < T\,], \qquad \mathrm{Post}_T(p) := \mathbb{E}[\, p_t(p) \mid t > T\,],$$

whenever these conditional expectations are defined.

The context C manifests the tendency to take habits *(relative to (P, ν, τ, π)) if*

$$\mathbb{E}_{p\sim\nu,\, T\sim\tau}\big[\mathrm{Post}_T(p) - \mathrm{Pre}_T(p)\big] > 0.$$

It manifests the tendency to reverse habits *if the above expectation is < 0.*

Remark 521 (Intuition and why the quantifiers matter)**.** *The quantities $\mathrm{Pre}_T(p)$ and $\mathrm{Post}_T(p)$ compare average propensities before and after a sampled "cut" time T. The outer expectation over $p \sim \nu$ and $T \sim \tau$ makes the definition intentionally meta-statistical: one is not declaring that* every *pattern increases, but that there is a systematic bias in the time direction on average, relative to a chosen ensemble of patterns and time windows.*

A simple example is the following. Suppose P is finite and for each $p \in P$ the scalar propensity is $p_t(p) = \min(1, a_p + bt)$ with $b > 0$. Then for any reasonable τ the average after T will exceed the average before T, yielding habit-taking. Conversely, exponential forgetting $p_t(p) = c_p\lambda^t$ with $0 < \lambda < 1$ yields habit-reversal.

Remark 522. *Definition 144 is intentionally "meta-statistical": it measures a bias in time-directional change averaged over a chosen pattern class and time sampling scheme. This matches Hyperseed's wording ("on average over patterns P in class C, and times T") while making the indexing explicit.*

Lemma 3 (Monotone time series imply habit-taking; antitone imply reversal)**.** *Assume $p_t(p)$ is nondecreasing in t for every $p \in P$. Then for every T and p for which the conditional expectations exist,*

$$\mathrm{Post}_T(p) \geq \mathrm{Pre}_T(p).$$

Consequently, the tendency-to-take-habits expectation in Definition 144 is ≥ 0.

If instead $p_t(p)$ is nonincreasing in t for every $p \in P$, then $\mathrm{Post}_T(p) \leq \mathrm{Pre}_T(p)$ and the tendency-to-reverse-habits expectation is ≤ 0.

Remark 523 (What the lemma is saying, in plain terms)**.** *If every pattern's scalar propensity is drifting upward over time, then the "after" average cannot be below the "before" average: the future is at least as supportive as the past, in this coarse statistical sense. Likewise, if everything drifts downward, then the future is (on average) less supportive. The lemma is not deep; its importance is methodological: it reduces a philosophical notion (habit-taking as a time-asymmetric tendency) to a verifiable monotonicity property of the time-indexed propensities.*

Remark 524 (How this connects forward)**.** *Later in this section we will define concrete update operators $s_{t+1} = \mathsf{Upd}(s_t)$. Proposition 17 will show these operators are monotone (order-preserving), and in inflationary regimes the induced scalarized series $p_t(p)$ often becomes monotone as well, giving an immediate bridge from dynamics to the habit-taking criterion of Definition 144.*

Remark 525 (On the role of conditional expectations)**.** *The lemma is phrased pointwise in (T, p): whenever $\mathrm{Pre}_T(p)$ and $\mathrm{Post}_T(p)$ are defined (as conditional expectations over the "before" and "after" portions of the time axis, conditioned on the cut time T and the pattern p), the stated inequality holds. In particular, no distributional assumptions are needed beyond existence: neither stationarity nor independence of the time series is invoked, and the inequality is not an "in expectation" statement but an inequality between two conditional averages computed from the same underlying monotone sequence. This is why the conclusion survives the subsequent outer averaging over (T, p) in Definition 144: the sign is already determined at the conditional level.*

Remark 526 (Finite-window intuition as a special case)**.** *Although* $\mathrm{Pre}_T(p)$ *and* $\mathrm{Post}_T(p)$ *may be defined via semi-infinite averages (or other conditional averages, depending on the model), the lemma is already evident in the finite-window case: if one defines, for integers* $m, n \geq 1$*,*

$$\mathrm{Pre}_{T,m}(p) = \frac{1}{m}\sum_{t=T-m}^{T-1} p_t(p), \qquad \mathrm{Post}_{T,n}(p) = \frac{1}{n}\sum_{t=T}^{T+n-1} p_t(p),$$

then monotonicity implies every term in the right block dominates every term in the left block, hence $\mathrm{Post}_{T,n}(p) \geq \mathrm{Pre}_{T,m}(p)$*. Any limiting or conditional-expectation definition of* $\mathrm{Pre}_T(p)$ *and* $\mathrm{Post}_T(p)$ *that is compatible with such windowed approximations inherits the same inequality whenever the limits exist.*

Proof. If a sequence is nondecreasing, then the average of its terms after T is at least the average of its terms before T (whenever these averages exist). Apply this pointwise to each pattern p, then average over p and T. The nonincreasing case is analogous.

For completeness, one can spell out the elementary comparison in the common case of block averages: if $a_0 \leq a_1 \leq a_2 \leq \cdots$, then for any indices $i < j$ we have $a_i \leq a_j$. Hence if I is any finite set of indices all $< T$ and J is any finite set of indices all $\geq T$, then

$$\frac{1}{|I|}\sum_{t\in I} a_t \;\leq\; \frac{1}{|J|}\sum_{t\in J} a_t,$$

since every term in the left sum is bounded above by every term in the right sum. Taking $a_t := p_t(p)$ gives Pre $\leq$ Post for these approximating averages; passing to the chosen conditional-expectation notion yields $\mathrm{Pre}_T(p) \leq \mathrm{Post}_T(p)$ whenever the conditional expectations exist. □

Proof sketch. The proof uses only the elementary fact that if $a_0 \leq a_1 \leq a_2 \leq \cdots$, then any average of later terms is at least any average of earlier terms, because later terms dominate earlier ones pointwise. We apply this to each pattern's propensity series $p_t(p)$ and then use linearity of expectation to lift the inequality through the outer averaging over p and T.

Equivalently, one may view $\mathrm{Pre}_T(p)$ and $\mathrm{Post}_T(p)$ as two Cesàro-type functionals applied to the left and right tails of the same monotone sequence. Monotonicity forces the right tail to lie above the left tail, and any averaging functional that is monotone with respect to pointwise order preserves this comparison. □

Remark 527 (Commentary and intuition)**.** *One may picture the propensity sequence for a fixed* p *as a curve on the unit interval. If the curve never goes down, then any horizontal "cut" at time* T *separates smaller values (to the left) from larger values (to the right), so the right-side mean dominates the left-side mean. The lemma is thus a formal version of a simple geometric picture: monotone curves have a built-in temporal bias.*

Remark 528 (When the inequality is strict (and when it is not))**.** *The lemma only asserts a weak inequality because constant stretches carry no directional information. If* $p_t(p)$ *is strictly increasing on a set of times with nonzero weight in the definition of* $\mathrm{Pre}_T(p)$ *and* $\mathrm{Post}_T(p)$ *(for example, if there exist indices* $t < T \leq t'$ *with* $p_t(p) < p_{t'}(p)$ *that are sampled with positive probability), then typically one obtains* $\mathrm{Post}_T(p) > \mathrm{Pre}_T(p)$*. Conversely, if the series is eventually constant (or if* T *is chosen so that both "before" and "after" averages sample only a flat region), then equality is expected and corresponds to a neutral "no-habit-signal" situation under the tendency statistic.*

Lemma 3 reduces the Hyperseed habit notions to verifiable monotonicity properties of a dynamical update rule. We now provide such update rules.

12.2 Pattern webs as V-relations and habit update operators

Definition 145 (V-valued reinforcement relation (pattern-flow kernel)). *Let P be a pattern class. A* reinforcement relation *(or* pattern-flow kernel*) on P is a V-valued relation*

$$A : P \times P \to V.$$

Intuitively, $A(p, q)$ measures how strongly the presence of pattern p tends to increase the support for pattern q at the next time step, within a given context.

Remark 529 (Intuition: a weighted directed graph of support flow). *Think of P as nodes in a directed graph. Then $A(p, q)$ is the weight on the arrow $p \to q$, but with weights living in a quantale V rather than in $\mathbb{R}$. In the* p-bit *toy case, $A(p, q) = (0.9, 0.1)$ might be read as: "when p is present, it provides strong positive pressure toward q, and slight negative pressure against q as well." That is: causal/associative support is itself permitted to be ambivalent.*

This is useful because it lets us treat pattern webs (Hyperseed-Concept 132) as algebraic objects whose propagation can be computed and iterated, connecting the informal "web" metaphor to explicit operators (compare the broader pattern-network picture in [5]).

Remark 530 (Categorical reading: A as a V-relation in $\mathbf{Rel}_V$). *It is often helpful to view A as a morphism in the quantale-enriched category of V-relations: objects are sets (or classes) like P, and a morphism $P \to P$ is exactly a function $P \times P \to V$. Under this reading, the operator $s : P \to V$ is a "V-valued predicate" (a V-subset) on P, and $A \star s$ is the standard action of a V-relation on a V-predicate (an enriched direct image). This perspective makes later constructions feel less ad hoc: one is simply using the native algebra of V-enrichment to push support forward along edges.*

Definition 146 (Relational image operator). *Given $A : P \times P \to V$ and a state $s : P \to V$, define the* image *(or one-step propagation)*

$$(A \star s)(q) := \bigoplus_{p \in P} A(p, q) \otimes s(p).$$

Here $\oplus$ and $\otimes$ are the quantale join and product; the join is taken in V.

Remark 531 (Well-definedness when P is large). *The expression $\bigoplus_{p \in P}$ uses arbitrary joins in V. Thus, when P is infinite, the definition still makes sense provided the quantale is complete (as assumed) and we are working at a set-theoretic level where the join over P is legitimate. In applications one often has either (i) P finite, (ii) s with finite support, or (iii) a sparsity/decay condition on A ensuring only "effectively many" p contribute materially to each q.*

Remark 532 (Notation unpacking: what $\star$, $\oplus$, and $\otimes$ do). *The symbol $\star$ is not new structure; it is simply a name for the standard "relational image" construction induced by the quantale operations. For each target node q, we look at all sources p, combine the edge strength $A(p, q)$ with the source support $s(p)$ using $\otimes$, and then aggregate all these contributions using $\bigoplus$ (the join in V). When $V = [0, 1]^2$ with componentwise max as $\oplus$ and componentwise multiplication as $\otimes$, this says: "q receives the strongest (componentwise) multiplicative contribution from any predecessor."*

In a finite example with $P = \{p_1, p_2\}$, we have

$$(A \star s)(q) = \big(A(p_1, q) \otimes s(p_1)\big) \oplus \big(A(p_2, q) \otimes s(p_2)\big),$$

which is a quantale-analogue of summing influences, except that we use the join operation appropriate to the chosen notion of graded truth/evidence.

Remark 533. ***Special cases: Boolean and*** $[0,1]$***-valued kernels*** *If* $V = \{\bot, \top\}$ *with* $\oplus = \vee$ *and* $\otimes = \wedge$*, then* A *is an ordinary binary relation on* P*,* s *is a subset indicator, and* $(A \star s)(q) = \top$ *exactly when there exists some* $p \in P$ *with* $s(p) = \top$ *and* $A(p,q) = \top$*. In other words,* $A \star s$ *becomes one-step reachability along directed edges. If* $V = [0,1]$ *with* $\oplus = \max$ *and* $\otimes = \cdot$*, then* $A \star s$ *computes a "max-product" propagation common in fuzzy relation equations and certain log-domain message-passing schemes; the present setup can be read as a multi-channel generalization of that idea.*

Remark 534. *If* P *is finite,* A *can be viewed as a* $|P| \times |P|$ *matrix over a quantale semiring, and* $A \star s$ *is the usual matrix-vector multiplication with* $\oplus$ *as addition and* $\otimes$ *as multiplication (Section 3.4).*

Remark 535 (Monotonicity: propagation respects the V-order)**.** *Because* $\otimes$ *is monotone in each argument and* $\bigoplus$ *is a join, the map* $s \mapsto A \star s$ *is monotone with respect to the pointwise order on* V^P*. Concretely, if* $s \leq t$ *pointwise, then* $(A \star s) \leq (A \star t)$ *pointwise. This is one of the reasons quantales are a convenient ambient algebra: order-theoretic properties needed for iterating updates (e.g. existence of least fixed points) come for free under mild additional assumptions.*

To allow both habit formation and habit decay (reversal), we include an explicit "persistence/forgetting" factor.

Definition 147 (Persistence/decay scalar)**.** *Let* $d \in V$*. Given a state* $s : P \to V$*, define the pointwise scaled state*

$$(d \odot s)(p) := d \otimes s(p).$$

For the p-bit *quantale* $V = [0,1]^2$ *with* $\otimes$ *given by componentwise multiplication, choosing* $d = (d^+, d^-)$ *with* $d^+, d^- \in [0,1]$ *scales down both positive and negative evidence.*

Remark 536 (Intuition: persistence as inertia, decay as forgetting)**.** *The role of* d *is to encode what remains of the old support if nothing else happens. If* $d = e$ *(the quantale unit), then* $d \odot s = s$ *and the past persists perfectly. If* d *is strictly smaller (in an appropriate scalar sense), then the past is discounted, capturing forgetting or habit reversal by attrition.*

In the p-bit *toy case with componentwise multiplication, taking* $d = (0.95, 0.95)$ *is literal exponential decay applied symmetrically to both evidence channels. One can also imagine asymmetric decay, e.g.* $(0.95, 0.7)$*, representing a context that retains positive evidence longer than negative evidence (or vice versa).*

Remark 537 (On choosing d: timescales and stability heuristics)**.** *Heuristically,* d *sets a memory timescale: values closer to the unit* e *correspond to long persistence, while values farther from* e *enforce faster turnover. In many concrete instantiations (e.g.* $V = [0,1]$ *or* $V = [0,1]^2$ *with multiplicative* $\otimes$*), choosing* d *strictly below* e *also prevents indefinite accumulation from persistence alone and makes it easier for new input* u_t *to reshape the state, which matches the intended "habit can change" reading.*

Definition 148 (Habit dynamics operator)**.** *Fix a reinforcement relation* $A : P \times P \to V$ *and a persistence/decay scalar* $d \in V$*. Let* $u_t : P \to V$ *be an external input sequence.*

Define the update operator $\mathsf{Upd}_{A,d,u_t} : V^P \to V^P$ *by*

$$\mathsf{Upd}_{A,d,u_t}(s) := u_t \oplus (d \odot s) \oplus (A \star s),$$

where $\oplus$ *on the right-hand side is applied pointwise in* V^P*.*

A habit dynamics *in a context is any process satisfying*

$$s_{t+1} = \mathsf{Upd}_{A,d,u_t}(s_t).$$

Remark 538 (Interpretation: superposition as join, not arithmetic addition)**.** *The use of $\oplus$ (join) rather than a numeric sum is deliberate: the update aggregates contributions according to the evidence-combination logic encoded by V. In max-like quantales, this corresponds to a "winner-take-strongest" or "most-supported" aggregation; in other quantales, $\oplus$ can encode alternative combination rules (e.g. logical disjunction, cost minimization, or other idempotent semiring behaviors). Thus, although the formula resembles a linear recurrence, it is best read as a generic evidence propagation rule parametrized by the choice of quantale semantics.*

Remark 539 (Iterating the operator: trajectories and equilibria)**.** *Given an initial state s_0, the dynamics defines a trajectory $s_0, s_1, s_2, \dots$ by repeated application of Upd_{A,d,u_t}. When $u_t = u$ is time-independent, one can ask for a (contextual) equilibrium state s^* satisfying*

$$s^* = u \oplus (d \odot s^*) \oplus (A \star s^*),$$

i.e. a fixed point of the update. Because the update is built from monotone operations, fixed-point methods (least/greatest fixed points, Kleene iteration) are natural tools when additional conditions ensuring convergence are available in the chosen V and in the scale of P.

Remark 540 (Intuition: three sources of support)**.** *The update is the join of three contributions: (i) u_t, the new stimulation (what the world, body, or other subsystems inject at time t); (ii) $(d \odot s)$, persistence (what the system carries forward from its own past); and (iii) $(A \star s)$, internal propagation through the pattern web. This is deliberately schematic: it abstracts the idea that habit is neither purely memory nor purely current stimulus, but a synthesis in which the web's structure re-expresses and amplifies what is already present.*

A minimal worked toy example: let $P = \{p, q\}$ and suppose u_t stimulates only p. If $A(p, q)$ is large, then even with $u_t(q) = \mathbf{0}$ the pattern q can grow over time because it is downstream of p. Thus "habit-taking" can appear as a derived phenomenon: repeated stimulation of one pattern recruits others via the web.

Remark 541 (Reading $A \star s$ as self-weaving reinforcement)**.** *The term $A \star s$ formalizes the "self-weaving" aspect of a pattern web: whenever a pattern becomes supported, it can in turn become a source of support for other patterns according to the context-specific kernel A. In this sense, A is not merely a static adjacency structure; it is a learned or given bias about which co-activations tend to follow which other activations, and the update equation makes that bias operational as a propagating field over P.*

Remark 542 (About $\mathbf{0}$ and "no input")**.** *When we write $\mathbf{0}$ for a relation or state, we mean the bottom element in the appropriate function space: for a state $s : P \to V$, $\mathbf{0}$ is the constant function $p \mapsto \bot_V$ (the bottom of V); for a relation $A : P \times P \to V$, $\mathbf{0}$ is the constant relation $(p, q) \mapsto \bot_V$. In the* p-bit *toy quantale, $\bot_V = (0, 0)$.*

It is worth emphasizing the semantic distinction between absence of evidence *and* negative evidence*: writing $\mathbf{0}$ encodes the former, i.e. that no support is present (or no coupling is present) in the sense of the order of V. This is not the same as assigning a special "inhibitory" value unless such inhibition is explicitly represented by elements of V and their order (in which case the bottom element would still be the least inhibitory/least supportive option, not an additional kind of signal). In particular, "no input" means that the exogenous drive term contributes the least possible value everywhere, not that the node is removed from P or that the dynamics is undefined.*

Concretely, if the update rule combines terms by $\oplus$ (a join), then using $\mathbf{0}$ behaves as an identity for "adding nothing" in the lattice-theoretic sense: $x \oplus \bot_V = x$. Likewise, using $A = \mathbf{0}$ means no propagation through the web, since every path contribution is uniformly bottom and hence cannot raise any join.

Remark 543 (Special cases)**.** • Pure reinforcement (no forgetting)*: $d = e$ and $u_t \equiv \mathbf{0}$ (bottom element), so $s_{t+1} = s_t \oplus (A \star s_t)$. This is inflationary and models cumulative habit formation. In this case, any node can only keep or increase its current level of support, and the only source of further increase is the propagation term $A \star s_t$. If one iterates this update from a given initial seed, one obtains an increasing chain of states (with respect to the pointwise order) whose growth is controlled entirely by the connectivity pattern encoded in A.*

- Pure decay (no reinforcement)*: $A = \mathbf{0}$ and $u_t \equiv \mathbf{0}$, so $s_{t+1} = d \odot s_t$. If d is strictly below the unit in an appropriate scalar sense, this models habit reversal via forgetting. Here the dynamics factorizes across nodes: each $s_t(p)$ evolves independently by repeated scaling, so any nontrivial long-range structure disappears and the web plays no role. This clarifies why forgetting alone cannot create new tendencies: it can only attenuate what is already present.*

- Driven dynamics*: nontrivial u_t models repeated external stimulation; the long-run effect depends on how A propagates and amplifies the input. In particular, even if u_t is localized in P (e.g. non-bottom on a small set of nodes), repeated application of the update can spread that support along edges where A is non-bottom, creating a broader pattern. Depending on whether decay dominates reinforcement, the result may settle to a stable pattern, oscillate in response to time-varying u_t, or keep accumulating if the update is inflationary.*

Proposition 17 (Monotonicity of the habit update)**.** *For fixed A and d, the map $s \mapsto \mathsf{Upd}_{A,d,u}(s)$ is monotone in s (order-preserving). It is also monotone in u and in A (pointwise order on relations).*

Remark 544 (Meaning and why it matters)**.** *This proposition says: if you start with more support, you cannot get less support after one update; likewise, stronger input and stronger couplings cannot decrease the next state. It is a minimal coherence condition for a reinforcement-style model. Without it, one could not reliably connect structural properties of A and u to the emergent time-bias criteria of Definition 144, nor could one safely apply standard fixed-point tools later in the section.*

Monotonicity is also the bridge to closure constructions: order-preserving inflationary operators are precisely the terrain in which Knaster–Tarski/Kleene style least-fixed-point reasoning becomes available, a theme that will recur in other Hyperseed stability analyses [10].

A further reason monotonicity matters is interpretability under parameter changes. If $A \leq A'$ pointwise, then any explanation phrased as "increasing a coupling" becomes unambiguous: the model guarantees that such a change cannot reduce *downstream support in the next step, so comparative statics can be done at the level of the order on V. Similarly, if $u \leq u'$, then increasing the external drive is guaranteed not to suppress any node, which matches the intended "reinforcement" reading of $\oplus$ as accumulation rather than competition.*

Proof. Each component of $\mathsf{Upd}_{A,d,u}(s)$ is built from $\oplus$ and $\otimes$ and a join over $p \in P$. In a quantale, $\otimes$ is monotone in each argument and distributes over arbitrary joins, and $\oplus$ is a join hence monotone. Therefore increasing s, u, or A can only increase the result.

More explicitly, the relevant order is the pointwise order on functions $P \to V$ and $P \times P \to V$: we write $s \leq s'$ iff $s(p) \leq s'(p)$ for all $p \in P$, and $A \leq A'$ iff $A(p,q) \leq A'(p,q)$ for all $p, q \in P$. Fix $p_0 \in P$. The value $\mathsf{Upd}_{A,d,u}(s)(p_0)$ is obtained by combining (via $\oplus$) contributions such as $(d \odot s)(p_0)$, $u(p_0)$, and the propagated term $(A \star s)(p_0) = \bigoplus_{p \in P} A(p_0, p) \otimes s(p)$. If $s \leq s'$, then for each p we have $A(p_0,p) \otimes s(p) \leq A(p_0,p) \otimes s'(p)$ by monotonicity of $\otimes$ in its second argument, hence taking the join over p preserves the inequality, yielding $(A \star s)(p_0) \leq (A \star s')(p_0)$. The same pointwise reasoning applies to $u \leq u'$ (monotonicity of $\oplus$ in the corresponding argument) and to $A \leq A'$ (monotonicity of $\otimes$ in its first argument), establishing monotonicity in all stated parameters. □

Proof sketch. The update operator is assembled from monotone building blocks. Pointwise, it is a join of three terms. Joins are monotone; $\otimes$ is monotone in each argument; and the $\bigoplus_{p\in P}$ aggregation preserves monotonicity because it is itself a join. Therefore any pointwise increase in s, u, or A propagates through the formula without creating decreases.

Equivalently, one can view $\mathsf{Upd}_{A,d,u}$ as a composition of monotone maps between complete lattices: first apply scalar/pointwise transformations (such as $s \mapsto d \odot s$), then apply the linear-propagation map $s \mapsto A \star s$, and finally merge all contributions by $\oplus$. Since the composition of monotone maps is monotone, the whole update is monotone. $\square$

Remark 545 (Visual intuition)**.** *If one imagines the web as channels that can only transmit or accumulate support (in the sense encoded by V), then "adding" an extra amount of support at any node cannot rationally lead to less support downstream if the update consists only of propagation and accumulation. The proposition is the algebraic reflection of this picture.*

The same picture applies to the parameters: increasing an edge weight in A corresponds to widening a channel, and increasing u corresponds to injecting additional support at some nodes. If the dynamics had subtractive or normalizing steps, such monotonicity could fail; the present formulation avoids that by restricting to the order-theoretic primitives $\oplus$, $\otimes$, and joins.

Monotonicity (Proposition 17) is a minimal sanity property: stronger present support or stronger couplings cannot lead to weaker next-step support. In particular, it ensures that iterating the update from $\mathbf{0}$ yields a well-defined increasing approximation process whenever the update is also inflationary, setting up the later use of least fixed points as canonical "habit closures" of a seed state.

12.3 Self-weaving webs and autocatalytic closure

Hyperseed's "self-weaving web" notion is meant to capture a pattern network whose own internal structure reinforces and recreates itself. In our setting, this becomes a fixed-point and closure story for the propagation operator.

Definition 149 (One-step closure operator)**.** *Fix $A : P \times P \to V$. Define the inflationary operator*

$$\mathsf{Cl}_A(s) := s \oplus (A \star s).$$

Remark 546 (Intuition: adding what the web can infer/propagate in one step)**.** $\mathsf{Cl}_A(s)$ *takes a support state and enriches it by one round of internal propagation. If s is a seed, then $(A \star s)$ is what the web can "grow" from that seed in one step, and the join $\oplus$ records that we keep the original seed support as well. This is the basic algebraic gesture behind "weaving": we do not replace the old pattern; we overlay it with its consequences.*

Definition 150 (Iterated closure and Kleene star)**.** *Define* $\mathsf{Cl}_A^{(0)}(s) := s$ *and* $\mathsf{Cl}_A^{(n+1)}(s) := \mathsf{Cl}_A(\mathsf{Cl}_A^{(n)}(s))$.

When V^P is a complete lattice (e.g. P finite and V complete), define the limit (join of the ascending chain)

$$\mathsf{Cl}_A^{(\omega)}(s) := \bigoplus_{n\geq 0} \mathsf{Cl}_A^{(n)}(s).$$

Also define powers of A by relational composition: $A^0 := I$ (identity relation) and $A^{n+1} := A^n \circ A$. Then define the Kleene star

$$A^* := \bigoplus_{n\geq 0} A^n.$$

Remark 547 (Notation unpacking: A^n and A^* as "all finite paths")**.** *The composition A^n is the n-step reinforcement relation: $A^2(p,r)$ aggregates reinforcement along all two-edge paths $p \to q \to r$, and so on. Thus A^* is the join of all A^n, i.e. the aggregate relation capturing reinforcement along* any finite chain*. This is the same algebraic pattern behind Kleene star in automata theory and Kleene algebras, here expressed in quantale language.*

Accordingly, $\mathsf{Cl}_A^{(\omega)}(s)$ is the seed s closed under repeated propagation: what you get by allowing the web to "echo" its own implications arbitrarily many times, without invoking any infinitary paths beyond the join already present in the lattice structure.

Theorem 12 (Closure as least fixed point; explicit A^* form)**.** *Assume P is finite and V is a commutative quantale. Then for every seed state $s : P \to V$:*

1. *The chain $\mathsf{Cl}_A^{(0)}(s) \le \mathsf{Cl}_A^{(1)}(s) \le \cdots$ is ascending and has a join $\mathsf{Cl}_A^{(\omega)}(s)$.*
2. *$\mathsf{Cl}_A^{(\omega)}(s)$ is a fixed point of Cl_A, and is the least fixed point of Cl_A above s.*
3. *The fixed point can be written as*
$$\mathsf{Cl}_A^{(\omega)}(s) = A^* \star s.$$

Remark 548 (Plain-English statement and why it is central here)**.** *Start with some initial support s. Apply one-step closure, then close again, and so on. Because closure only adds support (never subtracts), this produces an ascending sequence. The theorem says there is a well-defined "limit" state obtained by joining all these stages, and that this limit is exactly the smallest self-consistent state containing the seed: once you reach it, closing again adds nothing new.*

This is important because it gives a rigorous meaning to "self-weaving" as a fixed-point phenomenon. Instead of narrating that the web "recreates itself," we can point to a precise object $\mathsf{Cl}_A^{(\omega)}(s)$ and identify it both as a least fixed point and as an explicit propagation construction $A^* \star s$.

Remark 549 (Connection to the rest of the document)**.** *Fixed-point characterizations of "stable organization" recur in later discussions of agency and goal stability. The present theorem is a local, pattern-web-scale instance of that general motif, akin in spirit to other fixed-point applications in Hyperseed analyses [10].*

Proof. (1) Cl_A is inflationary because $\mathsf{Cl}_A(s) = s \oplus (A \star s) \ge s$, so iterating yields an ascending chain. Since V^P is complete (finite product of complete lattices), the join exists.

(2) Monotonicity of Cl_A and completeness of V^P imply the set of fixed points is nonempty and forms a complete lattice (Knaster–Tarski). Because Cl_A is inflationary, the join of the iterates from s is a post-fixed point; a standard argument (Kleene fixed-point theorem in complete lattices for such algebraic operators) gives it is the least fixed point above s.

(3) Unfolding the recurrence shows $\mathsf{Cl}_A^{(n)}(s) = \bigoplus_{k=0}^{n} A^k \star s$. Taking $\bigoplus_{n\ge 0}$ and using distributivity of $\otimes$ over joins yields $A^* \star s$. □

Proof sketch. The operator Cl_A is inflationary and monotone, so iterating it from a seed produces an ascending chain. In a complete lattice, the join of this chain exists. Standard fixed-point theory says that for such operators, this join is the least fixed point above the seed. Finally, expanding $\mathsf{Cl}_A^{(n)}(s)$ shows it collects exactly the contributions along paths of length at most n, hence the ω-join corresponds to summing over all finite path lengths, which is precisely $A^* \star s$. □

Remark 550 (Key steps: why they work)**.** *The essential technical facts are (i) completeness of V^P when P is finite, (ii) monotonicity and inflationarity of Cl_A, and (iii) distributivity of*

$\otimes$ over joins (the quantale axiom). Inflationarity ensures we have an increasing approximation sequence; distributivity ensures we can commute propagation with taking joins, so that "propagate after joining" matches "join after propagating." This is why the explicit formula $A^* \star s$ appears: it is the algebraic normal form of "all finite chains of reinforcement."

Concretely, when P is finite and V is complete, the pointwise order makes V^P a complete lattice, so the iteration $s \le \mathsf{Cl}_A(s) \le \mathsf{Cl}_A^2(s) \le \cdots$ has a well-defined join $\bigoplus_{n\ge 0} \mathsf{Cl}_A^n(s)$. Monotonicity is what guarantees that these iterates are comparable and that joins of approximants behave as expected under further applications of Cl_A; in standard fixed-point terms, this is exactly the hypothesis one needs for a least fixed point construction in a complete lattice. In typical quantale semantics one can also unpack A^* as a Kleene-style star, $A^* = \bigoplus_{n\ge 0} A^{\otimes n}$ (with $A^{\otimes 0}$ the identity relation), so that the closed-form expression $A^* \star s$ is literally the join of all n-step propagations $A^{\otimes n} \star s$. The distributivity axiom is what lets this decomposition be pushed through the $\star$-action: it ensures that accumulating alternative routes of support (joins) is compatible with composing successive reinforcements (tensor products), so that the closure captures "all ways of getting there" rather than privileging a particular bracketing of compositions.

Remark 551 (Hyperseed reading)**.** *$A^* \star s$ is the total "downstream closure" of an initial seed s under the reinforcement relation A: it aggregates the support transmitted along all finite reinforcement chains. This is a precise sense in which repeated co-occurrence and associative structure can "weave" a larger support pattern from a smaller seed.*

Equivalently, if one defines $s_0 := s$ and $s_{n+1} := s_n \oplus (A \star s_n)$, then the increasing family $(s_n)_{n\ge 0}$ is an explicit approximation to the closure, and $A^* \star s$ is the join of all stages of this self-amplifying propagation. This makes clear that no single application of A is privileged: what matters is the accumulation of support across any finite number of reinforcement steps, including the possibility of revisiting intermediate patterns and thereby compounding evidence. In particular, if s concentrates mass on a small set of generators, then $A^* \star s$ describes the full footprint of what those generators can collectively activate, modulated by the weights in A and the way $\otimes$ combines successive transmissions.

Remark 552 (Geometric/graph intuition)**.** *In graph terms, $A^* \star s$ assigns to each node q the aggregate influence of all directed paths starting at any seed node, with path contributions combined multiplicatively along edges (via $\otimes$) and aggregated across alternative paths (via $\oplus$). If one pictures each edge as a conduit that attenuates and possibly distorts evidence, then A^* is the total field of influence generated by repeatedly sending signals through the network.*

One can read A^* as the weighted reachability relation: $(A^*)(q,p)$ is the total support by which p can be reached from q through any finite directed walk, with composition of edges evaluated by $\otimes$ and competition/branching between walks evaluated by $\oplus$. On this reading, $A^* \star s$ is a path-sum (or walk-sum) semantics: it is the analogue of taking a transitive closure in the crisp case, but with a quantitative accumulation law determined by the chosen quantale. This is also why cycles matter: feedback loops correspond to families of paths that revisit nodes, and the star construction is the algebraic device that folds all such finite unfoldings into a single closed expression.

Definition 151 (Autocatalytic (self-weaving) support)**.** *Fix a reinforcement relation $A : P \times P \to V$ and a threshold $\theta \in V$.*

*A nonempty subset $S \subseteq P$ is called θ-*autocatalytic* if there exists a state $s : P \to V$ such that:*

1. *(support on S) for all $p \in S$, $s(p) \ge \theta$; and*

2. *(self-production) for all $p \in S$, $(A \star s)(p) \ge \theta$.*

A pattern web (P, A) *is a* self-weaving web *(at threshold* θ*) if it contains a* θ*-autocatalytic subset.*

The two clauses separate "having enough of the patterns present" from "being able to reproduce that presence using the web's own reinforcement dynamics." The existential quantifier over s *is important: it says that there is at least one coherent way of assigning support levels so that every element of* S *is simultaneously above threshold and is simultaneously regenerated above threshold by the influence coming from* S *(and possibly from outside* S *if* s *has additional mass elsewhere). In applications one often considers* s *that is concentrated on* S *(e.g. an indicator-like state in crisp cases, or a uniform* θ*-level assignment on* S *in graded cases), but the definition is stated to allow any state witnessing the closure property.*

Remark 553 (Intuition and a simple example)**.** *This definition formalizes the "autocatalytic set" motif (Hyperseed-Concept 61): a set* S *of patterns is self-sustaining if, once* S *is supported above threshold, the web dynamics generated by* S *re-produces support above threshold for every member of* S*. In the simplest crisp case where* $V = \{0, 1\}$ *and* $\theta = 1$*, the condition says: each node in* S *has at least one incoming edge from some node in* S *(support can be regenerated from within the set).*

The usefulness is conceptual: it provides a minimal criterion for "the web can keep itself going" independent of external input. In later discussions of minds and systems, this is the pattern-web analogue of closure under production dependencies.

In graded settings (e.g. $V = [0, 1]$ *with a t-norm for* $\otimes$*), the same clauses express that each member of* S *receives enough aggregate reinforcement from the current support configuration to stay above* θ*. The condition does not force a unique witness state* s*; rather, it identifies sets* S *for which there exists at least one support configuration making* S *self-maintaining, and this flexibility is often what one wants when modeling multiple possible "operating points" of a system. Graphically, the crisp characterization can be strengthened in familiar ways (e.g. insisting on a directed cycle through each node, or on strong connectivity), and the present definition should be read as the quantitative analogue of such internal-regeneration conditions, expressed at the level of the* $\star$*-propagation operation.*

Remark 554. *Definition 151 is intentionally minimal and matches the "autocatalytic set" motif: each pattern in* S *is supported by the reinforcement generated from patterns in* S *itself. Stronger definitions can require minimality of* S*, robustness under perturbations, or explicit compositional generation mechanisms (Section 9).*

For example, one may ask that S *be inclusion-minimal among* θ*-autocatalytic sets (no proper subset has the same property), or that the inequalities hold with a margin above* θ *to ensure persistence under small decreases of support. One may also require that the witness state* s *be supported* only *on* S *(a stricter internal-closure reading), or that self-production be witnessed not just in one step* $(A \star s)$ *but as a post-fixpoint condition* $s \leq \mathsf{Cl}_A(s)$*, making the closure operator itself the object of stability. These refinements become relevant when one wants to distinguish mere possibility of self-support from dynamical attractiveness or from modular compositionality of the generating mechanisms.*

12.4 Morphic resonance and morphic anti-resonance as cross-context coupling

Hyperseed defines morphic resonance as habit-taking among spatially separated patterns, and morphic anti-resonance as the reverse. We model "spatial separation" abstractly by indexing multiple contexts (locations, subsystems, or reality-systems) and adding coupling kernels between their pattern webs. This formalization is mathematically orthodox (coupled dynamical systems) while leaving room for the broader interpretive reading of morphic resonance as a nonlocal "field of habit" in the sense associated with Sheldrake [13]. Concretely, "coupled dynamical systems" here means that each context has its own local state-update rule, but the rule is allowed to depend (via an explicit input term) on the current states of other contexts; the only "distance" notion needed is membership in distinct indices $\ell \in \mathcal{L}$. The intent is that the coupling term is written in exactly the same algebra as internal reinforcement, so that cross-context influence can be treated as another instance of the same habit-amplifying mechanism, rather than as an ad hoc external disturbance.

Definition 152 (Family of contexts and internal habit kernels)**.** *Let $\mathcal{L}$ be an index set of contexts (e.g. locations). For each $\ell \in \mathcal{L}$, fix:*

- *a pattern class P_ℓ;*
- *an internal reinforcement relation $A_\ell : P_\ell \times P_\ell \to V$;*
- *a decay scalar $d_\ell \in V$; and*
- *an external input process $u_{\ell,t} : P_\ell \to V$.*

A global state at time t is a tuple $s_t = (s_{\ell,t})_{\ell \in \mathcal{L}}$ with $s_{\ell,t} : P_\ell \to V$.

Remark 555 (Intuition: many webs at once)**.** *One can think of each $\ell \in \mathcal{L}$ as its own local pattern web with its own internal reinforcement. The global state s_t is simply the collection of all local support states at time t. This is the minimal formal move needed to discuss "at a distance": we do not need literal Euclidean distance, only a multiplicity of contexts and a notion of cross-context influence.*

Remark 556 (What is shared vs. what is local)**.** *Each context ℓ has its own pattern vocabulary P_ℓ and its own reinforcement operator A_ℓ, so contexts can differ in what they can represent and how quickly they self-reinforce. At the same time, all contexts share the same value object V (and thus the same $\oplus, \otimes, \odot$ operations), so that internal and external influences can be aggregated in a uniform way. This "shared algebra, distinct vocabularies" split is what makes it possible to discuss cross-context influence even when P_ℓ and $P_{\ell'}$ are not identical: the coupling kernels will serve as the translation layer.*

Definition 153 (Morphic coupling kernel)**.** *For $\ell \neq \ell'$, a* morphic coupling kernel *from ℓ' to ℓ is a V-relation*

$$K_{\ell' \to \ell} : P_{\ell'} \times P_\ell \to V.$$

Its image on a state $s_{\ell',t}$ is the induced input on P_ℓ:

$$(K_{\ell' \to \ell} \star s_{\ell',t})(q) := \bigoplus_{p \in P_{\ell'}} K_{\ell' \to \ell}(p, q) \otimes s_{\ell',t}(p).$$

Remark 557 (Intuition and examples of what $K_{\ell' \to \ell}$ can encode)**.** *The kernel $K_{\ell' \to \ell}$ plays the same mathematical role as A, but across contexts rather than within one context. In applications, $K_{\ell' \to \ell}(p, q)$ could encode: (i) similarity or "translation" between pattern vocabularies $P_{\ell'}$ and P_ℓ; (ii) a learned association that when p is active in one context, q tends to become active elsewhere; or (iii) a hypothesized nonlocal coupling. In the simplest same-pattern case where $P_{\ell'} = P_\ell = P$ and $K_{\ell' \to \ell}(p, q)$ is nonbottom only when $p = q$, the coupling just transmits support for a pattern to the same pattern-index in the other context.*

Remark 558 (Algebraic reading of the $\star$-action). *The expression $K_{\ell' \to \ell} \star s_{\ell',t}$ is formally the same type of construction as applying a weighted adjacency matrix to a state vector, except that the weights and aggregations are taken in the semiring-like structure V. Intuitively, the induced support for $q \in P_\ell$ is an $\oplus$-sum over all source patterns $p \in P_{\ell'}$ of "(strength of link from p to q) $\otimes$ (current support of p)." This makes it explicit that cross-context influence is graded and compositional: multiple distinct source patterns can contribute to the same target pattern, and their contributions combine by the same aggregator used everywhere else in the habit dynamics.*

Remark 559 (Directionality, reciprocity, and sparsity). *Nothing in Definition 153 requires $K_{\ell' \to \ell}$ to equal $K_{\ell \to \ell'}$ (even when $P_\ell = P_{\ell'}$), so the model allows directed coupling (influence from ℓ' to ℓ without a matching reverse channel). In many applications one may impose additional structure, e.g. reciprocity ($K_{\ell' \to \ell}$ related to $K_{\ell \to \ell'}$), boundedness (to prevent unrealistically large induced inputs), or sparsity (only a small subset of inter-context pattern pairs interact). These are modeling choices rather than requirements of the formalism.*

Definition 154 (Morphic resonance dynamics). *Given internal dynamics (A_ℓ, d_ℓ) and couplings $(K_{\ell' \to \ell})$, define the coupled update for each ℓ by*

$$s_{\ell,t+1} = u_{\ell,t} \oplus (d_\ell \odot s_{\ell,t}) \oplus (A_\ell \star s_{\ell,t}) \oplus \bigoplus_{\ell' \neq \ell} (K_{\ell' \to \ell} \star s_{\ell',t}).$$

We call this a morphic resonance dynamics *when the couplings $K_{\ell' \to \ell}$ are intended to encode cross-context propagation of habit bias, rather than ordinary local causal influence.*

Remark 560 (Intuition: one equation, two interpretations). *The equation is formally just "local update plus cross-input from others." The interpretive distinction is in what we take the coupling term to mean. If the coupling is ordinary causal influence, we are modeling a standard interacting multi-system process. If the coupling is "morphic," we are treating cross-context similarity itself as a conduit for habit, in the sense that a stabilized pattern in one place can seed stabilization elsewhere without a mediated causal chain in the usual physical sense. The latter reading is the one Hyperseed associates to morphic resonance (Hyperseed-Concept 115) and that is historically linked to morphic field narratives [13].*

Remark 561 (Time-variation and learning of couplings). *Although the definition treats $K_{\ell' \to \ell}$ as fixed, nothing prevents using time-indexed couplings $K_{\ell' \to \ell, t}$ to represent learned or adaptive cross-context links (e.g. strengthening of translation correspondences between vocabularies). Under such a reading, morphic resonance can be modeled either as a static "field" (fixed K) or as a co-evolving structure where repeated co-activation across contexts modifies the coupling itself, producing a second-order habit: a habit of coupling.*

Remark 562 (Why this captures "habit-taking at a distance"). *If a pattern p becomes increasingly supported in context ℓ' due to its internal habit dynamics, then the induced term $K_{\ell' \to \ell} \star s_{\ell',t}$ becomes increasingly supported (by Proposition 17), providing an increasing drive for corresponding patterns in ℓ. Thus the coupled system can realize the same before/after bias of Definition 144 across separated contexts.*

Remark 563 (A minimal two-context picture). *For $\mathcal{L} = \{\ell_1, \ell_2\}$ the update for ℓ_1 contains exactly one cross term $K_{\ell_2 \to \ell_1} \star s_{\ell_2,t}$ (and symmetrically for ℓ_2). In this simplest setting, one can interpret morphic resonance as the claim that "whatever becomes easier to realize in ℓ_2 becomes, via the kernel, easier to realize in ℓ_1", with the particular mapping from "what" to "what" specified by the nonbottom entries of $K_{\ell_2 \to \ell_1}$. This makes explicit that the phenomenon is not a single scalar effect but a structured transport of bias over a pattern vocabulary.*

To model morphic *anti*-resonance, we need a way to transport "opposition" or "reversal pressure" across contexts. In the p-bit setting, negation swaps positive and negative evidence, so we can define an "oppositional channel" by precomposing with negation.

Definition 155 (Anti-resonance via negated-source coupling (p-bit case))**.** *Assume the* p-bit *negation* $\neg(v^+, v^-) = (v^-, v^+)$*. Define an anti-resonant coupling contribution by*

$$\mathsf{AntiRes}_{\ell' \to \ell}(s_{\ell',t}) := K^-_{\ell' \to \ell} \star (\neg \circ s_{\ell',t}),$$

where $K^-_{\ell' \to \ell} : P_{\ell'} \times P_\ell \to V$ *is a* V*-valued kernel. Here* $(\neg \circ s)(p)$ *means applying* $\neg$ *to the* p-bit *value* $s(p)$*.*

Remark 564 (How anti-resonance enters the coupled update)**.** *In direct analogy with Definition 154, one can incorporate anti-resonant influence by adding* $\bigoplus_{\ell' \neq \ell} \mathsf{AntiRes}_{\ell' \to \ell}(s_{\ell',t})$ *as an additional input term in the update for* $s_{\ell,t+1}$*. Operationally, this means that strong evidence for* p *in context* ℓ' *can become strong evidence* against *related* q *in context* ℓ*, with the mapping again controlled by the kernel* $K^-_{\ell' \to \ell}$*. This clarifies that "anti-resonance" is not merely weaker resonance, but a qualitatively different channel that reverses polarity at the level of evidence.*

Remark 565 (Resonance and anti-resonance as distinct channels)**.** *The formalism permits both kinds of coupling to coexist: one may have a positive (resonant) kernel* $K_{\ell' \to \ell}$ *and a negative (anti-resonant) kernel* $K^-_{\ell' \to \ell}$ *simultaneously, representing systems where some cross-context correspondences reinforce while others suppress. In the* p-bit *interpretation, this supports mixed phenomena such as: "pattern* p *in* ℓ' *makes* q *more plausible in* ℓ*, but makes* r *less plausible," with different targets and strengths specified by the respective kernels.*

Remark 566 (Intuition: transmitting "the other side" of evidence)**.** *If the source context* ℓ' *contains strong negative evidence against a pattern* p*, then under* p-bit *negation this becomes strong positive evidence for* $\neg p$ *(or, more cautiously, strong positive evidence in the "negative channel" for* p*). Feeding* $\neg \circ s_{\ell',t}$ *through a kernel and adding it to the target dynamics allows the target to be pushed away from the same patterns that the source is rejecting. This is an abstract formalization of morphic anti-resonance (Hyperseed-Concept 114): not merely absence of resonance, but active propagation of reversal pressure. Concretely, if one thinks of* $s_{\ell,t}(p)$ *as a two-channel evidential state (e.g.* $s_{\ell,t}(p) = (v^+_{\ell,t}(p), v^-_{\ell,t}(p))$*), then* p-bit *negation can be read as an operation that swaps and/or reinterprets these channels so that "evidence against* p*" becomes usable input for biasing the evolution of* p*-related coordinates elsewhere. In this view, the kernel is not merely a similarity map but a transport mechanism for* constraints *or* inhibitions*: the transported signal acts like an inhibitory coupling that suppresses the target's tendency to reinstantiate the rejected pattern. The qualifier "more cautiously" is important: in a paraconsistent setting, strong* v^- *for* p *need not entail weak* v^+ *for* p*, so what is reliably transmitted is the intensity of the negative channel (or the intensity of support for* $\neg p$*), rather than a forced flip to an exclusive alternative.*

The use of paraconsistent negation here also connects to later resonance/dissonance themes (Hyperseed-Concept 97): conflict can be transported and can seed further conflict elsewhere, rather than being suppressed by consistency constraints (cf. paraconsistent dynamics perspectives such as [24]). In particular, anti-resonant coupling can propagate a tension pattern *even when the target context contains its own positive evidence for* p*: the resulting superposition is precisely the kind of structured incompatibility that dissonance concepts are meant to track. This clarifies why anti-resonance is not simply "negative similarity": it is a mechanism by which one context exports a local veto-like signal, and the receiving context integrates it without requiring global agreement or resolution.*

Remark 567. *There are multiple reasonable choices for anti-resonance. The above is the minimal one that mirrors the toy computation in Section 5: it allows negative evidence in one context to be transmitted as negative (or even as positive-for-not) evidence in another, without enforcing consistency. This minimality is useful pedagogically because it makes the "sign flip" intuition explicit: first apply* $\neg$ *at the level of evidential states, then transport via the same (or an analogous) kernel used for resonance, and finally aggregate into the target update as an extra driving term. However, the choice of whether to transport* $\neg \circ s_{\ell',t}$ *or to transport* $s_{\ell',t}$ *and negate after transport can matter if the kernel is nonlinear, state-dependent, or channel-mixing; in such cases, the ordering encodes a modeling decision about whether "reversal" is a property of the source signal itself or a property of how the target interprets incoming information. More sophisticated anti-resonance operators can be built using two-channel kernels that mix* (v^+, v^-) *components asymmetrically. For instance, one may wish to model a setting where negative evidence is more portable than positive evidence (or vice versa), or where negative evidence produces a broad, diffuse repulsion in the target while positive evidence produces a narrow, pattern-specific attraction. One can also introduce saturation, thresholds, or gating so that weak negative evidence does not create spurious repulsion, while strong negative evidence yields a robust anti-resonant push.*

Remark 568 (Further modeling notes)**.** *Anti-resonance can also be interpreted as transporting a* constraint *rather than transporting a* hypothesis*. If the source learns that* p *is systematically incompatible with its own stable trajectories, then exporting* $\neg p$ *(or exporting a strong* v^- *for* p*) amounts to telling the target: "do not allocate attractor mass to* p *unless you have compensating evidence." This suggests a natural stability heuristic: anti-resonant couplings should often be scaled (e.g. by kernel normalization or context-dependent confidence weights) to avoid globally destabilizing the dynamics when many sources simultaneously export negative pressure. In the two-channel perspective, such scaling can be applied differently to the* v^+*-transport and* v^-*-transport pathways, yielding a controlled way to represent that a system may be more conservative about spreading rejections than about spreading endorsements (or the reverse), depending on the application.*

12.5 Stability, amplification, and decay

The Hyperseed story needs three qualitative regimes:

1. *amplification*: repeated exposure yields increasing pattern support (habit-taking);

2. *decay*: support fades away (habit-reversal);

3. *stabilization*: a nontrivial persistent pattern-support structure emerges (habits as stable attractors).

We give basic sufficient conditions for these regimes in a finite P setting.

Remark 569 (A philosophical aside: stability as "thirdness")**.** *In Peircean terms, a habit is a kind of lawfulness: not a single event (secondness) nor a mere quality (firstness), but a stabilizing generality across time [14]. Mathematically, this is precisely what fixed points and attractors encode: an organization that, once present, reproduces itself under the dynamics. The following estimates and fixed-point statements are small technical shadows of this broader idea.*

One can also read "thirdness" here as the appearance of constraints *that are not explicitly imposed at each time step, but are nevertheless respected by the evolution once they have formed. In dynamical terms, this corresponds to invariant sets, absorbing regions, or attractor basins: after transients, the system repeatedly returns to (or remains inside) a family of states characterized by the same structured regularities.*

Definition 156 (A scalar upper bound for the p-bit quantale)**.** *Assume $V = [0,1]^2$ with componentwise order. For $v = (v^+, v^-)$ define $\|v\|_\infty := \max(v^+, v^-)$. For a state $s : P \to V$ define*

$$\|s\|_\infty := \max_{p \in P} \|s(p)\|_\infty.$$

For a relation $A : P \times P \to V$ define

$$\|A\|_\infty := \max_{p,q \in P} \|A(p,q)\|_\infty.$$

Remark 570 (Intuition: measuring the largest evidence magnitude)**.** *The quantity $\|v\|_\infty$ ignores the distinction between positive and negative channels and simply records the larger of the two. This is a conservative measure: if either channel is large, then $\|v\|_\infty$ is large. For states and relations, taking the max over all patterns (or all edges) gives a simple global bound suitable for elementary contraction-style estimates.*

This norm-like bound is useful here not because it is subtle, but because it is easy: it lets us give a clean sufficient condition for forgetting/decay in the toy p-bit *model without developing a full spectral theory over quantales.*

It is also worth noting what is being discarded by this bound. Because $\oplus$ is max, there is no cancellation between positive and negative evidence at the level of the semiring/quantale operations, so an ℓ_∞-style "largest-entry" estimate is often remarkably faithful. However, the bound still throws away all distributional *information (how many entries are large, whether large entries are isolated or form reinforcing motifs, etc.), and therefore cannot distinguish between many qualitatively different webs that share the same single largest edge weight.*

Remark 571 (Operator-level intuition for the update)**.** *The homogeneous update*

$$s_{t+1} = (d \odot s_t) \oplus (A \star s_t)$$

has two contributions. The term $d \odot s_t$ is a pointwise persistence/discounting term: it keeps each pattern's current evidence but shrinks it by a per-pattern factor d. The term $A \star s_t$ is a propagation/reinforcement term: evidence at pattern p is transmitted along the edge (p,q) to contribute to pattern q, and the join $\oplus$ aggregates all such incoming contributions at q by taking a componentwise maximum. In this toy p-bit *semantics, the state at time* t+1 *is therefore "whatever survives locally"* or *"whatever is newly supported by at least one incoming source," channelwise.*

Theorem 13 (A simple decay criterion in the p-bit toy quantale)**.** *Assume P is finite, $V = [0,1]^2$ with $\oplus$ as componentwise max and $\otimes$ as componentwise multiplication. Consider the homogeneous (no input) single-context update*

$$s_{t+1} = (d \odot s_t) \oplus (A \star s_t), \qquad u_t \equiv \mathbf{0}.$$

Let $\rho := \max(\|d\|_\infty, \|A\|_\infty)$. Then

$$\|s_{t+1}\|_\infty \le \rho \, \|s_t\|_\infty.$$

In particular, if $\rho < 1$ then $\|s_t\|_\infty \to 0$ as $t \to \infty$, so scalar propensities $p_t(p) = \pi(s_t(p))$ decay to 0 *for both π_{pos} and π_{net}.*

Remark 572 (A quantitative consequence: geometric forgetting)**.** *The inequality $\|s_{t+1}\|_\infty \le \rho \, \|s_t\|_\infty$ iterates immediately to*

$$\|s_t\|_\infty \le \rho^t \|s_0\|_\infty.$$

Thus when $\rho < 1$ the decay is not only eventual but geometric, with a characteristic "forgetting timescale" controlled by ρ. For example, to guarantee $\|s_t\|_\infty \leq \varepsilon$, it suffices that $t \geq \frac{\log(\varepsilon/\|s_0\|_\infty)}{\log(\rho)}$, where $\log(\rho) < 0$. This makes explicit how stronger persistence/reinforcement (larger ρ) slows forgetting even in the still-decaying regime.

Remark 573 (Plain-English meaning)**.** *If every edge weight in the web and the persistence factor d are bounded by some $\rho < 1$ (in the conservative $\|\cdot\|_\infty$ sense), then the system cannot sustain evidence: each update step scales the maximum evidence down by at least a factor ρ. Thus, in the absence of ongoing input, whatever support the system had is eventually forgotten. This gives a clean sufficient condition for habit-reversal-by-decay.*

The key point is that the model has no mechanism for generating evidence "from nothing" under $u_t \equiv \mathbf{0}$: all evidence at time $t+1$ is obtained by multiplying previously existing evidence by quantities in $[0,1]$ and then taking maxima. When all multiplicative factors are uniformly < 1, even the most favorable reinforcement path cannot avoid overall shrinkage.

Remark 574 (Why this is connected to earlier habit definitions)**.** *Under $\rho < 1$, the scalar propensities $p_t(p)$ decrease to 0 regardless of scalarization choice among π_{pos} and π_{net}. Hence, for sufficiently large T, "after T" averages become smaller than "before T" averages, aligning with the habit-reversal direction in Definition 144.*

More explicitly, because both $\pi_{\text{pos}}(v)$ and $\pi_{\text{net}}(v)$ are bounded above by $\|v\|_\infty$ (up to the trivial clipping to $[0,1]$ in the net case), one has a uniform implication of the form

$$\|s_t\|_\infty \to 0 \quad \Longrightarrow \quad \pi(s_t(p)) \to 0 \text{ for each fixed } p \in P,$$

so any average-of-propensities criterion based on time windows will eventually detect a decline.

Proof. Fix $q \in P$. Using the definitions and that $\oplus$ is max while $\otimes$ is multiplication (componentwise), we have

$$\|(d \odot s_t)(q)\|_\infty \leq \|d\|_\infty \, \|s_t\|_\infty,$$

and also

$$\|(A \star s_t)(q)\|_\infty = \left\| \bigoplus_{p \in P} A(p,q) \otimes s_t(p) \right\|_\infty \leq \max_{p \in P} \|A(p,q)\|_\infty \, \|s_t(p)\|_\infty \leq \|A\|_\infty \, \|s_t\|_\infty.$$

Taking the max of these two bounds yields $\|s_{t+1}(q)\|_\infty \leq \rho \, \|s_t\|_\infty$. Finally maximize over $q \in P$. $\square$

Remark 575 (Where finiteness enters)**.** *The assumption that P is finite ensures that the maxima in Definition 156 are attained and that the propagation bound*

$$\left\| \bigoplus_{p \in P} A(p,q) \otimes s_t(p) \right\|_\infty \leq \max_{p \in P} \|A(p,q)\|_\infty \, \|s_t(p)\|_\infty$$

is literally a bound by a finite maximum. Conceptually, the same proof pattern extends to infinite P if one replaces maxima by sups and assumes the relevant sups exist in $[0,1]$. The present finite setting keeps the estimate elementary and avoids measure-theoretic or completeness issues that are orthogonal to the qualitative message about decay.

Proof sketch. Bound each component of the next state by separately bounding the persistence term and the propagation term. Because the join $\oplus$ is componentwise max, the magnitude of the join is at most the maximum of the magnitudes. Because $\otimes$ is componentwise multiplication, magnitudes multiply. Taking maxima over p (for propagation) and then over q (for the whole state) yields the stated inequality, which iterates to show convergence to 0 when $\rho < 1$. $\square$

Remark 576 (Commentary)**.** *The proof is a straightforward "largest-entry" estimate: it ignores cancellations (there are none, since $\oplus$ is max) and tracks only the largest evidence component present anywhere. This is why the conclusion is a* sufficient *condition: many webs will still decay even when $\rho \geq 1$, but $\rho < 1$ guarantees decay by a simple contraction argument.*

One can compare this to classical matrix norm bounds: in linear systems, a condition like $\|A\| < 1$ implies contraction and hence decay, while $\|A\| \geq 1$ is inconclusive because the true stability threshold is governed by more refined structure (eigenvalues/spectral radius). Here the estimate plays the same role: it is intentionally crude but robust, and it emphasizes the logical shape of the argument ("uniform shrinkage everywhere implies global forgetting") rather than the sharp boundary between stability and instability.

Remark 577 (Interpretation)**.** *The condition $\rho < 1$ says that neither persistence nor reinforcement is strong enough to maintain evidence; the web forgets. This is a clean sufficient condition for habit-reversal in the absence of ongoing input.*

Equivalently, every path by which evidence might persist—either by staying at a node via d or moving along an edge via A—incurs at most a factor $\rho < 1$ per step in the channelwise magnitude. Even if the system continually selects the "best" incoming support at each step (because $\oplus$ is max), it still cannot overcome the uniform multiplicative discounting.

Remark 578 (A minimal illustrative example)**.** *Consider $P = \{1, 2\}$, with a single nonzero edge $A(1, 2) = (a^+, a^-)$ and persistence $d(1) = (d_1^+, d_1^-)$, $d(2) = (d_2^+, d_2^-)$. If $\max(d_1^+, d_1^-, d_2^+, d_2^-, a^+, a^-) < 1$, then regardless of where evidence starts (at node 1 or node 2), each time step multiplies every available contribution by a factor < 1 before taking maxima, so the overall magnitude must shrink. This makes concrete that the condition does not depend on detailed topology: even a "chain" that can move evidence forward cannot preserve it without at least one unit-sized multiplicative channel somewhere.*

Amplification and stabilization typically require persistent input and/or autocatalytic structure.

Proposition 18 (Driven closure yields a stable attractor in the inflationary case)**.** *Assume $d = e$ (no decay) and $u_t \equiv u$ is constant. Then the update*

$$s_{t+1} = u \oplus s_t \oplus (A \star s_t)$$

produces an ascending chain $s_0 \leq s_1 \leq \cdots$ whose join $s_\infty := \bigoplus_{t \geq 0} s_t$ exists and satisfies

$$s_\infty = u \oplus (A \star s_\infty).$$

If $u \neq \mathbf{0}$ and A connects u to many patterns, then s_∞ exhibits habit-taking (Lemma 3). Moreover, the statement is order-theoretic: the inequality $s_0 \leq s_1 \leq \cdots$ is interpreted pointwise in V^P (i.e., for each pattern $p \in P$ we have $s_t(p) \leq s_{t+1}(p)$ in V), and the join $\bigoplus_{t \geq 0} s_t$ is taken in the complete lattice V^P (again pointwise).

Remark 579 (What this proposition says)**.** *With no forgetting ($d = e$) and a constant source of stimulation u, the system's support can only increase over time. Thus it converges (in the order-theoretic sense of taking the join of an ascending chain) to a stable state s_∞. The fixed-point* *equation $s_\infty = u \oplus (A \star s_\infty)$ says: at equilibrium, the support is exactly what is injected plus what the web can propagate from that equilibrium.*

This is the simplest formal incarnation of "habits as stable attractors" in this framework. It is not a metric convergence statement; it is the order-theoretic statement appropriate to quantale-valued, possibly paraconsistent support. In particular, nothing here presupposes that supports are real numbers with a topology, nor that successive states become close in any metric; instead, the chain stabilizes in the sense that it reaches the least upper bound of all iterates. Equivalently, s_∞ is the least element (with respect to $\le$) that simultaneously dominates the initial iterates and is closed under the update rule. Because the update includes the explicit persistence term s_t, the map $F(s) := u \oplus s \oplus (A \star s)$ is inflationary ($s \le F(s)$), and s_∞ can be viewed as the closure obtained by repeatedly applying F starting from s_0.

Proof. Inflationarity is immediate because $s_{t+1} \ge s_t$ pointwise. Completeness of V^P gives existence of s_∞. Monotonicity plus distributivity of $\otimes$ over joins yields the fixed-point equation at the join. More explicitly, define $F(s) := u \oplus s \oplus (A \star s)$. The update is $s_{t+1} = F(s_t)$, and since F is monotone and inflationary, the sequence $(s_t)_{t\ge0}$ is an ascending chain. By completeness of V^P, the join $s_\infty = \bigoplus_{t\ge0} s_t$ exists. Then, using monotonicity of F and that $\oplus$ computes joins, one has

$$F(s_\infty) = u \oplus s_\infty \oplus (A \star s_\infty) = u \oplus \Big(\bigoplus_{t\ge0} s_t\Big) \oplus \Big(A \star \bigoplus_{t\ge0} s_t\Big),$$

and the distributivity/continuity property for $\star$ (spelled out in Remark 580 below) yields $A \star (\bigoplus_{t\ge0} s_t) = \bigoplus_{t\ge0}(A \star s_t)$, so

$$F(s_\infty) = u \oplus \bigoplus_{t\ge0} s_t \oplus \bigoplus_{t\ge0}(A \star s_t) = \bigoplus_{t\ge0}\big(u \oplus s_t \oplus (A \star s_t)\big) = \bigoplus_{t\ge0} s_{t+1} = s_\infty,$$

where the last equality uses that the join of the tail $\{s_{t+1} : t \ge 0\}$ is the same as the join of the whole chain $\{s_t : t \ge 0\}$. Finally, since $s_\infty = s_\infty \oplus u \oplus (A \star s_\infty)$ implies $s_\infty \ge u \oplus (A \star s_\infty)$ and also $s_\infty \le u \oplus (A \star s_\infty) \oplus s_\infty$, the displayed fixed-point identity $s_\infty = u \oplus (A \star s_\infty)$ follows because $\oplus$ is idempotent and $s_\infty \oplus s_\infty = s_\infty$. □

Proof sketch. The update map is inflationary, so iterating it yields an ascending chain. In a complete lattice, the join of this chain exists. Taking the join on both sides of $s_{t+1} = u \oplus s_t \oplus (A \star s_t)$ and using that $\otimes$ distributes over joins lets us pass the join through the propagation term, producing the fixed-point equation for s_∞. One can read this as a standard "iterate-and-take-the-supremum" construction: s_∞ collects everything that can be reached from the seed s_0 by any finite number of applications of the forcing u and the propagation $A \star (\cdot)$, with persistence preventing any loss. This is the order-theoretic analogue of reaching equilibrium by repeatedly applying an expanding operator until no genuinely new support can be added. □

Remark 580 (Why the distributivity step is the hinge)**.** *The subtlety (such as it is) lies in justifying that $A \star (\bigoplus_t s_t) = \bigoplus_t (A \star s_t)$. This is exactly where the quantale axioms matter: $\otimes$ distributes over arbitrary joins, so the propagation operator commutes with the limit-by-join. Without this property, the closure and fixed-point story would lose its clean algebraic form. Concretely, writing $(A \star s)(p) = \bigoplus_{q\in P} A(p,q) \otimes s(q)$ (the usual quantale-enriched matrix–vector product), we compute*

$$(A\star\bigoplus_t s_t)(p) = \bigoplus_{q\in P} A(p,q)\otimes\Big(\bigoplus_t s_t(q)\Big) = \bigoplus_{q\in P}\bigoplus_t\big(A(p,q)\otimes s_t(q)\big) = \bigoplus_t\bigoplus_{q\in P}\big(A(p,q)\otimes s_t(q)\big) = \bigoplus_t (A\star s_t)(p),$$

where the interchange of joins is justified by completeness and the distributivity of $\otimes$ over arbitrary joins. Thus, $\star$ is Scott-continuous with respect to the order structure induced by $\oplus$, and the fixed-point argument is a direct application of that continuity.

Remark 581 (Least fixed point and "driven closure")**.** *The equality $s_\infty = u \oplus (A \star s_\infty)$ exhibits s_∞ as a fixed point of the monotone map*

$$G(s) := u \oplus (A \star s).$$

Because the actual update uses $F(s) = s \oplus G(s)$, iteration from any s_0 produces a post-fixed chain $s_t \leq s_{t+1}$ that approaches the least fixed point above s_0 in the order. In particular, if one starts from the empty state $s_0 = \mathbf{0}$, then s_∞ is the least solution of $s = G(s)$, i.e., the smallest stable support pattern compatible with both the constant drive u and the propagation web A. This is the sense in which the attractor is a "closure": it is the minimal closed (stable) element containing the forced content.

12.6 A worked micro-example reaching self-weaving and morphic resonance

We now give a small numerical instance (compatible with the toy model style in Section 5) that shows:

- morphic resonance creating a paraconsistent "both-sides" state; and
- internal reinforcement weaving a larger support pattern from that seed.

The example is deliberately minimal (two contexts and two patterns) so that the mechanisms can be read off from the update equations themselves: the "morphic" step is an *external* injection of evidence into a target context, while the "self-weaving" step is an *internal* propagation of evidence along a small directed web of pattern-to-pattern reinforcement links.

Example 12 (Morphic resonance seeds a self-weaving two-cycle)**.** *Work in the* p-bit *quantale $V = [0,1]^2$ with $\oplus$ as componentwise max and $\otimes$ as componentwise multiplication (Section 3.4). Here a value $(x^+, x^-) \in [0,1]^2$ is read as a* pair *of evidential degrees: x^+ measures positive support and x^- measures negative support. The key choice is that $\oplus =$* max accumulates *evidence (it never retracts prior evidence in either coordinate), while $\otimes$* gates *or* attenuates *evidence multiplicatively (so a weak coupling or weak premise yields a weak contribution). This combination is what makes it easy to exhibit paraconsistent states: the negative coordinate can remain high even as the positive coordinate is increased by new inputs.*

Consider two contexts (locations) C_1 and C_2 that share a small pattern class $P = \{p, q\}$. Interpret p as a "seed" pattern and q as a downstream pattern that can participate in a reinforcing loop with p inside C_2. The intended reading is that C_1 already "knows" (or has stabilized) a habit supporting p, while C_2 has not stabilized it and may even have reasons to reject it; nevertheless, C_2 can be nudged by a morphic coupling that carries only partial and possibly one-sided influence.

State in C_1 (source). *Assume C_1 strongly supports p:*

$$s^{(1)}(p) = (0.9, 0.1), \qquad s^{(1)}(q) = (0.1, 0.1).$$

Thus, in the source context C_1, p has high positive evidence and only a small amount of negative evidence, while q is essentially neutral/weak in both directions. One can think of this as p being an established habit in C_1 and q not yet being a meaningful downstream consequence there.

Initial state in C_2 (target). *Assume C_2 initially leans against p:*

$$s_0^{(2)}(p) = (0.2, 0.7), \qquad s_0^{(2)}(q) = (0.1, 0.1).$$

So before any cross-context influence, C_2 has relatively low positive support for p but relatively strong negative evidence against it. This is the setup in which a purely monotone, non-retractive update rule is most visibly paraconsistent: later increases in the positive coordinate for p need not (and in this model, will not) remove or "explain away" the pre-existing negative coordinate.

Morphic coupling $C_1 \to C_2$. *Let the morphic field strength be $K = (0.6, 0.2)$, and apply a direct same-pattern coupling to p:*

$$s_1^{(2)}(p) := s_0^{(2)}(p) \oplus (K \otimes s^{(1)}(p)).$$

This update should be read as: the new state of p in the target is obtained by taking the old state and then adding *(via $\oplus$) a coupled contribution obtained by attenuating the source evidence by K (via $\otimes$). Because $\otimes$ is componentwise multiplication, K plays the role of a pair of channel strengths: it transmits positive evidence with weight 0.6 and negative evidence with weight 0.2. Compute*

$$K \otimes s^{(1)}(p) = (0.6 \cdot 0.9,\ 0.2 \cdot 0.1) = (0.54, 0.02),$$

so

$$s_1^{(2)}(p) = (0.2, 0.7) \oplus (0.54, 0.02) = (0.54, 0.7).$$

Thus C_2 receives positive support for p without erasing its negative support: it enters a paraconsistent "both positive and negative" regime. Concretely, after coupling we have simultaneously *(i) relatively strong positive evidence for p (raised from 0.2 to 0.54) and (ii) the original strong negative evidence against p unchanged at 0.7. The point is not that this is "inconsistent" in a classical sense, but that the state now encodes a live tension: p is pushed forward as a candidate habit while remaining counter-supported. In a classical single-score model, one would typically be forced to collapse this to a single compromise value; in the* p-bit *model the two-sidedness is explicit and stable under $\oplus$.*

Internal reinforcement in C_2. *Now define an internal reinforcement relation in C_2 by*

$$A_2(p, q) = (0.9, 0.1), \qquad A_2(q, p) = (0.8, 0.2),$$

and take all other pairs to have value $(0, 0)$. These two nonzero entries specify a tiny directed web: p pushes evidence toward q, and q pushes evidence back toward p, forming a two-cycle. The values also allow the web to transmit both positive and negative evidence (albeit with different strengths), so that downstream patterns can inherit not only support but also potential counter-support. In particular, $A_2(p, q) = (0.9, 0.1)$ says that if p is present, it tends to generate q with a strong positive channel and a weak negative channel; $A_2(q, p) = (0.8, 0.2)$ similarly gives a feedback link.

Update q once by

$$s_1^{(2)}(q) := s_0^{(2)}(q) \oplus (A_2(p, q) \otimes s_1^{(2)}(p)).$$

This is the local "weaving" step: the newly morphically-amplified state of p in C_2 is used as an input that propagates along the internal edge $p \to q$. Because $s_1^{(2)}(p)$ already contains a paraconsistent tension, the propagated contribution can, in principle, carry forward both aspects of that tension. Compute

$$A_2(p, q) \otimes s_1^{(2)}(p) = (0.9 \cdot 0.54,\ 0.1 \cdot 0.7) = (0.486, 0.07),$$

hence

$$s_1^{(2)}(q) = (0.1, 0.1) \oplus (0.486, 0.07) = (0.486, 0.1).$$

Here the positive coordinate of q jumps substantially (from 0.1 *to* 0.486*), while the negative coordinate of q does not increase because the pre-existing negative evidence* 0.1 *dominates the newly imported* 0.07 *under* max*. This illustrates a general feature of $\oplus = \max$: once a coordinate is already at some level, additional weaker contributions in that coordinate do not change it, whereas stronger contributions do. In other words, the web transmits* new *evidence when it exceeds what is already locally present.*

Finally, propagate back from q to p (one step of self-weaving closure):

$$s_2^{(2)}(p) := s_1^{(2)}(p) \oplus (A_2(q,p) \otimes s_1^{(2)}(q)).$$

This feedback step is the smallest nontrivial instance of "closure": evidence that was triggered by p and flowed to q is now allowed to flow back and potentially further reinforce p. In larger webs, iterating such steps (or taking a least fixed point) is what builds up an extended habit-supporting substructure from a small initiating seed. Compute

$$A_2(q,p) \otimes s_1^{(2)}(q) = (0.8 \cdot 0.486,\ 0.2 \cdot 0.1) = (0.3888, 0.02),$$

so

$$s_2^{(2)}(p) = (0.54, 0.7) \oplus (0.3888, 0.02) = (0.54, 0.7).$$

In this specific numeric instance, the back-propagation does not further increase p because p is already saturated in positive evidence and remains high in negative evidence; but it does demonstrate the closure mechanism and shows how a morphically seeded p produces downstream q within C_2. Said differently: the loop $p \to q \to p$ is present and active, but the idempotent nature of $\oplus = \max$ means that once the dominant positive and negative coordinates for p have been reached (here, positive 0.54 *and negative* 0.7*), additional weaker returns do not alter the state. This is a feature rather than a bug: it models a kind of "stability after saturation," whereby a context can become locked into a conflicted yet persistent stance.*

Hyperseed interpretation. *Relative to scalarization π_{pos}, q in C_2 has increased from* 0.1 *to* 0.486 *after the morphic seeding of p, which is a direct instance of "habit-taking at a distance" (morphic resonance) followed by local habit closure on the internal web. The scalarization π_{pos} is used here only to make the growth easy to read numerically; the underlying state remains two-dimensional, and in other scenarios one might equally track π_{neg} or a combined measure. Because negative evidence for p persisted (it stayed at* 0.7*), the same example also illustrates how morphic resonance can create ambivalent or conflicted habit structures without logical explosion. In particular, the model permits the following qualitative narrative: a remote context can make a pattern feel "compelling" (increasing positive evidence) while local countervailing constraints, memories, or inhibitions remain in place (maintaining negative evidence). The internal web then turns this unstable co-presence into additional structured consequences (here, support for q), which is the minimal sense in which a seed becomes a weave.*

Remark 582 (What the example is meant to teach)**.** *The arithmetic is not the point; the point is the qualitative possibility. A coupling term can inject new positive evidence into a context without removing existing negative evidence, creating a stable paraconsistent tension. Then, internal reinforcement can transmit that tension downstream, producing new supported patterns (here q) as a consequence of the web structure. This is precisely the sense in which morphic resonance can be* *a* seed *and the web's closure can be the* weave*. One may also view the example as separating two kinds of "cause": an external cause (the morphic field term) that changes what is locally available to the system, and an internal cause (the reinforcement web) that determines what the system can build from whatever is available. The two-step structure matters: without the morphic injection, p would remain low in positive evidence in C_2, and the edge $p \to q$ would not generate a substantial increase in q; without the internal web, the morphic injection would remain a local change to p without generating additional downstream organization.*

12.7 Notes and bridges to later sections

Where attention and effort enter. The update operators above are "structural." In Hyperseed, attention (Hyperseed-Concept 60) and effort (Hyperseed-Concept 100) modulate which pattern classes are tracked and which reinforcement links are strengthened. Formally, attention can be implemented as a time-varying reweighting of A and u_t (and even of the pattern class P itself) driven by resource constraints from Section 8. Concretely, one may treat attention as a gating field w_t that rescales the effective adjacency and reinforcement updates (e.g., $A \mapsto w_t \odot A$ and $u_t \mapsto w_t \odot u_t$ with appropriate normalization), so that limited processing budget is expressed directly as selective amplification/suppression of candidate pattern links. On this view, "effort" can be modeled not only as a scalar budget but also as a constraint on the allowable complexity of the currently tracked subweb (e.g., limiting the number of active nodes/edges, the depth of multi-step propagation, or the entropy of the attention weights), thereby coupling computational cost to the dynamics of habit-formation. This makes explicit how the same structural operator can yield markedly different learning trajectories under different resource regimes: under scarcity, updates become sparse and conservative; under abundance, they become denser and can support rapid structural reconfiguration. This perspective aligns with the general cognitive-systems view that attention is a resource-allocation operator acting on inference/learning dynamics (see, e.g., [19]).

Relation to resonance/dissonance (Section 3.9). Section 3.9 sketches a logic-to-complex mapping and an interference-based resonance score. In the present section, morphic resonance is implemented as a coupling kernel $K_{\ell' \to \ell}$ that transports pattern support across contexts. One can combine these views by: (i) using paraconsistent interference scores to adaptively learn K; and/or (ii) interpreting high interference-coherence as a signal that two contexts share a near-morphism between their pattern webs, warranting stronger morphic coupling. In more operational terms, $K_{\ell' \to \ell}$ may be taken as a (row-)stochastic or otherwise mass-preserving operator so that "transport" can be read literally as redistribution of support, with constraints (e.g., positivity, bounded norm, or decay with contextual distance) preventing spurious amplification. Likewise, when interference is used as a learning signal, it can be used either to increase coupling for coherent overlaps (resonance) or to decrease coupling when overlaps are systematically contradictory (dissonance), yielding a unified knob that can implement both attraction and repulsion between webs depending on the sign/structure of the paraconsistent evidence. The near-morphism interpretation can be made explicit by asking whether there exists a structure-respecting map that approximately preserves key relational signatures (connectivity motifs, implication-like edges, or compositional paths) from one web to the other; high coherence then indicates that such a map is available with low distortion, making cross-context transfer reliable rather than merely associative. This is one natural meeting point between paraconsistent evidence dynamics and resonance-style measures [24].

Reality-systems and beyond. In later sections (reality-systems, intersubjective reality, eurycosm), the same coupled-web formalism can be re-used with $\mathcal{L}$ indexing different reality-systems and K encoding cross-system transduction pathways. This provides a mathematically explicit "port" for discussing morphic resonance in settings where "spatial separation" is generalized to separation across representational, social, or cosmological contexts (Hyperseed-Concept 149, Hyperseed-Concept **??**, Hyperseed-Concept **??**; see also [18]). Here it is helpful to read "transduction" broadly: K can stand for translation between symbol systems, alignment between agents internal models, propagation through communication networks, or coupling across scales (e.g., individual $\to$ group $\to$ institution) when $\mathcal{L}$ is organized hierarchically. In such cases, constraints on K can encode empirical or normative limitations (bandwidth limits, trust/credibility filters, institutional friction), making the same mathematics serve both descriptive and prescriptive roles: describing how habits and meanings spread, and prescribing how to shape coupling to improve coordination or reduce pathological contagion. This framing also anticipates later uses where one distinguishes "within-system" stabilization (habit consolidation inside a reality-system) from "between-system" transfer (morphic resonance across reality-systems), since the two can be tuned independently by the intra-web reinforcement rules versus the inter-web kernel K.

13 Mind, representation, and perception

This section introduces the representational layer of Hyperseed [1]. The preceding sections provide (i) an observer-relative notion of distinction/weakness, (ii) patterns as simplicity-improving representations, and (iii) dynamical operators (habits and morphic resonance) that move pattern support across contexts. Here we focus on how a system becomes a *mind* by supporting *registration* of patterns, *representation* of what is registered, and the beginnings of *closed-loop organization* (with control treated formally in Section 14).

Remark 583. *Conceptually, this section is the hinge between the "static" side of the formalism (distinctions, weakness, and patterns) and the "active" side (prediction, control, and attention). A mind, in the Hyperseed sense, is not merely a container of data; it is a system that can* stabilize *some internal stand-ins for what it encounters, and then use these stand-ins to guide future behavior. This framing aligns with the emphasis in [19] on internal representational dynamics as the substrate for flexible cognition.*

13.1 Systems, minds, and recognition processes

Hyperseed uses "system" in the autopoietic sense: not every arbitrary distinguished collection counts as a system; a system must have internal coherence and internal production. For this paper, it is useful to model "system" at two complementary levels: *(i) a process level* (how state evolves) and *(ii) a pattern level* (what compressive regularities are stably present).

Definition 157 (Process and system)**.** *A* process *is a triple* (T, Σ, δ) *where:*

- T *is a proto-time index (a poset, interpreted as a partial order of "before/after"),*
- Σ *is a (possibly structured) state space,*
- $\delta : T \to (\Sigma \to \Sigma)$ *assigns to each* $t \in T$ *a state-update map.*

A system *is a finite directed multigraph* $\mathcal{S} = (P, E)$ *whose nodes* $p \in P$ *are processes and whose edges encode* production dependencies*:* $(p \to q) \in E$ *means that the evolving state of* p *supplies* *part of the input (or constraint) for the evolution of q. We say $\mathcal{S}$ is* inter-producing *if every node lies on a directed cycle.*

Remark 584. *A few notational clarifications help anchor this definition. The symbol T denotes a partially ordered set (poset): one should read $t \preceq t'$ as "t is no later than t'" in the system's proto-time (Hyperseed-Concept 142). The state space Σ is the mathematical home of instantaneous configurations, and $\delta(t) : \Sigma \to \Sigma$ is the time-indexed update map (so the state at t advances according to $\delta(t)$). Thus, the composite object (T, Σ, δ) is a minimalist process in the style of dynamical systems theory, but allowing partial time order fits well with later branching-time and context machinery.*

The shift from a single process to a system $\mathcal{S} = (P, E)$ is a shift from "one evolving thing" to "many evolving things with dependencies." A directed multigraph *allows multiple edges between the same pair of processes, which is useful when a module can depend on another in several distinct ways. The inter-producing condition (every node lies on a directed cycle) is a concise way of insisting on mutuality: nothing in the system is purely a passive input; every component is also (perhaps indirectly) sustained by others. This resonates with process-ontological intuitions in the background of Hyperseed (compare [15]) and with Hyperseed's emphasis on self-maintaining webs (Hyperseed-Concept 168).*

Remark 585. *The "inter-producing" condition is a minimal formal proxy for the informal Hyperseed idea that systems are coherent sets of inter-producing processes. In Section 12 we strengthen this idea using autocatalytic closure properties expressed on pattern webs.*

Definition 158 (Mind)**.** *A* mind *is a system $\mathcal{M} = (P, E)$ equipped with additional structure:*

1. *A distinguished* registration interface *(a "sensory" subgraph) $\mathcal{S}_{\text{in}} \subseteq \mathcal{M}$.*
2. *A* representation space *$\mathcal{R}$ (objects, tokens, or states that can stand in for other entities).*
3. *A* reference relation $\text{Ref}_C \subseteq \mathcal{R} \times \mathcal{U}$ *for each context/aspect C, where $\mathcal{U}$ denotes the ambient universe of entities under discussion.*
4. *An* update rule *that turns registrations into representational changes (e.g. $r_{t+1} = \mathsf{Update}(r_t, \text{Reg}_t)$ for some internal state $r_t \in \mathcal{R}$).*

The remaining sections refine these components and give semantics in terms of patterns, weakness, and paraconsistent evidence.

Remark 586. *This definition should be read as a deliberately spare "constitution" rather than a detailed psychology. A mind is, first, a system in the sense above: an interdependent complex of processes. But it becomes a mind by having (i) a privileged gateway where the world impresses itself upon the system (registration; Hyperseed-Concept 153), (ii) an internal realm of stand-ins (representation; Hyperseed-Concept 157), and (iii) a relation* Ref_C *that ties stand-ins to what they are about (reference; Hyperseed-Concept 152). The context index C matters philosophically: it encodes the Russellian insistence that meaning is not floating in a void; it is always meaning* under some way of taking *the world, i.e. under some partition of distinctions (Hyperseed-Concept 86).*

A simple example: let $\mathcal{U}$ contain physical objects, and let $\mathcal{R}$ contain internal feature vectors or symbolic tokens. A camera-like subsystem can serve as $\mathcal{S}_{\text{in}}$. Then $\text{Ref}_C(r, u)$ *may mean "token r currently refers to object u as seen in visual context C." The update rule is the bridge from mere causal impact to sustained internal content. This is why Hyperseed treats registration as weaker than perception: the update rule can fail, be blocked, or be too noisy to stabilize representation. The general program is consonant with the cognitive-systems stance of [19], while remaining compatible with the pattern/emergence framing in [5].*

Definition 159 (Pattern recognition process)**.** *Fix a context/aspect C and a set of candidate patterns $\mathcal{P}_C$. Assume each system-state S at time t determines a (possibly fuzzy) intensity map $\mathrm{Int}_{S,t} : \mathcal{P}_C \to V$ into the quantale V from Section 3. A process Y is a* pattern recognition process aimed at *an entity X (in aspect C) if there exists a nonempty set $\mathcal{P}_{X,C} \subseteq \mathcal{P}_C$ such that for each $P \in \mathcal{P}_{X,C}$:*

1. *(alignment) $\mathrm{Int}_{Y,t}(P) \leq \mathrm{Int}_{X,t}(P)$ for all relevant t, and*
2. *(learning) $\mathrm{Int}_{Y,t}(P)$ is nondecreasing in t (w.r.t. the order on V), with strict increase for at least one P at least once.*

Remark 587. *Here $\mathcal{P}_C$ is the repertoire of patterns that the context C makes available (Hyperseed-Concept 130). The quantale V supplies a graded scale of "how much a pattern is present": the order $\leq$ on V is the comparison of intensities, and the monoidal structure (introduced in the formal core) is what ultimately makes these intensities compositional. The notation $\mathrm{Int}_{S,t}(P)$ is the intensity of pattern P in the system-state S at time t; one may picture it as the system's current "degree of embodiment" of P.*

Intuitively, Y recognizes X when Y comes to mirror (some of) X's patterns, and to do so ever more stably. Condition (alignment) prevents us from calling arbitrary growth in Y a recognition of X; it must be growth in patterns that are genuinely patterns of X. Condition (learning) demands a temporal direction: recognition is not a static coincidence but a historical acquisition. A toy example: if X is a melody and P ranges over rhythmic/melodic motifs, then a listener-process Y recognizes X as it internalizes these motifs (its $\mathrm{Int}_{Y,t}(P)$ rises), while remaining within what is actually present in the melody (alignment).

This concept is useful because it makes recognition expressible without presupposing crisp symbols or propositional truth: recognition is framed in the same graded pattern vocabulary as the rest of the theory. That uniformity becomes crucial once we allow paraconsistent evidence, habit dynamics, and cross-context resonance (Hyperseed-Concept 151).

A further point of the quantale-valued formulation is that "presence" need not be probabilistic or frequency-like: depending on the chosen V, intensities can encode salience, constraint-satisfaction, degree of activation, similarity, or any other orderable evidence measure that supports the required compositional operations. In particular, allowing $\mathrm{Int}_{S,t}$ to be fuzzy means that Y can partially recognize X—e.g. strongly for some motifs and weakly for others—without forcing a binary recognized/not-recognized cut. The set $\mathcal{P}_{X,C}$ can be read as the (aspect-relative) collection of patterns through which X is "trackable" by Y in the given context; different choices of C can therefore yield different recognition relations even between the same X and Y.

The clause "for all relevant t" is intentionally flexible: in applications one may take t to range over a training episode, over a window in which X is presented, or over a period of interaction in a shared environment. Nothing in the definition requires t to be discrete; the monotonicity condition in (learning) can be interpreted for continuous time (as an order-preserving map along the temporal order) as readily as for stepwise updates. Likewise, (learning) allows plateaus: $\mathrm{Int}_{Y,t}(P)$ may stabilize once Y has acquired the pattern, but the requirement of at least one strict increase rules out the degenerate case where Y merely happens to match X without any acquisition at all.

Remark 588. *Definition 159 formalizes a core Hyperseed intuition: recognition means that, through interaction, the recognizer comes to contain more of the same patterns that are present in what it recognizes. When combined with habit dynamics (Section 12), this becomes an explicit model of perceptual learning. In that combined picture, the monotone rise of $\mathrm{Int}_{Y,t}(P)$ can be understood as the trace left by repeated successful engagements with P—a memory-like accumulation that need* *not be explicit or symbolic. The alignment condition then plays the role of an external constraint: it ties the direction of learning to the target entity X rather than to arbitrary self-amplification within Y, and it permits a clean distinction between "becoming more patterned" and "becoming more patterned* in the way that matches *X." The nonemptiness of $\mathcal{P}_{X,C}$ similarly enforces that recognition is about at least one concrete pattern channel in the specified aspect, making explicit that recognition is always selective and aspect-relative rather than an undifferentiated global relation.*

Remark 589. *It can be helpful to view $\mathcal{P}_{X,C}$ as encoding what counts as "evidence about X" for the recognizer in context C: if $P \notin \mathcal{P}_{X,C}$, then even large values of $\mathrm{Int}_{Y,t}(P)$ do not contribute to recognition* of X in that aspect*. This separation makes room for familiar phenomena such as confounds and misattribution: Y may increase intensity on patterns that are predictive in its environment but are not actually patterns of X, in which case (alignment) fails and the process is better described as learning a surrogate. Conversely, the definition allows recognition to be partial and distributed: Y need not match X on all patterns in $\mathcal{P}_C$, only on some nonempty subset, and only to the extent measured in V. In settings where one wants to model over-shooting or hallucination (i.e. $\mathrm{Int}_{Y,t}(P) > \mathrm{Int}_{X,t}(P)$ for some P), one can treat such departures as a distinct kind of process rather than folding them into recognition; the present definition deliberately marks that boundary by requiring alignment.*

13.2 Contexts and aspects

Hyperseed treats most predicates as context-dependent. For representation, this context dependence is not optional: what a token represents is always "a representation of B *in some aspect C*."

Definition 160 (Context and aspect extraction)**.** *Let* **Ctx** *be a (small) poset of contexts with order $C \preceq D$ meaning "D refines C" (makes at least as many distinctions). An* aspect extraction family *is a family of maps*

$$\mathrm{asp}_C : \mathcal{U} \to \mathcal{U}_C \qquad (C \in \mathbf{Ctx})$$

with the property that if $C \preceq D$ then there is a canonical "forgetful" map $\pi_{D\to C} : \mathcal{U}_D \to \mathcal{U}_C$ satisfying $\mathrm{asp}_C = \pi_{D\to C} \circ \mathrm{asp}_D$. We write $X|C := \mathrm{asp}_C(X)$ for the aspect of X in context C.

Remark 590. *The notation is doing quiet but important work. The poset* **Ctx** *is a bookkeeping device for "ways of carving reality": $C \preceq D$ means that D is at least as discriminating as C (Hyperseed-Concept 86). The map asp_C is a projection that forgets everything about X that C is not sensitive to. The codomain $\mathcal{U}_C$ is the universe as viewed through C: one may think of it as equivalence classes, coarse descriptors, or structured observations, depending on the application.*

A simple example is geometric: let $\mathcal{U}$ be the set of 3D objects, and let C be "silhouette shape" while D is "full 3D mesh." Then D refines C, and $\pi_{D\to C}$ maps a 3D mesh to its silhouette descriptor; extracting the silhouette directly from the object or extracting the mesh and then forgetting down to silhouette yield the same result. Another example is linguistic: C might keep only "part of speech," while D keeps full syntactic parse; again, D refines C.

This definition is necessary because reference and representation will be indexed by C, and without a disciplined notion of aspect we risk equivocation: a token can be a faithful representation in one aspect (e.g. location) while being wildly unfaithful in another (e.g. color). Hyperseed's insistence that meaning is aspect-relative makes this explicit and prevents category mistakes.

Remark 591. *The condition $\mathrm{asp}_C = \pi_{D\to C} \circ \mathrm{asp}_D$ says that refining context and then forgetting back down is equivalent to extracting the coarse aspect directly. This formalizes the idea that "aspects" are stable observer-relative projections.*

Remark 592. *It is helpful to view the family* $\{\mathcal{U}_C\}_{C\in\mathbf{Ctx}}$ *as a system of compatible "views" of* $\mathcal{U}$*, where refinement introduces additional structure but never contradicts coarser views. Concretely, if* $C \preceq D \preceq E$*, then one typically expects the forgetful maps to compose coherently, i.e.* $\pi_{E\to C} = \pi_{D\to C}\circ\pi_{E\to D}$*, so that there is a unique way to forget from a very fine context down to a very coarse one. This kind of coherence is often implicit when one says the map* $\pi_{D\to C}$ *is "canonical," and it mirrors the informal idea that there is not more than one principled way to discard distinctions.*

Remark 593. *The adjective "small" for* **Ctx** *is primarily a set-theoretic convenience: it ensures that the indexing of contexts does not introduce size issues when later constructions quantify over contexts, form products over families of contexts, or speak of "all" contexts relevant to an agent. Intuitively, it corresponds to the modest claim that the agent's repertoire of ways-of-carving is enumerable within the theory, rather than a proper class of all imaginable measurements.*

Remark 594. *In many applications, each* asp_C *may be understood as inducing an equivalence relation on* $\mathcal{U}$*: two entities* $X, Y \in \mathcal{U}$ *are* C*-equivalent if* $X|C = Y|C$*. Under this reading,* $\mathcal{U}_C$ *can be taken (up to isomorphism) as the quotient of* $\mathcal{U}$ *by* C*-equivalence, and* $\pi_{D\to C}$ *expresses that* D*-equivalence refines* C*-equivalence when* $C \preceq D$*. This can clarify the slogan that a context "forgets distinctions": it identifies many fine-grained states as the same coarse state.*

Definition 161 (Contextualized groupings)**.** *For a grouping (collection)* $G \subseteq \mathcal{U}$ *and context* C*, define the* contextualization *of* G *to* C *by*

$$G|C := \{\, x|C : x \in G \,\} \subseteq \mathcal{U}_C.$$

Remark 595. *This is the natural lifting of aspect extraction from individuals to sets (Hyperseed-Concept 103). Intuitively, if* G *is "the set of all cups on the table," then* $G|C$ *is that same set as seen through context* C*—for example, perhaps as a set of silhouettes, or as a set of rough positions, depending on what distinctions* C *preserves.*

The usefulness is pragmatic: later constructions (pattern webs, attention allocation, prediction) often operate on collections rather than single entities. By contextualizing the collection, we can compare group-level phenomena across contexts without pretending that the contexts share the same granularity.

Remark 596. *Note that the definition uses an ordinary set image, so distinct elements of* G *may collapse to the same element of* $\mathcal{U}_C$ *when context* C *is coarse. This is not a bug: it records the fact that, relative to* C*, those distinct individuals are indistinguishable. When multiplicity matters (e.g. "two identical-looking cups" vs. "one cup"), one may later choose to work with multisets, measures, or probability distributions on* $\mathcal{U}_C$ *rather than plain subsets, but the present definition captures the minimal invariant needed for many aspect-relative comparisons.*

Remark 597. *Contextualization interacts with basic set operations in the expected monotone way. If* $G \subseteq H$ *then* $G|C \subseteq H|C$*, and if* $\{G_i\}$ *is any family of groupings then*

$$\Big(\bigcup_i G_i\Big)|C = \bigcup_i (G_i|C).$$

In general, contextualization does not commute with intersections: $(G\cap H)|C$ *may be strictly smaller than* $(G|C) \cap (H|C)$*, because two different elements—one from* G *and one from* H*—may become* C*-indistinguishable even if the original sets were disjoint. This is another manifestation of how a context can erase distinctions, and it will be relevant whenever later arguments reason about "overlap" between groupings in an aspect-relative way.*

13.3 Registration, sensory systems, and perception

Registration is Hyperseed's primitive "information intake" notion. It is weaker than perception: perception requires that registration triggers an internal representation. In particular, registration is meant to capture the minimal sense in which the system's dynamics come to *depend* on some aspect of the world, even when that dependence is too coarse, too unstable, or too weakly integrated to count as content-bearing cognition. This makes registration suitable as a common substrate for later distinctions: for instance, one can speak of registration that is accurate but nonconceptual, registration that is noisy or ambiguous, and registration that is driven by internal couplings (as in dreams) rather than exogenous causes (as in ordinary sensing).

Definition 162 (Registration)**.** *Fix a context C and an equivalence relation $\sim_C$ on $\mathcal{U}_C$ (interpreted as "indistinguishable in context C" for the registering system). A system X* registers *an entity A at time t (in context C) if there exists $A' \in \mathcal{U}$ such that $A'|C \sim_C A|C$ and $A'|C$ becomes a pattern in X by time t. Concretely, this can be witnessed by a pattern $P \in \mathcal{P}_C$ such that*

$$\mathrm{Int}_{X,t}(P) \not\leq \theta \qquad \text{and} \qquad \mathrm{Ref}_C(P, A|C) \text{ is nontrivial},$$

for some threshold $\theta \in V$.

Remark 598. *Registration (Hyperseed-Concept 153) is intentionally defined so that it can occur without any rich internal model. The equivalence relation $\sim_C$ encodes what the system cannot tell apart in context C (Hyperseed-Concept* **??***). Thus, registration is compatible with vagueness: to register A is not necessarily to pin down A as a unique individual, but to have one's internal dynamics come to embody a pattern that is at least compatible with A under the system's current discriminations.*

A minimal example: let C be a low-resolution visual context in which many distinct objects share the same coarse "blob" descriptor. Then $\sim_C$ identifies objects with the same blob. The system registers a particular object A when a blob-pattern becomes salient in the system ($\mathrm{Int}_{X,t}(P)$ *crosses threshold) and is linked by reference to the extracted aspect $A|C$. Here the notation* $\mathrm{Int}_{X,t}(P) \not\leq \theta$ *means "the intensity is above threshold" in the quantale order; in a numeric quantale this would read as the usual inequality "greater than θ," but the order-theoretic phrasing accommodates nonstandard evidence domains.*

This definition is useful because it separates (i) being impacted by the world *from (ii)* constructing an internal token that stands for the world*. That separation is needed for later distinctions among mere sensation, perception, hallucination, and reflective awareness.*

Two further clarifications help fix the intended reading. First, the role of A' is to accommodate the fact that the system may only ever interact with (or encode) a surrogate *that is equivalent to A under the coarse-graining imposed by C and $\sim_C$; one should not read the definition as requiring access to A "as it is in itself," but only to some entity that is indistinguishable from A at the resolution that matters for the registering system. Second, the "becomes a pattern in X by time t" clause is temporal in a permissive way: it allows registration to be an event that takes time to settle (e.g., integration over a short window, the closing of a feedback loop, or the accumulation of evidence), rather than an instantaneous snapshot. In settings where t is discrete and updates are synchronous, this can be read as "at or before the t-th update."*

It is also useful to distinguish nontrivial reference *from* maximally specific reference*. The condition* $\mathrm{Ref}_C(P, A|C)$ *nontrivial demands that the pattern is not merely active, but active* as about *(or at least systematically linked to) the contextual aspect $A|C$. However, the definition does not force the pattern to determine a unique referent beyond the equivalence class fixed by $\sim_C$: the same P may be compatible with many distinct A's in $\mathcal{U}$ so long as their C-aspects are identified.*

This is the intended locus of perceptual ambiguity at the level of registration (e.g., "something moved" or "a sound occurred" without a stable object assignment).

Definition 163 (Sensory system)**.** *Let X be a system and let $\mathcal{U}^{\text{ext}} \subseteq \mathcal{U}$ denote those entities considered "external" to X in a given modeling decomposition. A* sensory system *for X is a coherent subsystem $S \subseteq X$ such that:*

1. *most registrations produced by S have referents in $\mathcal{U}^{\text{ext}}$, and*

2. *the update dynamics of S are driven primarily by coupling to $\mathcal{U}^{\text{ext}}$ (rather than by coupling internal to X).*

Remark 599. *The point is not that the sensory system is metaphysically "outside-facing," but that, under a chosen decomposition into "system" and "environment," its causal drivers are predominantly exogenous. In robotics this might literally be sensors; in social cognition it might be language interfaces; in introspective cognition it might even be sub-systems that "sense" other parts of the mind. The definition thus accommodates both the ordinary case and the more Peircean/Whiteheadian view that there are many layers of mutual prehension, some treated as external only by pragmatic abstraction [14, 15].*

As an example, in a neural network model of an agent, an early vision stack could serve as S if its inputs are mostly pixels from the environment and its learned features are mostly driven by those pixels. The utility of naming S is that perception, attention, and control will later be analyzed as transformations that begin at such interfaces and propagate inward.

The qualifier "most" in item (1) is deliberate: many realistic sensory subsystems also generate registrations whose immediate referents are internal variables (e.g., gain control states, prediction error channels, or learned latent features) while still being primarily shaped by exogenous coupling. Similarly, item (2) is intended to be robust under modeling choices: one may refine or coarsen the system–environment boundary, and the definition only asks that, under the chosen decomposition, the dominant causal influence on S comes from $\mathcal{U}^{\text{ext}}$. This keeps the notion compatible with settings in which sensorimotor loops blur the boundary (e.g., active sensing where X moves to create informative inputs) while still allowing one to identify subsystems whose input channels *are anchored in the external world.*

It is also helpful to note that coherence of S is functional rather than anatomical: a sensory system may be distributed (e.g., multiple modalities or parallel transducers) so long as it forms a relatively unified interface from the standpoint of downstream processing (for instance, by supporting stable patterns $P \in \mathcal{P}_C$ that later stages can treat as evidence).

Definition 164 (Perception)**.** *A mind M* perceives *an entity A at time t (in context C) if:*

1. *M registers A at time t (Definition 162), and*

2. *this registration causally triggers the emergence of a representation token $R \in \mathcal{R}$ with $\mathrm{Ref}_C(R, A|C)$ nontrivial.*

In slogan form: perception is registration that causes representation.

Remark 600. *Perception (Hyperseed-Concept 134) is the first place where the theory demands a causal bridge from world-impact to internal content. Item (2) is what blocks a trivialization: mere registration can be fleeting, local, and unintegrated, whereas perception is registration that organizes the mind's representational economy by producing a token R that can participate in later inference, memory, and action.*

A simple example: a thermostat may "register" a temperature (its state changes in response to heat), but unless it produces an internal token that stands for "it is hot" in a way that can be recombined with other tokens, we would hesitate to call it perception in this framework. Conversely, an agent that forms an explicit map entry or object-file when stimulated by A meets the condition. This is why perception is the natural bridge to the prediction/control machinery of Section 14.

The "causally triggers" clause is meant to exclude cases where a representation happens to co-occur with a registration without being appropriately dependent on it. For instance, if R is generated by a purely endogenous process and merely coincides with the time at which M registers A, then (2) fails even if $\mathrm{Ref}_C(R, A|C)$ is nontrivial. Conversely, if the registration initiates a cascade (possibly mediated by attention, gating, or working memory) that yields R, then the perception condition is satisfied even when the representation is delayed relative to the initial registration, so long as the causal dependence is preserved.

It is also important that (2) requires a representation token *rather than merely a strengthened pattern. Intuitively, a token $R \in \mathcal{R}$ is something the mind can reuse, store, compare, and bind into larger structures; it is the kind of internal item that can later be evaluated for accuracy, recalled, or used as a premise in reasoning. Thus, perception is not merely "strong sensation": it is the emergence of a content-bearing element whose reference to $A|C$ is stabilized enough to enter the mind's representational repertoire.*

Proposition 19 (Perception implies registration)**.** *If a mind M perceives A at time t in context C, then M registers A at time t in context C.*

Proof. Immediate from Definition 164, item (1), which requires that M registers A at time t in context C as a precondition for perception. □

Remark 601. *Intuitively, this proposition says: if you genuinely perceived something (in the present formal sense), then you must at least have been affected by it in the weaker registration sense. The result is not surprising, but it is structurally important: it guarantees that perception is a strengthening of registration rather than a separate notion that could drift away. This monotonic relationship will be quietly used later when we model attention as selectively modulating the pipeline from registration to representation.*

Proof. Immediate from Definition 164, item (1). □

Proof sketch. Unpack the definition of perception: registration is literally a required conjunct. □

Remark 602. *The key step "item (1)" is doing all the work because perception was defined as a two-part condition, with registration as the first part. One may think of this as a design choice: the formalism encodes a conceptual hierarchy of notions (registration $\Rightarrow$ perception) directly into the logical form of the definitions.*

13.4 Representation as reference plus pattern inheritance

Hyperseed defines representation as "re-presentation": there must be a *reference* relation to what is represented, and the representation must inherit (some of) the patterns of the represented entity. We now formalize both components.

Definition 165 (Pattern signature in an aspect)**.** *Fix a context C and a finite pattern basis $\mathcal{B}_C \subseteq \mathcal{P}_C$. The* pattern signature *of an entity X in aspect C is the map*

$$\mathrm{Sig}_C(X) : \mathcal{B}_C \to V, \qquad \mathrm{Sig}_C(X)(P) := \mathrm{Int}_X(P),$$

where $\mathrm{Int}_X(P)$ *denotes the intensity of pattern* P *in* X *as defined in Section 9 (or its later refinement).*

Remark 603. *The pattern signature is an "aspect-relative fingerprint" of an entity in terms of a chosen basis* $\mathcal{B}_C$ *(Hyperseed-Concept 141). Concretely,* $\mathcal{B}_C$ *is a finite list of patterns we have decided are salient for the present discussion; the signature* $\mathrm{Sig}_C(X)$ *then assigns each basis pattern* P *an intensity value in* V *measuring how strongly* P *is present in* X*.*

A simple example: if C *is a sensory context and* $\mathcal{B}_C$ *is a set of visual features (edges, colors, textures), then* $\mathrm{Sig}_C(X)$ *is analogous to a feature vector. If* C *is a relational context and* $\mathcal{B}_C$ *is a set of graph motifs, then* $\mathrm{Sig}_C(X)$ *is a profile of how much* X *exhibits those motifs. The definition is useful because representation will be defined by comparing signatures: to represent is, in part, to share patterns in a controlled (typically reduced) way. This directly reflects Hyperseed's notion of patterns as compressive regularities [5].*

Definition 166 (Strong pattern inheritance)**.** *Let* $A, B \in \mathcal{U}$ *and context* C *be given. We say that* A inherits patterns from B *in aspect* C *if*

$$\mathrm{Sig}_C(A|C)(P) \leq \mathrm{Sig}_C(B|C)(P) \qquad \forall P \in \mathcal{B}_C.$$

Equivalently, $\mathrm{Sig}_C(A|C) \leq \mathrm{Sig}_C(B|C)$ *pointwise.*

Remark 604. *The inequality is intentionally one-sided: inheritance means "*A *has no more of each basis-pattern than* B *does," so* A *is (at most) as pattern-rich as* B *in the monitored directions. In a numeric setting, if* Sig_C *were feature activations in* $[0,1]$*, then inheritance would say each activation in* A *is bounded above by the corresponding activation in* B*.*

A toy example is projection: if B *is a high-resolution image and* A *is a compressed thumbnail, then the thumbnail inherits many coarse patterns (large-scale edges) but not the fine ones; in a basis that monitors only coarse patterns, one expects* $\mathrm{Sig}_C(A) \leq \mathrm{Sig}_C(B)$*. The definition is useful because it captures, in a single monotone condition, the intuition that a representation should be a simplification: it may discard detail, but should not invent detail in the same aspect without further explanation.*

Definition 167 (Representation in an aspect)**.** *Let* $A, B \in \mathcal{U}$ *and context* C *be given. We say that* A represents B *in aspect* C *if:*

1. *(reference)* $\mathrm{Ref}_C(A, B|C)$ *is nontrivial, and*

2. *(inheritance)* $A|C$ *inherits patterns from* $B|C$ *in the sense of Definition 166.*

Remark 605. *This definition makes precise Hyperseed's slogan that representation is "re-presentation":* A *presents again, in a cheaper form, something that is already present in* B*. The reference condition ensures "aboutness" (Hyperseed-Concept 152), while inheritance ensures a structured similarity in the chosen aspect (Hyperseed-Concept 157). Either condition alone is insufficient: mere similarity without reference yields accidental resemblance, and mere reference without inherited patterns yields a bare pointer with no internal content.*

As a simple example, a written name "Paris" may refer to Paris (reference), but in a sensory context it inherits almost none of Paris's sensory patterns; thus it is not an icon. In a relational context, however, it can inherit relational patterns (linked to "France," "capital-of," etc.), hence it can count as a symbol. The usefulness of the definition is that it lets us treat iconic, indexical, and symbolic representation uniformly and then specialize by aspect.

Remark 606. *The inheritance condition is deliberately "one-way": representations are allowed (and usually expected) to drop patterns. Dropping patterns is what makes a representation simpler and cheaper to manipulate.*

Proposition 20 (Transitivity of representation under compositional reference)**.** *Assume the reference relation composes in the following weak sense: if* $\mathrm{Ref}_C(A, B|C)$ *and* $\mathrm{Ref}_C(B, C|C)$ *are nontrivial, then* $\mathrm{Ref}_C(A, C|C)$ *is nontrivial. Then representation is transitive: if* A *represents* B *in aspect* C *and* B *represents* C *in aspect* C*, then* A *represents* C *in aspect* C*.*

Remark 607. *In plain terms: if* A *stands for* B*, and* B *stands for* C*, then (under a mild assumption on how reference chains behave)* A *stands for* C*. This is the familiar idea that representations can be layered: a mental image can represent a drawing which represents an object; a symbol can represent a definition which represents a concept; and so on. In particular, the "mild assumption" is doing the standard compositional work one expects of any usable notion of reference: when one token is used* via *another to pick out a target, the mediated link is still a bona fide instance of reference rather than a mere accidental correlation. The point is not that* every *associative chain composes (spurious co-occurrences should not), but that the chains that satisfy the definition's reference clause are closed under concatenation.*

What may be slightly surprising is that we also get the inheritance part "for free" by order transitivity: if each layer only drops patterns, then the composite also only drops patterns. Put another way, if passing from C *to* B *forgets (at most) some structure and passing from* B *to* A *forgets (at most) some additional structure, then passing from* C *to* A *cannot have introduced any new structure not already present in* C*; it can only have forgotten what the intermediate steps forgot. This is the precise sense in which "pattern inheritance" behaves like information monotonicity along a pipeline.*

This proposition connects the present section to later ones in two ways. First, prediction and control will often operate on multi-step representational pipelines, so transitivity ensures that the end-to-end token still counts as representing the target. Here one can think of a learned model whose internal states represent latent variables that in turn represent environment-level quantities: even if the agent only ever directly manipulates internal states, the claim guarantees that such manipulation is still, in the defined sense, manipulation of a representation of *the distal target. Second, attention allocation may be described as choosing which representational chains to extend; transitivity guarantees that extending a chain does not break representation, provided reference composes. This matters because attention policies often introduce new intermediate codes (additional "layers"), and we want a criterion under which adding such codes preserves representational status rather than requiring a fresh justification from scratch at each extension.*

Proof. By assumption, nontrivial reference composes. Here "nontrivial" rules out degenerate cases in which everything is taken to refer to everything (or reference is satisfied vacuously); the intended assumption is that whenever (A, B) and (B, C) meet the reference clause of Definition 167, then so does (A, C). This isolates the reference-conjunct from any additional constraints coming from inheritance and makes clear that the compositional step is a closure property of the reference relation itself.

For inheritance, if $\mathrm{Sig}_C(A|C) \leq \mathrm{Sig}_C(B|C)$ and $\mathrm{Sig}_C(B|C) \leq \mathrm{Sig}_C(C|C)$ pointwise, then by transitivity of $\leq$ we have $\mathrm{Sig}_C(A|C) \leq \mathrm{Sig}_C(C|C)$ pointwise. The word "pointwise" is essential: it means that for each coordinate (each pattern-dimension tracked by the signature), the inequality holds separately, so inequalities can be chained coordinate by coordinate without any need for aggregation or weighting. In particular, nothing like convexity, linearity, or an averaging argument is required; the conclusion follows purely from the order structure on the codomain of $\mathrm{Sig}_C(\cdot \mid C)$.

Thus both the reference and inheritance conditions of Definition 167 hold for (A, C). Equivalently, the composite map from C-relevant patterns to those preserved in A factors through B but does not depend on which factorization is chosen: any intermediate layer that merely deletes patterns cannot enable A to exceed C in signature strength. □

Proof sketch. The proof separates the two conjuncts in the definition of representation. Reference transitivity is assumed directly. Inheritance transitivity is obtained by chaining pointwise inequalities of pattern signatures. One can regard this as a "two-channel" argument: the semantic channel (reference) composes by hypothesis, while the structural channel (inheritance) composes because it is expressed as an order constraint, and orders are designed to support such chaining. □

Remark 608. *The key move is the pointwise ordering on signatures: it turns "inherits patterns" into an ordinary order-theoretic statement. Once that translation is made, the proof becomes an instance of the simplest Russellian principle: if $a \leq b$ and $b \leq c$ then $a \leq c$. Visually, one can picture signatures as vectors in a positive cone and inheritance as coordinatewise domination; then domination is clearly transitive. In more concrete terms, if each coordinate tracks the salience, presence, or strength of a given pattern relative to C, then "X inherits patterns from Y" means X does not score higher than Y on any such coordinate, i.e. X never claims to preserve a pattern more strongly than its source. The positive-cone picture is helpful because it emphasizes that we are not comparing vectors by length or angle (which could behave non-monotonically under composition), but by the product order, for which transitivity is immediate.*

It is also worth noting what this does not *require. The argument does not assume that any layer is lossless, only that loss is monotone in the sense captured by $\leq$. Nor does it require that signatures be complete descriptions of internal states; they only need to be the features relevant to the inheritance clause. As long as inheritance is expressed as coordinatewise non-increase of these features, any number of intermediate representational formats can be inserted without endangering the inheritance relation from the initial target to the final token.*

13.5 Semiotic modes: icon, index, symbol

Hyperseed adopts a simple Peircean triad [14]. All three modes are special cases of representation, distinguished by which aspect C is being preserved. In this framing, the triad is not a claim that there are three disjoint kinds of things "in the world," but that there are three recurring emphases in *how* a token functions as a representation: it may primarily preserve sensory patterning, spatiotemporal placement, or relational constraints. Which mode is appropriate can therefore depend on the analytic choice of aspect C (and thus on what the agent is treating as relevant structure) rather than on the token alone.

Definition 168 (Sensory, spatiotemporal, and relational aspects)**.** *Assume the context poset* $\mathbf{Ctx}$ *contains (at least) three marked sub-posets:*

- $\mathbf{Ctx}_{\mathrm{sens}}$ *(sensory domains),*
- $\mathbf{Ctx}_{\mathrm{st}}$ *(spatiotemporal positioning domains),*
- $\mathbf{Ctx}_{\mathrm{rel}}$ *(relational/network domains).*

These need not be disjoint; a single context may mix multiple concerns.

Remark 609. *This definition is a convenience: it declares three families of aspects that correspond, roughly, to "how it looks/feels," "where/when it is," and "how it relates." The sub-posets may* *overlap because real representational systems rarely separate these cleanly: a perceptual token may encode both sensory features and spatial location, and a symbol may have sensory typography. What matters is that we can talk about emphasizing one family of patterns over another when classifying a representational mode. This prepares the ground for the icon/index/symbol definitions (Hyperseed-Concept* **??**, **??**, *184).*

The role of the marked sub-posets is not to constrain what representations can *exist, but to provide a vocabulary for which invariances are being appealed to when we say "A represents B." For instance, a single token may preserve a sensory pattern (e.g. a silhouette) while also locating an event (e.g. a timestamped recording); the present taxonomy says that these are different representational* aspects*, even if realized by the same artifact. In later applications, this separation allows one to ask whether an inference step is justified by sensory similarity, by spatiotemporal anchoring, or by relational constraints in a model.*

Definition 169 (Icon)**.** *An entity A is an* icon *for an entity B if there exists a sensory context $C \in \mathbf{Ctx}_{\mathrm{sens}}$ such that A represents B in aspect C.*

Remark 610. *An icon is, in effect, a representation that preserves sensory-pattern structure. A photograph is the standard example: in an appropriate sensory context it inherits many of the visual patterns of its referent (though often with distortions). Another example is a melody hummed from memory: it can be iconic of the original tune insofar as auditory patterns are preserved.*

The definition is intentionally broad about what counts as "sensory." Many scientific and technical representations function iconically once a suitable sensory context is fixed: a spectrogram can be an icon of an acoustic event in a visual sensory context; a plot of a signal over time can be iconically related to the underlying process insofar as shape, periodicity, and relative magnitude are preserved. Even schematic diagrams (e.g. circuit diagrams) can be partially iconic if the relevant sensory aspect is taken to be geometric adjacency or shape-based regularities, rather than photorealism.

The usefulness of the definition is that it reduces "iconicity" to the general representation notion plus a restriction on aspect. This makes it possible to treat icons within the same mathematical machinery used for symbols, rather than as an unrelated primitive. In particular, the present viewpoint allows degrees and failures of iconicity to be stated as failures to preserve specific sensory patterns (e.g. loss of resolution, occlusion, aliasing), rather than as a vague departure from "resemblance."

Definition 170 (Index)**.** *An entity A is an* index *for an entity B if there exists a spatiotemporal context $C \in \mathbf{Ctx}_{\mathrm{st}}$ such that A represents B in aspect C.*

Remark 611. *An index preserves spatiotemporal positioning patterns: it is a pointer, a trace, or a coordinate-like token. A deictic gesture "that" is indexical; a memory address in a computer is indexical; smoke can be indexical of fire when treated in a spatiotemporal/causal-trace context.*

The spatiotemporal aspect may be literal (a GPS coordinate, a clock time, a bounding box in an image) or implemented via a proxy that is treated as preserving location-like structure (e.g. a database key that is stable under operations interpreted as "moving through" a record space). What matters for the present classification is that the representation is used primarily to pick out *an occurrence or region by its placement within some ordering of space, time, or traceable causal propagation, rather than to encode its detailed sensory qualities.*

Indices are theoretically useful because they allow reference with minimal inherited content. In many control and prediction settings, what you need is not a rich description but a stable handle to the relevant portion of the world. Indexicality supplies this handle in a form that can later be elaborated into richer representation by adding further aspects. This also clarifies why indexical *tokens often appear in pipelines: an agent may first secure an index to "the object over there" and only subsequently attach iconic features (appearance) or symbolic labels (category, name) once additional processing becomes available.*

Definition 171 (Symbol)**.** *An entity A is a* symbol *for an entity B if there exists a relational context $C \in \mathbf{Ctx}_{\mathrm{rel}}$ such that A represents B in aspect C. In addition, symbolic representations are assumed to participate in a* combinational system *(Section 9): symbols can be composed and recombined, and their referents are constrained by their relationships to other symbols.*

Remark 612. *A symbol is a representation whose salient preserved structure is relational, not sensory. The word "electron" does not look like an electron; it inherits its meaning from the web of relations it bears to other symbols (laws, measurement terms, mathematical operators). The additional requirement of participation in a combinational system captures this: symbols are not isolated labels; they live in a grammar, calculus, or graph of constraints (Hyperseed-Concept 77).*

On this view, "conventionality" or "arbitrariness" is not a separate axiom but a common consequence: if what is preserved is primarily relational structure, then many different tokens could in principle occupy the same node in the relational web without changing the role they play. Conversely, if the relational neighborhood changes (e.g. the inferential rules governing a term), then the symbol's meaning shifts even if the token's sensory form remains identical. This matches everyday cases in which a symbol retains its typography while acquiring new use through altered definitions, laws, or embedding discourse.

This definition is valuable because it connects semiotics to computation. Once symbols are combinable, they support systematic inference and counterfactual reasoning; hence symbolic representation is a key substrate for the later sections on prediction, causality, and control. The move also echoes Peirce's emphasis on the triadic, law-like mediation characteristic of symbols [14] (compare also Hyperseed-Concept 190). A further consequence is that symbolic systems typically admit explicit notions of well-formedness and equivalence (syntactic validity, derivability, rewriting), which can be treated as additional relational constraints internal to $\mathbf{Ctx}_{\mathrm{rel}}$.

Remark 613. *These definitions deliberately leave room for hybrid tokens. For instance, a labeled photograph may be both an icon (sensory similarity) and a symbol (networked relationship to other labeled items).*

Hybridity is not an exception but a common mechanism of grounding and coordination: an index may anchor a symbolic description to a particular event, while an icon may provide a perceptual interface for symbolic manipulation (e.g. diagrammatic reasoning where visual similarity guides steps that are nonetheless licensed by relational rules). In practice, agents often move between modes by changing which aspect C they treat as primary: the same token can be read iconically (attend to resemblance), indexically (attend to location or provenance), or symbolically (attend to its role in a combinational system).

13.6 Soggy predicates and paraconsistent truth

Hyperseed's "soggy predicates" are intended as a bridge between: (i) fuzzy truth values attached to predicates, and (ii) probabilistic semantics grounded in (possibly hypothetical) collections of observations. We now define soggy predicates in a way that is compatible with the $[0,1]^2$ (paraconsistent) evidence domain [23, 24].

Definition 172 (p-bit-valued predicate)**.** *Let X be a universe of discourse. A* p-bit-valued predicate *on X is a function $F : X \to [0,1]^2$. We interpret $F(x) = (F^+(x), F^-(x))$ as degrees of positive and negative evidence for the statement "x has property F."*

Remark 614. *A* p-bit*-valued predicate replaces a single truth degree with a pair of evidential degrees: how much evidence supports the predicate and how much evidence opposes it. The notation* $F^+(x)$ *and* $F^-(x)$ *simply refers to the first and second components of* $F(x)$*, respectively. This is a natural fit for paraconsistent reasoning: one can simultaneously have high positive and high negative evidence without collapsing into triviality (Hyperseed-Concept 198).*

A simple example: let X *be a set of patients and* $F(x)$ *encode evidence that patient* x *has a disease. A lab test might contribute positive evidence while a conflicting scan contributes negative evidence. Then* $F(x)$ *can legitimately be* $(0.8, 0.7)$*, reflecting serious conflict rather than forcing an artificial resolution. This is useful later because habit dynamics, prediction, and control will often propagate and transform such evidential pairs rather than crisp truths.*

Remark 615. *It is helpful to keep distinct (i)* evidence *and (ii)* truth *in the classical sense. In a* p-bit*-valued predicate, the pair* $(F^+(x), F^-(x))$ *is not required to satisfy* $F^-(x) = 1 - F^+(x)$*, and therefore it is not a probability assignment or a fuzzy membership degree by default. Instead, it records two potentially independent aggregates: "how much pushes toward acceptance" and "how much pushes toward rejection." This independence is precisely what allows explicit representation of conflict, as well as "informational gaps" where both coordinates are small.*

A common derived reading (not assumed, but often useful as intuition) is to view

$$\mathit{conflict}(x) \ := \ \min(F^+(x), F^-(x)), \qquad \mathit{ignorance}(x) \ := \ 1 - \max(F^+(x), F^-(x)),$$

so that $(1, 0)$ *indicates maximal support with no opposition,* $(0, 1)$ *indicates maximal opposition with no support,* $(1, 1)$ *indicates maximal conflict, and* $(0, 0)$ *indicates maximal lack of evidence either way. The framework itself only commits to the evidential pair; any downstream "decision rule" (accept/reject/undetermined) can be layered on later, depending on the application.*

Definition 173 (Soggy predicate)**.** *Fix a finite observation set* $\mathcal{O}$ *and weights* $w_o \geq 0$ *with* $\sum_{o \in \mathcal{O}} w_o = 1$*. Assume each observation* $o \in \mathcal{O}$ *yields an evidential evaluation* $e_o : X \to [0, 1]^2$*. Define the* soggy predicate *induced by* $(\mathcal{O}, w, e)$ *as*

$$F(x) := \sum_{o \in \mathcal{O}} w_o \, e_o(x),$$

where the sum is taken componentwise in $[0, 1]^2$*.*

Remark 616. *A soggy predicate (Hyperseed-Concept 172) is, mathematically, just an average of evidential evaluations across an ensemble. The normalization* $\sum_o w_o = 1$ *ensures* $F(x)$ *remains in* $[0, 1]^2$ *when each* $e_o(x)$ *does. Componentwise summation means:*

$$F^+(x) = \sum_o w_o e_o^+(x), \qquad F^-(x) = \sum_o w_o e_o^-(x).$$

Intuitively, each $o \in \mathcal{O}$ *is a possible "way of looking" (an observation, measurement, or test), and* w_o *measures its importance or frequency.*

A simple example: let $\mathcal{O}$ *be a set of diagnostic tests. Each test* o *yields a pair* $e_o(x)$ *of support/opposition for "*x *has condition* F*." Then* $F(x)$ *aggregates them. This is useful for two reasons. First, it grounds fuzzy/paraconsistent truth in an observation model, which is important for the later philosophy-of-science stance. Second, it provides a canonical way to combine heterogeneous evidence without prematurely forcing complementarity; this aligns with the paraconsistent motivation emphasized in [23, 24].*

Remark 617. *Because the weights $(w_o)_{o\in\mathcal{O}}$ form a simplex (nonnegative and summing to* 1*), the map $F(x) = \sum_o w_o e_o(x)$ is a* convex combination *of the points $\{e_o(x)\}_{o\in\mathcal{O}} \subseteq [0,1]^2$. Thus $F(x)$ lies in the convex hull of the per-observation evidential evaluations, and in particular cannot introduce out-of-range evidence values. This convexity perspective is often the right mental model: "sogginess" amounts to pooling an ensemble of perspectives without forcing them to agree.*

In the intended applications, $\mathcal{O}$ can be read either extensionally (a literal finite set of measurements) or intensionally (a finite set of measurement types *or contexts). Correspondingly, the weights w_o can be read as empirical frequencies, reliabilities, priors over contexts, or (in engineered settings) design choices that allocate attention among sensors or sub-models.*

Remark 618. *Soggy predicates are "simple observation grounded" in the sense that $F(x)$ is the (weighted) average evidential assessment over an ensemble of observations. The ensemble $\mathcal{O}$ need not be the mind's actual observations; it may encode hypothesized observations, cultural priors, or counterfactual experiments.*

Remark 619. *The finiteness of $\mathcal{O}$ is a convenience rather than a deep restriction: it ensures the sum is elementary and avoids measure-theoretic overhead. Conceptually, one can regard $(\mathcal{O}, w)$ as a finite probability space on "observation modes" and $e_o(x)$ as a random evidential evaluation; then $F(x)$ is the expectation of that random evaluation. This probabilistic reading is deliberately weak: it treats weights as a bookkeeping device for aggregation, without requiring that the evidential coordinates themselves be probabilities.*

Proposition 21 (Probabilistic semantics as a special case)**.** *Suppose that for every observation o and entity x the evidence is complementary, meaning $e_o^-(x) = 1 - e_o^+(x)$. Then the induced soggy predicate F satisfies $F^-(x) = 1 - F^+(x)$ for all x. Thus $F^+(x)$ can be read as an ordinary fuzzy membership degree in $[0,1]$ and, if $e_o^+(x)$ are interpreted as per-observation probabilities, then $F^+(x)$ is the expected probability of satisfaction.*

Remark 620. *This proposition says that the paraconsistent framework strictly generalizes the familiar probabilistic (or fuzzy) one. If every observation insists that "negative evidence is exactly one minus positive evidence," then the two-coordinate representation collapses back down to a single number, and soggy predicates become ordinary expectations. This is important because it reassures us that we have not abandoned classical semantics; we have merely stopped assuming that the world (or the observer) always provides perfectly complementary information.*

The result connects backward to the earlier probability-flavored phrasing of habits (Section 12.1) and forward to prediction and control (Section 14), where one may sometimes choose to work in the complementary subcase for convenience.

Remark 621. *The complementarity assumption $e_o^-(x) = 1 - e_o^+(x)$ can be understood as embedding a single scalar evaluation into the square $[0,1]^2$ via the diagonal map $p \mapsto (p, 1-p)$. Under this embedding, the soggy construction commutes with averaging: averaging on the diagonal in $[0,1]^2$ is the same as averaging in $[0,1]$ and then re-embedding. In this sense, soggy predicates are "conservative" over ordinary fuzzy/probabilistic semantics: the extra coordinate does not change anything when the data already lives on the diagonal, but it becomes available when the data departs from complementarity.*

It is also worth noting what complementarity rules out: if two observations deliver $e_{o_1}(x) = (0.9, 0.1)$ and $e_{o_2}(x) = (0.1, 0.9)$, then each observation is individually complementary, yet the disagreement between observations is not represented as within-observation conflict; rather, it manifests as uncertainty in the aggregate when averaged. By contrast, genuinely paraconsistent evidence allows an individual observation mode (or model) to carry its own internal tension, e.g. $(0.9, 0.8)$*, which is a different phenomenon than mere inter-observation disagreement.*

Proof. Compute componentwise:

$$F^-(x) = \sum_o w_o e_o^-(x) = \sum_o w_o(1 - e_o^+(x)) = 1 - \sum_o w_o e_o^+(x) = 1 - F^+(x).$$

□

Proof sketch. Use the complementarity assumption $e_o^- = 1 - e_o^+$ inside the weighted sum, then pull out the constant 1 using $\sum_o w_o = 1$. □

Remark 622. *The decisive step is the normalization of weights. Without $\sum_o w_o = 1$, one would obtain $F^-(x) = (\sum_o w_o) - F^+(x)$ instead. Geometrically, complementarity restricts evidence pairs to the diagonal line $v^- = 1 - v^+$ in the unit square; averaging preserves this line, so the soggy predicate stays on the diagonal and can be identified with its first coordinate.*

Remark 623. *In later sections, it is sometimes useful to treat F as defining a family of classical predicates by thresholding one or both coordinates, e.g. "accept F at level α" meaning $F^+(x) \geq \alpha$ (support-based), or "reject F at level β" meaning $F^-(x) \geq \beta$ (opposition-based), or a three-way policy that separates accept/reject/undecided by simultaneously requiring high support and low opposition. The point of the soggy construction is that such policies can be formulated* after *aggregation, once the evidential landscape is explicit, rather than being silently forced by an assumption of complementarity at the outset.*

Moreover, because F is an affine combination of the e_o, any downstream affine transformation of evidence (for example, a linear calibration map applied to each observation mode) can be moved inside the sum when convenient. This algebraic flexibility is part of why soggy predicates behave well as building blocks for habit-updates and for compositional models of perception.

Remark 624. *The point of the $[0, 1]^2$ form is that complementary evidence is not required. A mind may have strong positive and strong negative evidence simultaneously for the same predicate (conflict), or may have neither (lack of evidence). Soggy predicates simply average such evidence profiles over an observation ensemble. In particular, the two coordinates can be read as* independently accumulated *support-for and support-against signals, rather than as probabilities that must sum to one. This makes room for familiar cognitive situations: perceptual ambiguity (both channels low), illusion or misinformation (high negative evidence against a claim that is nevertheless asserted), and genuine inconsistency in a knowledge base (both channels high due to incompatible but salient cues). Averaging over an ensemble should be understood as smoothing over time, viewpoints, or sub-systems (e.g. different sensory modalities), so that a "stable" soggy predicate can coexist with momentary spikes of conflict without forcing an immediate collapse to a single bivalent verdict.*

13.7 Micro-example: registering and representing a pattern

We illustrate the chain

$$\text{external pattern} \to \text{registration} \to \text{representation}$$

on a minimal finite instance, aligned with the toy universe style of Section 5. The intent is to separate (i) what is present in the external entity, (ii) what the sensory apparatus can extract in a particular situation, and (iii) what the cognitive system subsequently stabilizes as a manipulable internal item. Even in this minimal setting, the example shows that "representation" is not a single relation but a family of context-indexed relations, each preserving different structural constraints.

Example 13 (Icon, index, and symbol for one referent)**.** *Let $\mathcal{U}$ contain an external entity B. Assume a mind M has a sensory subsystem S that registers B in a sensory context $C_{\text{sens}} \in \mathbf{Ctx}_{\text{sens}}$. Registration produces a token $r_{\text{icon}} \in \mathcal{R}$ whose sensory signature matches a subset of B's sensory signature, i.e. $\text{Sig}_{C_{\text{sens}}}(r_{\text{icon}}) \leq \text{Sig}_{C_{\text{sens}}}(B)$. Here the order $\leq$ can be read as "no more detailed than" or "contained within" the external signature as constrained by the context (e.g. limited resolution, occlusion, viewpoint, or modality). Thus, even when B has a rich sensory profile, the registered icon may preserve only a small pattern family (edges but not texture; pitch but not timbre; silhouette but not color), and the context index specifies* which *family is being compared. If $\text{Ref}_{C_{\text{sens}}}(r_{\text{icon}}, B|C_{\text{sens}})$ is nontrivial, then r_{icon} is an icon for B. Nontriviality can be taken to rule out purely accidental resemblance or degenerate cases where the token fails to track B at all in that context (e.g. noise that happens to match a feature).*

Now suppose the same registration also yields a spatiotemporal pointer token $r_{\text{index}} \in \mathcal{R}$ (e.g. "the thing at location ℓ at time t"), with nontrivial reference in some $C_{\text{st}} \in \mathbf{Ctx}_{\text{st}}$. Then r_{index} is an index for B. The index need not share sensory features with B; its fidelity is instead to the coordinate structure of the spatiotemporal context (tracking, co-location constraints, persistence conditions, and so on). This makes explicit how a mind can keep track of "that thing there" even when the iconic channel is weak or corrupted, and conversely how an icon may be vivid without being anchored to a stable pointer.

Finally, suppose M maintains a relational knowledge graph in a context $C_{\text{rel}} \in \mathbf{Ctx}_{\text{rel}}$. A new node token $r_{\text{sym}} \in \mathcal{R}$ is introduced into this graph and linked via learned relations (e.g. "is-a", "part-of", "causes"). If r_{sym} represents B in C_{rel} and participates in the graph's combinational operations (composition/inference rules), then r_{sym} is a symbol for B. The emphasis on participation is crucial: the symbol is not merely a label, but a handle that supports rule-governed recombination (e.g. inheritance along "is-a", constraint propagation along "part-of", or abductive links along "causes"). In this sense the symbol preserves a pattern family that is primarily relational *rather than sensory or spatiotemporal, and its adequacy is tested by the success of downstream inferences rather than by immediate resemblance.*

In this way, one referent B can simultaneously have iconic, indexical, and symbolic representations within the same mind, each preserving different pattern families. The three tokens may be created together by a single episode, but nothing in the setup requires a one-to-one correspondence: a single referent can spawn many icons (different viewpoints), many indices (different tracking frames), and many symbols (different conceptual roles), and conversely a single token can sometimes serve multiple roles when contexts align.

Remark 625. *This example highlights why the aspect index C is not decorative. The same referent B can generate three tokens with three different "fidelities," each faithful in its own slice of structure. The icon inherits sensory patterns; the index inherits spatiotemporal patterns; the symbol inherits relational patterns and gains power from combinational constraints. In realistic cognitive architectures, these modes interact: symbols can cue imagery, indices can anchor symbolic facts, and icons can be annotated symbolically. The present formalism supports that interaction precisely because all modes are instances of the same representation schema. More formally, the context index indicates (i) which signature map is in play, (ii) which reference conditions count as nontrivial tracking, and (iii) which transformations are licensed as "structure-preserving" within that mode. Interactions across modes can then be modeled as context-bridging operations (e.g. an index-to-symbol update that binds a pointer to a graph node, or a symbol-to-icon query that retrieves a stored prototype), rather than as an informal mixing of incomparable representational types. This also clarifies how conflict can arise and be managed: an icon may strongly support a property while the symbol-graph entails its negation, yielding the kind of simultaneous positive and negative* *evidence that motivates the soggy/paraconsistent treatment above, without forcing an immediate collapse of either representational channel.*

13.8 What this buys us for later sections

This section sets up the representational vocabulary needed for later parts of the paper: in particular, it provides a disciplined way to move between (a) causal interaction with the world, (b) internal state that carries information across time, and (c) the system's own graded assertions about what is the case. The payoff is that later sections can rely on these distinctions without having to re-argue them each time, and can state claims in a way that is stable under changes of implementation details (e.g. the chosen evidence calculus).

- In Section 14, prediction and control can be defined over representations, with sensory registration providing the perception channel. This means that what gets predicted (and what gets steered) is not raw stimulation as such, but the system's internal stand-ins that persist and can be compared, composed, and acted upon; registration then functions as the principled interface by which the environment constrains and corrects those stand-ins.
- In Section 15, attention can be modeled as selective updating of subsets of the representation/predicate network. On this framing, "attention" is not a mysterious extra faculty but a policy over which representational tokens and which predicate-attachments are revised given new registrations; this makes it natural to treat attentional bottlenecks and synergy effects as properties of update locality, bandwidth, and coupling between subnets.
- In Sections 16 and 17, self models and reflective content will be formalized as representational fixed points and higher-order registrations (e.g. "M registers that M registers A"). The fixed-point language is intended to capture the way a stable "self" representation can be maintained even as particular subordinate representations change, while higher-order registration provides a uniform syntax for reflexive and meta-level content (for example, when the system not only registers A but also registers something about its own registering of A).

Remark 626. *In philosophical terms, we have separated three layers that are often conflated: (i) the world's impact on a system (registration), (ii) the system's stabilized internal stand-ins (representation tokens), and (iii) the evidential grading of assertions about entities (soggy predicates). This separation is what permits later sections to talk rigorously about agency: prediction and control operate on representations, attention shapes which representational subnets are updated, and reflective consciousness can be treated as iterated registration/representation operating on the system itself (Hyperseed-Concept 166, 85). A useful way to read (i)–(iii) is as a progression from causal contact, to internal re-identification, to doxastic stance: registration is the "impression" or incoming constraint, representation tokens are the stabilized carriers that allow re-use and cross-context comparison, and soggy predicates express not just whether a claim is stated but how strongly it is supported given the system's currently available registrations and representational structure. In particular, soggy predicates make room for the possibility that the same representation token can be maintained while its evidential status shifts (e.g. strengthened, weakened, or put into tension by new registrations), which will matter later when we discuss conflict, revision, and partial observability.*

Mathematically, the benefit is modularity: one may change the evidence domain (e.g. Boolean, probabilistic, p-bit*-paraconsistent) or change the context poset, while keeping the same definition-shape of mind, perception, and representation. This is a recurring theme in the Hyperseed program [1]. Concretely, the definitions are arranged so that (a) representation-management operations (e.g. prediction, control, and selective update) depend primarily on the abstract interfaces provided by* *the chosen evidence domain and context structure, and (b) the perception channel can be treated as a morphism-like linkage from registrations into representational updates. As a result, later claims can be phrased at a level where one can swap out, for instance, a crisp two-valued evidential semantics for a graded or paraconsistent one, and still interpret the same formal roles for "perception," "belief-like grading," and "self-referential registration" without rewriting the surrounding conceptual architecture.*

14 Prediction, attraction, causality, and control

14.1 From patterns to forecasts and interventions

Sections 9–13 built a scaffold in which an observer/context O (a mind, or a mind-plus-environment slice) (i) makes distinctions, (ii) registers patterns, (iii) organizes those patterns into hierarchies/webs, and (iv) maintains representations whose content is indexed by contexts and aspects.

This scaffold is intentionally descriptive: it explains how a structured "world of patterns" can be available *to* an observer, without yet committing to any particular stance on time, action, or counterfactual dependence. In particular, the indexing-by-context machinery implies that what counts as "the same" pattern may vary with aspect (what features are being attended to) and with the surrounding representational commitments (what background regularities are currently assumed). Forecasting and intervention add further structure: they require that the observer's stored patterns be usable not only as compressions of what has been registered, but also as guides to what is likely, what is avoidable, and what is achievable under feasible actions.

Remark 627. *In the Hyperseed framing, the passage from "patterns" to "agency" is not a metaphysical jump but a change of grammatical tense: we move from describing what is coherently present to describing what is* expected *to become present, and what may be* made *to become present by action. This shift is precisely what brings prediction, control, and therefore causality into focus, and it connects the pattern-oriented representational layer to the later resource-bounded attentional layer (Section 15). See [1, 5] for the motivating ontology-level narrative.*

One can read this "tense shift" as adding a minimal temporal semantics to the representational architecture: patterns are no longer merely relations among currently co-present distinctions, but also constraints on transitions between contexts. In that sense, the same representational web that supports recognition ("this looks like that") is repurposed into a transition model ("from here, that tends to follow"). Likewise, the same distinction-making that supports categorization is repurposed into a space of candidate interventions: an "action" is, at minimum, an internally available distinction whose enactment changes which subsequent contexts become accessible.

This section adds the "forward arrow" needed for agency: *prediction* (how likely are future patterns/events?) and *control* (how can actions steer future patterns/events?), as well as the intermediate notion of *causality* (Hyperseed-Concept 70).

A useful way to separate these three is by their roles, not their vocabulary. Prediction concerns inference under uncertainty: given present context/aspects and available evidence, what distribution over future distinctions is warranted? Control concerns selection under constraints: given possible actions and limited resources, which action policies best steer the distribution of future contexts toward desired regions? Causality, in this framing, is the bridge that makes control non-magical: it is the claim that some distinctions (candidate actions, conditions, or structural changes) make a *systematic difference* to future patterns beyond mere co-occurrence, thereby licensing intervention planning rather than passive extrapolation.

Hyperseed's key move here is to make the dependence notions explicitly *differential*. For decision making, what matters is rarely $P(B \mid A)$ by itself, but rather how different $P(B \mid A)$ is from $P(B \mid \neg A)$. This is packaged in the notions of *attraction*, *predictive implication*, and *predictive attraction* (Hyperseed-Concept **??**).

Concretely, a non-differential statement like "B is likely" can be true in a way that is irrelevant to agency: B may be likely regardless of what the agent does, because of background regularities that dominate the dynamics. Differential dependence, by contrast, asks whether A changes the likelihood of B *relative to a baseline*, where the baseline is typically "not A" or "the default policy" in the given context. This is why notions like attraction naturally support ranking and prioritization: if two candidate actions both yield high $P(B \mid A)$, but one of them yields only a tiny improvement over $P(B \mid \neg A)$, then that action carries less leverage and is typically less valuable for control.

It is also where the representational indexing by context matters operationally. The quantities $P(B \mid A)$ and $P(B \mid \neg A)$ are only meaningful relative to a specified evidential context, including which aspects are held fixed, which are allowed to vary, and which background conditions are treated as stable. Thus, the "difference" being computed is not merely a numerical subtraction but a context-sensitive comparison between two nearby worlds (or two nearby policy regimes) as represented by O. When later sections introduce resource-bounded attention, this contextuality becomes even more pronounced: an agent may only be able to approximate such differences using compressed, aspect-limited summaries of the evidence.

From the standpoint of interventions, it is often helpful to distinguish evidential conditioning from interventional forcing: $P(B \mid A)$ can be high because A is a symptom of hidden causes, even if setting A would not increase B. Hyperseed's "control" reading therefore implicitly invites a distinction between "observing A" and "doing A"—the latter corresponding to an intervention that breaks certain background dependencies. Even when the formalism is written in ordinary conditional-probability terms, the intended use is counterfactual: the agent is comparing what happens under a contemplated action to what would have happened without it, within the same contextual slice.

Remark 628. *The differential stance is philosophically modest but practically decisive: it acknowledges that many future outcomes are overdetermined by background regularities, and that an agent's action matters only insofar as it* tilts *the odds relative to what would have happened otherwise. This is also where ordinary probability talk (Hyperseed-Concept 139) becomes insufficient on its own: in borderline, vague, or internally conflicted contexts, we often possess evidence both for and against an event, and the* difference *between conditional propensities must be computed from that evidence rather than assumed crisp at the outset. Paraconsistent treatments of evidence streams of this sort are developed in various logical settings; see, e.g., [23, 24].*

A further pragmatic consequence is that differential notions can be estimated and improved incrementally. An observer may begin with crude qualitative comparisons ("A seems to help B") and refine them into more stable graded relations ("A attracts B more strongly than A' does") as additional evidence accumulates, aspects are reweighted, or confounders are represented explicitly. In this sense, attraction-like quantities function as "handles" for learning and control: they are directly tied to what changes when the agent changes something, and thus to the empirical signature of agency within a pattern-based world-model.

14.2 Event types, timelines, and paraconsistent occurrence data

We assume the temporal scaffolding from Section 7: a (possibly branching, partially ordered) timeline $(T, \preceq)$ for a given context/observer, where $t \preceq t'$ means "t is not later than t' as experienced/represented by O."

Remark 629. *The notation $(T, \preceq)$ should be read as follows: T is a set of time indices, and $\preceq$ is a partial order encoding the observer's "before/after" structure (Hyperseed-Concept 142). The possibility that $\preceq$ is not total allows branching and incomparability, which is useful when the observer's model has multiple consistent continuations or when retrospective reconstruction leaves some order relations undecided.*

Remark 630. *It is helpful to keep three distinct readings of $t \in T$ in mind, depending on the application: (i) t may be a physical clock reading (as in sensor timestamps), (ii) t may be an internal computational step or belief-state index (as in an agent's recurrent update cycle), or (iii) t may be a reconstructed "scene time" used to order remembered or narrated events. The partial order $\preceq$ is deliberately flexible enough to cover all three cases while remaining agnostic about whether time is continuous, discrete, or hybrid.*

Remark 631. *When $\preceq$ is partial, one can still speak about* histories *(or* branches*) as chains $H \subseteq T$ such that any two elements of H are $\preceq$-comparable. Many constructions later can be understood as first restricting attention to a particular chain H (a single "possible continuation" as tracked by O), and only then applying sequence-like reasoning. This is one way to connect branching time intuitions with sequence-based prediction rules.*

Definition 174 (Event types and event tokens)**.** *Let $\mathcal{E}$ be a set of* event types *(also called "event predicates"), such as `kiss(Ben)` or `get(ball)`. An* event token *is a pair (A, t) with $A \in \mathcal{E}$ and $t \in T$. We write $A@t$ for "event type A occurs at time t." We assume the event language is closed under a formal negation operator $A \mapsto \neg A$, read as "not A". Because boundaries may be vague or inconsistent, it is allowed that both $A@t$ and $(\neg A)@t$ carry substantial evidence.*

Remark 632. *Intuitively, an* event type *is a reusable description (a predicate schema), while an* event token *is a particular alleged occurrence located at a particular time index. The notation $A@t$ is a compact "addressing" convention: it keeps the type A and the time t visible so we can talk about temporal relations between occurrences.*

Remark 633. *The operator $\neg$ is treated here as* syntactic *negation: it simply forms a new event type $\neg A$ from A. In particular, we do not assume that $\neg A$ exhausts all alternatives to A, or that it behaves like a classical complement with respect to evidence. This matters in practice: for many perceptual or social predicates, "not A" is not a well-delimited natural kind, and the observer may have independent reasons to support both A and $\neg A$ (e.g., due to incompatible measurement channels or shifting criteria of application).*

Remark 634. *A simple example is: let $A =$`get(ball)` and let t be the moment a camera frame shows a hand grasping a ball. Then $A@t$ is the token claim "the ball is gotten at time t." If the camera view is occluded, one may simultaneously have evidence for $A@t$ (a motion consistent with grabbing) and for $(\neg A)@t$ (no clear visual confirmation). Allowing both is not a flaw here; it is a way of keeping track of the epistemic situation without prematurely forcing a crisp boundary between "occurs" and "does not occur." This connects back to Hyperseed's emphasis on distinction-making as observer-relative (Sections 3 and 13).*

Remark 635. *In examples like* `kiss(Ben)` *or* `get(ball)`*, the event type may implicitly carry arguments (participants, objects, locations). One can regard $\mathcal{E}$ as a set of fully instantiated predicates (ground atoms), or as a set of predicate schemas paired with a domain of entities. Nothing below depends on this choice, as long as the notation $A@t$ picks out a well-formed token claim that can be supported or opposed by the observer's evidence.*

Remark 636. *This definition is useful because it cleanly separates (i) the* syntax *of events (what we are talking about), (ii) the* temporal indexing *(when we are talking about it), and (iii) the* evidence semantics *(how strongly we support or deny the token). That separation will let us define prediction and control without assuming an underlying classical truth assignment.*

Hyperseed is explicitly comfortable with borderline, context-dependent, and even inconsistent boundaries. We therefore allow paraconsistent evidence about event occurrences.

Definition 175 (Paraconsistent occurrence evidence)**.** *Fix an observer/context O. A* paraconsistent occurrence assignment *is a map*

$$E_O : \mathcal{E} \times T \to [0,1]^2, \qquad E_O(A@t) = (E_O^+(A@t), E_O^-(A@t)),$$

where E_O^+ is the degree of positive evidence for occurrence and E_O^- is the degree of negative evidence for occurrence. No consistency constraint is imposed; it may happen that $E_O^+(A@t) + E_O^-(A@t) > 1$.

Remark 637. *The pair $(E_O^+(A@t), E_O^-(A@t))$ is the* p-bit*-style encoding of evidence: the first coordinate is support for occurrence, the second is support for non-occurrence. The subscript O emphasizes that this is* observer-indexed *evidence, not an observer-independent fact (Hyperseed-Concept* **??** *is treated elsewhere).*

Remark 638. *A useful way to read $(p, q) \in [0,1]^2$ is as answering two distinct questions that need not be complements: "How much do I have reasons for $A@t$?" (measured by p) and "How much do I have reasons against $A@t$?" (measured by q). Paraconsistency enters precisely by refusing the classical identification of "reasons against" with "lack of reasons for," thereby allowing the agent to represent conflict, ambiguity, or model mismatch without forcing an immediate resolution.*

Remark 639. *As a toy example, suppose a microphone picks up a sound that is somewhat like a door slam. An audio classifier might assign $E_O^+ = 0.7$ for $A =$*`door-slam` *at time t, while a concurrent vision module that sees no door movement assigns $E_O^- = 0.6$. Then $E_O^+ + E_O^- = 1.3 > 1$, which records a genuinely conflicted evidential state. This is especially useful when modeling agents that must act under contradictory cues rather than wait for idealized consistency.*

Definition 176 (Derived evidence diagnostics (consistency, conflict, and indeterminacy))**.** *Given a token $A@t$ with evidence $(p, q) = E_O(A@t)$, define:*

$$\mathrm{conf}_O(A@t) := \min(p, q), \qquad \mathrm{gap}_O(A@t) := 1 - \max(p, q), \qquad \mathrm{bal}_O(A@t) := |p - q|.$$

Remark 640. *The quantity $\mathrm{conf}_O(A@t)$ measures* conflict*: it is large only when both occurrence and non-occurrence are substantially supported. The quantity $\mathrm{gap}_O(A@t)$ measures* indeterminacy *(or evidential "silence"): it is large when neither side is strongly supported. Finally, $\mathrm{bal}_O(A@t)$ measures how* decisive *the net evidence is, regardless of whether the decisiveness arises from consistent support (large p with small q) or consistent refutation (small p with large q). These diagnostics are optional but often clarify which kind of uncertainty is present: "both" (conflict) versus "neither" (gap).*

Remark 641. *This definition is necessary for later sections where "self/other" boundaries and other high-level partitions can be simultaneously supported and resisted (Section 16). It also aligns with the broader paraconsistent stance that contradiction need not entail collapse of inference, but may instead be treated as structured information [23, 24].*

To speak about attraction, we want a scalar "plausibility" derived from a p-bit. Many choices are possible; the following is algebraically convenient and reduces to ordinary probabilities in the consistent case.

Definition 177 (Plausibility projection)**.** *Define* $\pi : [0,1]^2 \to [0,1]$ *by*

$$\pi(p,q) := \frac{1+p-q}{2}.$$

We call $\pi(E_O(A@t))$ *the* plausibility *of* $A@t$ *for* O*.*

Remark 642. *The symbol* π *here is a* projection *from two-dimensional evidence to a single scalar in* $[0,1]$*. If* p *is positive evidence and* q *is negative evidence, then* $p-q$ *is a signed net tendency toward occurrence; the affine transformation* $(1+(p-q))/2$ *merely rescales this net tendency so that* 0 *corresponds to "strongly implausible,"* 1 *corresponds to "strongly plausible," and* $1/2$ *corresponds to a neutral balance.*

Remark 643. *The mapping* π *has a few immediate properties that motivate its later use as an "attraction proxy." First, it is monotone in the intended directions: increasing* p *(holding* q *fixed) increases plausibility, and increasing* q *decreases it. Second, it is symmetric around the neutral point: swapping* p *and* q *sends* $\pi(p,q)$ *to* $1-\pi(p,q)$*, expressing that "more reasons against" mirrors "more reasons for." Third, in a consistent probabilistic special case where the observer's evidence is such that* $q = 1-p$*, one obtains* $\pi(p, 1-p) = p$*, so* π *reduces to the familiar single probability parameter.*

Remark 644. *It is also worth emphasizing what* π *does* not *do: it does not distinguish between high-conflict and low-information states when they have the same net difference* $p-q$*. For example,* $(p,q) = (1,0)$ *and* $(p,q) = (0.6,0)$ *both yield high plausibility, while* $(0.9, 0.9)$ *and* $(0.1, 0.1)$ *both yield* $\pi = 1/2$*. This is intentional at this stage: attraction-oriented dynamics later will often be driven by a one-dimensional "direction" (toward/away), while diagnostics such as* $\mathrm{conf}_O(A@t)$ *and* $\mathrm{gap}_O(A@t)$ *can be carried alongside* π *when it matters to distinguish "conflicted" from "uninformative" neutrality.*

Remark 645. *Alternative scalarizations are possible (e.g., using* p *alone, using* $p/(p+q)$ *when* $p+q > 0$*, or using a nonlinear squashing of* $p-q$*). The choice of* π *is a minimal linear map that preserves the qualitative ordering induced by net evidence while keeping values in* $[0,1]$*, which makes it convenient for coupling to later definitions that resemble probabilistic prediction or utility-like attraction scores without presupposing classical semantics.*

Remark 646. *For example,* $\pi(1,0) = 1$*,* $\pi(0,1) = 0$*, and* $\pi(0.7, 0.6) = \frac{1+0.1}{2} = 0.55$*, reflecting that the token is only slightly more plausible than not. This scalarization is useful because attraction is defined as a difference of conditional plausibilities, and differences are most straightforwardly taken in a totally ordered set like* $[0,1]$*.*

Remark 647 (Consistent case)**.** *If the evidence is consistent in the sense that* $E_O^-(A@t) = 1 - E_O^+(A@t)$*, then* $\pi(E_O(A@t)) = E_O^+(A@t)$*. Thus the projection* π *exactly recovers the "usual" probability-like degree.*

Remark 648. *The consistent case remark shows that we are not abandoning classical probabilistic intuition (Hyperseed-Concept 139); rather, we are extending it so that classical probability appears as the special case where positive and negative streams are perfectly complementary. This is a common pattern in foundational work: one seeks a conservative extension whose additional degrees of freedom encode epistemic subtleties rather than metaphysical extravagance.*

14.3 Prediction and attraction

14.3.1 Conditionals

To define attraction we need conditionals. We deliberately stay lightweight and treat conditionals as something computed by the observer's modeling machinery (statistical estimation, simulation, logical inference, or combinations).

Definition 178 (Predictive conditional operator)**.** *Fix a lag window Δ (e.g. a set of allowed lags, or an interval $[\delta_{\min}, \delta_{\max}]$). A* predictive conditional operator *for O is a map*

$$\mathrm{Cond}_{O,\Delta} : \mathcal{E} \times \mathcal{E} \to [0,1]^2, \qquad (A, B) \mapsto \mathrm{Cond}_{O,\Delta}(B \mid A),$$

where $\mathrm{Cond}_{O,\Delta}(B \mid A)$ is intended to represent evidence about "B occurs at some time t' with $t \prec t'$ and $t' - t \in \Delta$, given that A occurs at t."

Remark 649. *Notation unpacking: $\mathrm{Cond}_{O,\Delta}(B \mid A)$ is a* p-bit*-valued object in $[0,1]^2$, not a single probability. The vertical bar "$|$" is read "given," and Δ specifies what counts as an acceptable temporal separation between the antecedent token time t and the consequent token time t'. The strict order $t \prec t'$ (derived from $\preceq$) encodes temporal direction.*

Remark 650. *Intuitively, $\mathrm{Cond}_{O,\Delta}$ is the observer's* forecasting interface*: it answers the question, "if A happens, how much evidence do I have that B will happen soon after (within the window Δ)?" A simple example is: $A =$`press(button)`, $B =$`light(on)`, and $\Delta = \{1\}$ in discrete time. Then $\mathrm{Cond}_{O,\Delta}(B \mid A)$ captures the learned (or inferred) reliability of the button-to-light connection.*

Remark 651. *This definition is useful because it remains neutral about* how *the observer computes conditionals: from frequencies, from simulation, from mechanistic modeling, or from logical rules. This neutrality matters for Hyperseed because minds may contain multiple inference processes whose outputs must be fused (Section 15 discusses such multi-process regimes; see also [19] for a broader cognitive-systems perspective).*

Remark 652 (Empirical instance)**.** *In a finite dataset of event tokens, one may estimate $\mathrm{Cond}_{O,\Delta}(B \mid A)$ from relative frequencies of co-occurrence of $A@t$ and $B@t'$ with $t' - t \in \Delta$, separately for positive and negative evidence streams. We use the abstract operator $\mathrm{Cond}_{O,\Delta}$ so the formalism can also cover more structured inference.*

14.3.2 Attraction

Definition 179 (Attraction)**.** *For event types $A, B \in \mathcal{E}$ and lag window Δ, define the* attraction

$$\mathrm{Att}_{O,\Delta}(A, B) := \pi\big(\mathrm{Cond}_{O,\Delta}(B \mid A)\big) - \pi\big(\mathrm{Cond}_{O,\Delta}(B \mid \neg A)\big).$$

This is a real number in $[-1, 1]$.

Remark 653. *Attraction is the simplest formal embodiment of the "difference that makes a difference." If* $\mathrm{Att}_{O,\Delta}(A, B)$ *is positive, then (in the observer's model) A makes B* more *plausible than it would be under $\neg A$; if it is negative, A suppresses B relative to the $\neg A$ baseline. This is the formal heart of Hyperseed's* PredictiveAttraction *notion (Hyperseed-Concept* **??***).*

Remark 654. *A concrete example: let $A =$*`water(plant)` *and $B =$*`plant(healthy)` *within a two-week lag window Δ. If the model estimates $\pi(\mathrm{Cond}(B \mid A)) = 0.8$ but $\pi(\mathrm{Cond}(B \mid \neg A)) = 0.5$, then attraction is 0.3: watering provides a substantial differential lift. Conversely, if a healthy plant is likely anyway due to rain (0.75 without watering), then even a high absolute conditional (0.8) yields low attraction (0.05), signaling weak control leverage.*

Remark 655. *The definition is necessary because control and planning should be built on* leverage, *not on mere correlation: if B happens regardless, then A is not a good handle on the world. Attraction is the low-level quantity that will later be mixed with temporal precedence and simplicity bias to yield a causal notion (Section 14.5).*

Proposition 22 (Basic properties of attraction)**.** *For all A, B and Δ:*

(a) (Boundedness.) $\mathrm{Att}_{O,\Delta}(A, B) \in [-1, 1]$.

(b) (Negation antisymmetry.) $\mathrm{Att}_{O,\Delta}(\neg A, B) = -\mathrm{Att}_{O,\Delta}(A, B)$.

(c) (Independence gives zero.) If $\pi(\mathrm{Cond}_{O,\Delta}(B \mid A)) = \pi(\mathrm{Cond}_{O,\Delta}(B \mid \neg A))$ *then* $\mathrm{Att}_{O,\Delta}(A, B) = 0$.

Remark 656. *This proposition says that attraction behaves like a signed, normalized measure of differential predictive influence: it cannot exceed 1 in magnitude, flipping the antecedent to its negation flips the sign, and if the antecedent makes no difference to the consequent (in the projected conditional plausibility), attraction vanishes. These are not deep theorems; rather, they are sanity checks that the formal definition matches the intended conceptual role.*

Remark 657. *The connection to later material is direct: control strength will be defined using causal implication, and causal implication will incorporate predictive attraction. Thus, verifying simple algebraic properties here prevents later definitions from inheriting unintended asymmetries or scale problems.*

Proof. (a) Each term is in $[0, 1]$, hence their difference lies in $[-1, 1]$. (b) Swap A and $\neg A$ in the definition. (c) Immediate. □

Proof sketch. All three items follow by reading the definition literally. The key observation is that the projection π maps into $[0, 1]$, so subtraction yields a quantity in $[-1, 1]$, and exchanging A with $\neg A$ simply swaps the minuend and subtrahend, reversing the sign. In slightly more detail: for any conditional object $\mathrm{Cond}(\cdot \mid \cdot)$ in the definition, the scalarization $\pi(\mathrm{Cond}(\cdot \mid \cdot))$ is by construction a real number between 0 and 1. Therefore, any expression of the form $\pi(\mathrm{Cond}(B \mid A)) - \pi(\mathrm{Cond}(B \mid \neg A))$ is automatically bounded below by $0 - 1 = -1$ and above by $1 - 0 = 1$. Moreover, the "antisymmetry under negation" is not a separate theorem but a one-line algebraic check:

$$\pi(\mathrm{Cond}(B \mid \neg A)) - \pi(\mathrm{Cond}(B \mid \neg\neg A)) = -\big(\pi(\mathrm{Cond}(B \mid A)) - \pi(\mathrm{Cond}(B \mid \neg A))\big),$$

using only $\neg\neg A = A$ and commutativity of subtraction in the sense of swapping operands. □

Remark 658. *The proof works because the definition of attraction is intentionally built from very rigid pieces: a bounded scalarization followed by subtraction. The "negation antisymmetry" is not a mysterious logical fact; it is an algebraic symmetry that we engineered into the definition so that "doing A" and "not doing A" are treated as complementary alternatives. Note that this design also forces a clear interpretation of the sign: positive attraction means that, after projection, B is more plausible conditional on A than conditional on $\neg A$; negative attraction means the opposite; and attraction near* 0 *means that A carries little* differential *information about B compared to its negation, even if both one-sided conditionals are individually high.*

Remark 659 (Why attraction matters)**.** *Suppose B is a goal condition and A is an action. Even if $\pi(\mathrm{Cond}(B \mid A))$ is large, taking action A is not very useful if $\pi(\mathrm{Cond}(B \mid \neg A))$ is equally large. Attraction measures the* differential *predictive value of A for B. This is the basic reason attraction is closer to the intuitive notion of a "handle" or "lever": it discounts baseline prevalence of B that would be present regardless of whether A occurs. In particular, if B is already near-certain in the background circumstances (so both conditionals project close to* 1*), then attraction correctly reports that A adds little, whereas a raw conditional may misleadingly suggest that A is strongly associated with B.*

14.3.3 Predictive implication and predictive attraction

Hyperseed distinguishes ordinary implication from *predictive implication* (implication plus a temporal precedence constraint). In the present lightweight setting, we simply make this temporal aspect explicit via Δ. Operationally, Δ should be read as a fixed prediction horizon: we are not merely asking whether B is compatible with A, but whether B is expected to occur *after* A within a specified window, so that the resulting quantity is tied to forecasting and (later) to action evaluation.

Definition 180 (Predictive implication and predictive attraction)**.** *Define the* predictive implication strength *as*

$$\mathrm{PImp}_{O,\Delta}(A, B) := \pi\big(\mathrm{Cond}_{O,\Delta}(B \mid A)\big) \in [0, 1].$$

Define the predictive attraction *as*

$$\mathrm{PAtt}_{O,\Delta}(A, B) := \mathrm{PImp}_{O,\Delta}(A, B) - \mathrm{PImp}_{O,\Delta}(\neg A, B).$$

Remark 660. *Here $\mathrm{PImp}_{O,\Delta}(A, B)$ is the one-sided, probability-like strength of the forward conditional "A predicts B within Δ" (after projection). It is intentionally* not *yet causal: it does not require that A precedes B typically in the stronger sense, nor that there be any intensional connection. Predictive attraction* PAtt *then restores the differential stance by contrasting A against $\neg A$. One can also view* PImp *as a score assigned to the ordered pair (A, B), whereas* PAtt *is a score assigned to the* contrast *between two rival predictors, A and $\neg A$, holding B fixed. This contrastive structure is what makes* PAtt *more stable as a decision signal in settings where the background rate of B fluctuates across contexts.*

Remark 661. *Example: if a smoke detector rings (A) then a person wakes up (B) with high conditional plausibility, say* $\mathrm{PImp} = 0.9$*. But if the person would wake anyway because of a loud storm even without the detector (*$\mathrm{PImp}(\neg A, B) = 0.85$*), then* $\mathrm{PAtt} = 0.05$*. The model is saying: the detector is a good predictor but a weak* lever*. This distinction becomes crucial once we interpret A as an action or intervention candidate in control. The same arithmetic also clarifies the limiting cases: if* $\mathrm{PImp}(\neg A, B) \approx 0$*, then* $\mathrm{PAtt} \approx \mathrm{PImp}(A, B)$ *and the action-like reading of A becomes more credible; if* $\mathrm{PImp}(A, B) \approx \mathrm{PImp}(\neg A, B)$*, then* $\mathrm{PAtt} \approx 0$ *and A provides little incremental predictive advantage even if the absolute prediction is strong.*

Remark 662 (Relationship to attraction)**.** *With the above definitions,* $\mathrm{PAtt}_{O,\Delta}(A,B) = \mathrm{Att}_{O,\Delta}(A,B)$*. We keep both notations because (i) the ontology uses both; and (ii) in richer formalisms one may separate "mere conditional dependence" from "dependence with a specific temporal semantics." In particular, future refinements may encode the* Δ*-constraint in the conditional object itself (e.g., as an event construction) rather than as an external parameter, at which point it can become useful to reserve* Att *for an atemporal notion and* PAtt *for the explicitly forward-looking notion used in prediction and control.*

Remark 663. *This duplication of notation is philosophically telling: in the minimal formalism, the concepts coincide; in richer settings, they may come apart. It is often fruitful in foundational work to keep two names for what is presently the same quantity, if one expects later refinements to split the notion along different conceptual joints (as happens below when we separate extensional from intensional predictive attraction). Concretely, one expects such a split once the formalism distinguishes (a) extensional regularities in observed sequences and (b) intensional linkages that support counterfactual and interventional reasoning. The present section keeps the arithmetic simple, but the duplicated naming convention acts as a reminder that the surrounding interpretation can change even when the underlying number happens to be computed by the same formula at this stage.*

Remark 664 (Range and interpretive calibration)**.** *Because* $\mathrm{PImp}_{O,\Delta}(A,B) \in [0,1]$ *by definition, it follows immediately that* $\mathrm{PAtt}_{O,\Delta}(A,B) \in [-1,1]$*. The endpoints have a clear meaning:* $\mathrm{PAtt} = 1$ *occurs only when* $\mathrm{PImp}(A,B) = 1$ *and* $\mathrm{PImp}(\neg A,B) = 0$*, i.e.,* A *perfectly predicts* B *within* Δ *and* $\neg A$ *perfectly predicts* $\neg B$ *within the same horizon (after projection);* $\mathrm{PAtt} = -1$ *reverses these roles. Intermediate values can be read as a signed "margin" of predictive advantage, and the sign convention is fixed so that* $\mathrm{PAtt} > 0$ *favors* A *over* $\neg A$ *as a predictor for* B*.*

Remark 665 (Dependence on the projection π)**.** *The role of* π *is to force a common numeric scale for comparison, independent of the internal representation of* $\mathrm{Cond}_{O,\Delta}(B \mid A)$*. This makes the subtraction in* PAtt *well-typed and ensures boundedness, but it also means that the qualitative behavior of* PImp *and* PAtt *is sensitive to how* π *treats uncertainty, indeterminacy, or graded evidence. Accordingly, later sections can change the empirical behavior of predictive attraction either by changing the conditional object* Cond *or by changing the projection* π*, without changing the surrounding algebraic facts used above.*

14.4 Sequential and parallel temporal composition

Hyperseed emphasizes that predictive dependence concepts should compose along time. In the original ontology this is expressed using operators such as `SequentialAND`, `SimultaneousAND`, and `SimultaneousOR`. Here we sketch one clean way to realize this using the quantale and enriched-category machinery from Section 3.4.

Remark 666. *The guiding intuition is that a mind rarely reasons about isolated one-step predictions. It reasons about* chains *(if I do this, then that happens, then something else becomes possible) and about* bundles *(multiple conditions jointly supporting a later outcome). Quantales provide a compact algebraic language for this kind of composition: a tensor* $\otimes$ *aggregates along a sequence, and a join* $\oplus$ *aggregates across alternatives. This style is consonant with the pattern-web machinery used earlier (Sections 9 and 12) and foreshadows later planning/optimal-control principles (Section 26; see [21]).*

14.4.1 Sequential composition as quantale multiplication

Let $\mathcal{E}$ be viewed as a set of "states" or "event-conditions" and suppose the observer has a p-bit-valued predictive relation

$$R_{O,\Delta} : \mathcal{E} \times \mathcal{E} \to [0,1]^2, \qquad R_{O,\Delta}(A,B) := \mathrm{Cond}_{O,\Delta}(B \mid A).$$

If we interpret $R_{O,\Delta}(A,B)$ as an "edge weight" from A to B, then sequential composition of two predictive steps corresponds to relational composition, with the quantale tensor as the multiplicative aggregator.

Remark 667. *Notation unpacking: $R_{O,\Delta}$ is a V-valued relation (here $V = [0,1]^2$ with* p-bit *operations), so $R_{O,\Delta}(A,B)$ is the edge weight from A to B. The symbol $\otimes$ is the quantale tensor (multiplicative aggregation along a path), and $\oplus$ is the quantale join (additive aggregation across alternative intermediate nodes). This is the same algebraic pattern used in enriched-category composition, but here read operationally as "compose predictions across time."*

Definition 181 (Two-step predictive composition)**.** *Define the composite relation*

$$(R_{O,\Delta} \circ R_{O,\Delta'})(A,C) := \bigoplus_{B \in \mathcal{E}} R_{O,\Delta}(A,B) \otimes R_{O,\Delta'}(B,C),$$

where $\otimes$ and $\oplus$ are the tensor and join of the p-bit *quantale (Section 3.4).*

Remark 668. *This is the familiar "sum over intermediates, multiply along edges" pattern, generalized from classical probability or weighted automata to the* p-bit *quantale setting. One may visualize $\mathcal{E}$ as nodes in a directed graph of event-types; then $(R \circ R')(A,C)$ aggregates the strength of all two-step paths $A \to B \to C$.*

Remark 669. *A simple example: if A predicts B strongly and B predicts C strongly, then the tensor $R(A,B) \otimes R'(B,C)$ yields a strong composite for that B. If there are multiple plausible bridges B, the join $\oplus$ allows them to compete/cooperate depending on the quantale's join. This definition is useful because it makes explicit what is often left informal in planning discussions: the semantics of chaining predictions is not automatic; it is a chosen algebra.*

Remark 670 (Reading)**.** *The join $\oplus$ aggregates over intermediate events B ("there exists a reasonably good bridge"), while the tensor $\otimes$ aggregates evidence across a temporal chain ("both steps work"). This is the algebraic content behind the informal operator `SequentialAND`.*

14.4.2 A tiny worked schematic

Consider an action sequence (cf. the ontology's example):

`Teacher says fetch` $\to$ `I get the ball` $\to$ `I bring the ball` $\to$ `I get a reward`.

If each arrow has a predictive implication strength (in $[0,1]$ after projection π), then the overall sequence can be given a composite strength by multiplying along the chain (tensor) and joining over alternative intermediate paths. Predictive attraction then compares the "do the sequence" case with the "do not do the sequence" case, exactly as in the single-step definition.

Remark 671. *Even this schematic illustrates an important philosophical point: "the plan works" is not a primitive fact but a compositional judgment assembled from local predictive regularities. The Hyperseed approach tries to keep such judgments* graded *and* evidence-sensitive*, so that a plan may be adopted with appropriate humility rather than with binary certainty.*

14.5 Causality as attraction plus temporal precedence plus simplicity bias

The ontology proposes that causality is not captured by extensional dependence alone. Rather, causal judgments combine: (i) a temporal precedence constraint; (ii) a surprising extensional dependence (predictive attraction); (iii) an intensional (property-level) connection; and (iv) a simplicity/weakness bias.

These four ingredients are meant to be read as jointly necessary for the ordinary, practice-guided use of "cause" in modeling and intervention. Temporal precedence rules out purely symmetric associations as candidates for causal direction; predictive attraction encodes the idea that causes provide leverage beyond background expectations; intensional linkage encodes the idea that the dependence should be mediated by comparatively stable properties rather than arbitrary labels; and the simplicity/weakness bias resolves underdetermination by preferring causal stories that introduce as little representational "force" as possible.

Remark 672. *Temporal precedence here is a constraint on admissible directionality rather than a full dynamical model: it says that if A is judged a cause of B at resolution Δ, then the dependence must be expressible with A occurring "before" B in the observer's discretization. This keeps the causal notion compatible with the predictive setup (which is indexed by Δ) while allowing that different observers—or the same observer at different time scales—may legitimately report different causal relations when the ordering becomes ambiguous at coarse granularity.*

Remark 673. *The simplicity/weakness bias is not merely aesthetic. It functions as a regularizer on causal attribution: among multiple hypotheses that fit extensional predictive facts equally well, prefer the one that commits to weaker predicates, fewer special cases, and less brittle boundary drawing. In the Hyperseed framing, this is the same pressure that, in other contexts, selects simpler patterns as better compressive descriptions, but here it is applied to causal predicates and their associated intervention rules.*

Remark 674. *This cluster deliberately echoes several long-standing tensions in philosophy of science: Humean regularity (extensional dependence) is not enough for the lived concept of cause; yet pure metaphysical necessity is too heavy a tool for scientific practice. Hyperseed's compromise is operational: define causality as a* structured *kind of predictive leverage, constrained by time and guided by an Occam-like preference for weak distinctions (Hyperseed-Concept 202, and in the quantale form, Hyperseed-Concept 143). For related discussions of weakness as a central organizing principle, see [2, 3].*

14.5.1 Extensional and intensional predictive attraction

Definition 182 (Extensional predictive attraction)**.** *The* extensional predictive attraction *is the predictive attraction computed on the level of occurrence of event types:*

$$\mathrm{PAtt}^{\mathrm{ext}}_{O,\Delta}(A,B) := \mathrm{PAtt}_{O,\Delta}(A,B).$$

Remark 675. *Calling this "extensional" emphasizes that it looks only at the surface fact of whether A and B occur, not at what internal structure A and B may have as patterns or bundles of properties. In many empirical settings, extensional attraction is the easiest to estimate directly from time series data, and so it often serves as the first approximation to causal influence.*

Remark 676. *One can also read $\mathrm{PAtt}^{\mathrm{ext}}_{O,\Delta}(A,B)$ as a statistic of* type-level *tokens: it aggregates over the observer's instances of A and asks whether B is enriched in the future of those instances relative to an appropriate baseline. In this sense it is closer to population-level causal evidence than* *to a single mechanistic explanation; it answers "does A carry predictive leverage about B?" rather than "through which internal channel does A bring about B?"*

Remark 677. *Example: if we take $A =$`take(aspirin)` and $B =$`headache(reduces)`, extensional attraction asks only whether the aspirin-token tends to be followed by a reduction-token, compared to the baseline where aspirin is not taken.*

Remark 678. *The same example also illustrates why extensional attraction alone is not the full causal story: the observed dependence might be mediated by confounders represented (or not represented) by O, by selection effects in when aspirin is taken, or by hidden structure within the event types (dose, timing, severity). The role of the intensional layer below is to make explicit some of the within-type structure that can stabilize causal attribution across contexts.*

To define the intensional counterpart we use the property machinery from Section 9. Recall that the *property set* of an entity/event is the fuzzy set of patterns in it, weighted by pattern intensity (Hyperseed-Concept 130).

Definition 183 (Property events)**.** *Fix a finite "property basis" $\mathcal{P}$ (patterns-as-properties) and a map $\mathrm{Prop}_O : \mathcal{E} \to [0,1]^{\mathcal{P}}$. For $p \in \mathcal{P}$ we write $p \in_O A$ for the derived "property event type" "pattern/property p is present in A" and set*

$$\pi(p \in_O A) := \mathrm{Prop}_O(A)(p) \in [0,1].$$

Remark 679. *Notation unpacking: $\mathcal{P}$ is a set of properties (implemented as patterns), and $\mathrm{Prop}_O(A)$ is a function $\mathcal{P} \to [0,1]$ assigning each property p an intensity for event type A. The expression $p \in_O A$ is not literal set membership but a* derived event type *whose plausibility is defined to be $\mathrm{Prop}_O(A)(p)$. The subscript O again signals observer-relative representation.*

Remark 680. *The requirement that $\mathcal{P}$ be finite is a pragmatic restriction that matches how an observer/model typically operates: causal claims are made in a bounded vocabulary of features, measurements, or patterns. Technically, finiteness ensures that the averaging constructions below are unproblematic, while conceptually it emphasizes that intensionality is always relative to a chosen representational basis (which may be expanded when the observer learns new patterns).*

Remark 681. *Intuitively, this turns "A has property p" into something that can be fed back into the same predictive machinery used for ordinary events. For example, if A is* `fire(burning)` *and p is the pattern/property* `hot`*, then $\pi(p \in_O A)$ is the degree to which the observer's representation of the event-type includes hotness. This is useful because it lets us ask not only whether A predicts B, but whether the* properties *characteristic of A predict the properties characteristic of B.*

Remark 682. *In particular, property events let the same observer represent two different "internal decompositions" of the same extensional event type. For instance, the event type* `take(aspirin)` *may include properties such as* `dose(large)` *or* `dose(small)` *with different intensities in different subpopulations or contexts. If those properties have different downstream predictive signatures, the intensional analysis can distinguish them even when the extensional event label is the same.*

Remark 683. *The purpose of introducing property events is theoretical: it provides a bridge between the "pattern as compressive description" view (Section 9) and causal judgments, by allowing causal dependence to be sensitive to intensional structure rather than only to extensional co-occurrence. This is one way to formalize the thought that causation should reflect not merely what happens, but something about* why *it happens, insofar as "why" is accessible to the observer's representational vocabulary.*

Remark 684. *A further benefit is robustness under redescriptions: if two event types are extentionally similar but differ in property profile, then extensional attraction may be unstable across shifts in data collection or coding, while intensional attraction can remain informative provided $\mathcal{P}$ captures the stable aspects of the phenomenon. Conversely, if $\mathcal{P}$ omits the relevant mechanistic properties, then the intensional score will collapse back toward an extensional proxy, which is appropriate: the observer cannot legitimately claim a structured causal story without the representational capacity to express it.*

Definition 184 (Intensional predictive attraction)**.** *Define the* intensional predictive attraction *by averaging predictive attraction over properties:*

$$\mathrm{PAtt}^{\mathrm{int}}_{O,\Delta}(A,B) := \sum_{p\in\mathcal{P}}\sum_{q\in\mathcal{P}} w_{p,q}\,\mathrm{PAtt}_{O,\Delta}(p \in_O A,\, q \in_O B),$$

where $w_{p,q} \geq 0$ are weights that may be chosen, for example, proportional to $\mathrm{Prop}_O(A)(p)\,\mathrm{Prop}_O(B)(q)$ and normalized to sum to 1*.*

Remark 685. *The weights $w_{p,q}$ implement a choice about what it means for a property-level linkage to be "about" A and B. Taking $w_{p,q} \propto \mathrm{Prop}_O(A)(p)\mathrm{Prop}_O(B)(q)$ focuses the average on properties that are actually present in the two event types, while still allowing rare but highly diagnostic properties to matter if their associated* PAtt *terms are large. Other weighting schemes are possible (e.g. emphasizing only properties of A, or penalizing very common q to reduce trivial predictability), and can be understood as different observer policies for extracting mechanistically meaningful signal from the same raw dependence statistics.*

Remark 686. *This definition says: look at all property pairs (p,q), measure how much the presence of p in A predicts the presence of q in B (differentially, via* PAtt*), and then average these numbers with weights $w_{p,q}$ emphasizing the properties actually salient in A and B. The result is a single scalar capturing structured, property-level predictive linkage.*

Remark 687. *When $\mathcal{P}$ contains a very coarse property corresponding to the event's own occurrence (or a near-indicator pattern that tracks it), the intensional construction can recover the extensional one as a special case: the average places most of its mass on the indicator-like property pair and $\mathrm{PAtt}^{\mathrm{int}}_{O,\Delta}(A,B)$ approaches $\mathrm{PAtt}^{\mathrm{ext}}_{O,\Delta}(A,B)$. This provides a consistency check: intensional attraction refines extensional attraction rather than replacing it with an unrelated quantity.*

Remark 688. *A simple schematic example: let A be `strike(match)` and B be `fire(ignites)`. If properties like `friction` and `heat` are strongly present in A, and properties like `heat` and `light` are present in B, then property-level attractions such as $\mathrm{PAtt}(\texttt{friction} \in_O A, \texttt{heat} \in_O B)$ and $\mathrm{PAtt}(\texttt{heat} \in_O A, \texttt{light} \in_O B)$ should be positive, raising $\mathrm{PAtt}^{\mathrm{int}}(A,B)$.*

Remark 689. *In that match example, the intensional score is closer to what one informally calls a mechanism: it does not merely say that the labels `strike(match)` and `fire(ignites)` are statistically associated, but that specific properties characteristic of striking (e.g. friction) are linked to specific properties characteristic of igniting (e.g. heat). This is also where the simplicity/weakness bias interacts with intensionality: if two candidate causal explanations fit the extensional data, the preferred one is the one whose property linkages can be expressed with fewer and weaker distinguishing properties (for example, a small, stable set of features rather than a highly conjunctive, brittle property list).*

Remark 690. *This notion is useful because it can distinguish between (i) brute co-occurrence and (ii) co-occurrence mediated by shared structure in the observer's vocabulary of patterns-as-properties. In complex systems, many correlations are accidental; intensional attraction is one principled way to bias causal inference toward correlations that align with stable internal descriptions (cf. [5] on hierarchical/ heterarchical pattern structure).*

Remark 691. *A further intuition is that "shared structure" should be understood as invariance under reasonable changes of presentation: if the observer refines, factorizes, or re-encodes a situation using roughly equivalent internal predicates, genuinely causal linkages should remain expressible with similar property-level dependencies. By contrast, accidental correlations often disappear under such re-descriptions because they do not correspond to a stable pattern-level relation in the observer's representational scheme.*

Remark 692 (Interpretation)**.** $\mathrm{PAtt}^{\mathrm{int}}$ *is high when the properties of A (as patterns) tend to predict the properties of B. This captures the intuitive idea that a causal connection is not merely a statistical regularity, but reflects a structured relationship between what A* is like *and what B* is like.

Remark 693. *In particular,* $\mathrm{PAtt}^{\mathrm{int}}$ *is meant to be sensitive to "mechanism-shaped" features: even if A and B co-occur frequently, intensional attraction should increase only when the mapping from salient attributes of A to salient attributes of B is compressible in the observer's property language (e.g. the same few properties of A explain many properties of B). This helps separate mere proxy variables from variables that participate in a coherent descriptive pipeline.*

14.5.2 Causal implication and simple causal implication

Definition 185 (Causal implication)**.** *Fix a lag window Δ and a mixing parameter $\lambda \in [0,1]$. Define the* causal implication strength

$$\mathrm{CImp}_{O,\Delta}(A,B) := \big(\lambda\,\sigma(\mathrm{PAtt}^{\mathrm{ext}}_{O,\Delta}(A,B)) + (1-\lambda)\,\sigma(\mathrm{PAtt}^{\mathrm{int}}_{O,\Delta}(A,B))\big)\cdot \mathbf{1}[A \prec B],$$

where $\mathbf{1}[A \prec B]$ is an indicator that A typically precedes B in the relevant context, and $\sigma : [-1,1] \to [0,1]$ is the affine rescaling $\sigma(x) = (1+x)/2$.

Define also the strong *(product) variant*

$$\mathrm{CImp}^{\times}_{O,\Delta}(A,B) := \sigma(\mathrm{PAtt}^{\mathrm{ext}}_{O,\Delta}(A,B))\;\sigma(\mathrm{PAtt}^{\mathrm{int}}_{O,\Delta}(A,B))\;\mathbf{1}[A \prec B].$$

Remark 694. *One can read λ not only as "trust in statistics" versus "trust in structure," but also as a tuning between two kinds of robustness: extensional attraction can be robust to vocabulary drift (it depends less on how properties are named) but brittle under distribution shift, whereas intensional attraction can be robust across contexts where the same mechanism holds but brittle under changes in the observer's property set. The mixture is therefore an explicitly observer-relative compromise.*

Remark 695. *Notation unpacking: σ converts a signed attraction in $[-1,1]$ into a $[0,1]$ score, so that negative attraction maps below $1/2$ and positive attraction maps above $1/2$. The indicator $\mathbf{1}[A \prec B]$ enforces temporal direction: even a strong predictive linkage does not count as causal implication if A does not typically precede B in the observer's time-ordering.*

Remark 696. *The affine rescaling is chosen so that a "neutral" attraction of 0 maps to $1/2$, which functions as a convenient baseline when combining multiple sources of evidence. In particular, the product variant then has the interpretation that a neutral score in either extensional or intensional attraction yields a mid-level contribution, while strongly negative attraction in either channel pushes the overall score downward even when the other channel is strong.*

Remark 697. *Intuitively,* $\mathrm{CImp}_{O,\Delta}(A, B)$ *is a compromise between two ideas of cause: "A makes B happen (extensional leverage)" and "A is connected to B through properties the observer recognizes (intensional structure)." The parameter* λ *expresses how much the observer (or modeling choice) trusts extensional statistics versus property-level structure.*

Remark 698. *The two variants also correspond to different stances on "defeaters." In the sum form, a strongly mechanistic-looking intensional linkage can partially rescue a weak extensional signal (e.g. when the available samples are sparse), and conversely strong extensional predictability can partially rescue an immature vocabulary. In the product form, either channel can act as a defeater: if the observer cannot express a stable property-level relation, or if extensional evidence is strongly negative, then causal implication is suppressed.*

Remark 699. *A simple example: in a world where barometers correlate with storms, extensional attraction* $\mathrm{PAtt}^{\mathrm{ext}}(\texttt{barometer(low)}, \texttt{storm})$ *may be high. But the intensional attraction might be low if the properties of* `barometer(low)` *do not structurally connect to the properties of storms in the observer's mechanistic vocabulary. The mixing/product choices then control whether barometer readings are treated as causes or merely predictors.*

Remark 700. *The same distinction shows up in "common cause" settings: a hidden atmospheric-pressure variable may generate both* `barometer(low)` *and* `storm`*, producing high extensional attraction, while a mechanistic vocabulary that explicitly represents pressure as an intermediate property could raise intensional attraction for* $\texttt{pressure(low)}\to\texttt{storm}$ *and reduce it for* $\texttt{barometer(low)}\to\texttt{storm}$*. Thus, intensional attraction can be interpreted as a bias toward models that expose plausible intermediates in the observer's descriptive hierarchy.*

Remark 701 (Temporal precedence as a statistic)**.** *One may implement* $A \prec B$ *in many ways, e.g. as a thresholded statistic computed from the same occurrence data used for* $\mathrm{Cond}_{O,\Delta}$*: conditional on co-occurrence of* A *and* B *within a broad window, the median (or mean) lag* $\mathrm{lag}(A, B)$ *is positive. The ontology treats precedence as context-relative (observer-relative time and event boundaries), so this indicator should be understood as relative to* O*.*

Remark 702. *The role of the lag window* Δ *is to encode a causal timescale hypothesis: if* Δ *is too small, genuine delayed effects will be missed; if it is too large, unrelated events may be treated as eligible for precedence tests, washing out directionality. In practice, one can treat* Δ *as a hyperparameter and evaluate sensitivity of* $\mathrm{CImp}_{O,\Delta}$ *to its choice, which is itself a kind of "simplicity" consideration (prefer time-scale assumptions that do not require fine-tuning).*

Remark 703 (Sum vs product)**.** *The "sum" form aligns with the ontology's* `SimpleCausalImplication` *intuition (a weighted average of extensional and intensional aspects), while the "product" form aligns with the ontology's* `CausalImplication` *intuition (both aspects must be simultaneously strong).*

Remark 704. *In a decision-theoretic reading, the sum form behaves more like an expected-evidence aggregator (useful for ranking many candidate causes when evidence is heterogeneous), while the product form behaves more like a conjunction of tests (useful when one wants high precision and is willing to sacrifice recall). This difference matters when causal implication is later used for control: permissive attribution can increase exploratory interventions, whereas severe attribution can reduce spurious control attempts.*

Remark 705. *The product form is, in a sense, more severe: it demands that extensional and intensional evidence cohere. The sum form is more permissive: it allows a cause to be inferred from strong extensional leverage even if the property vocabulary is impoverished, or from strong* *intensional coherence even if the raw statistics are noisy. This mirrors a practical tradeoff in scientific reasoning between mechanistic understanding and purely statistical prediction (cf. [20] for a related philosophy of science stance).*

Remark 706. *Edge cases help clarify interpretation: if $\mathbf{1}[A \prec B] = 0$ then both scores are 0, making the temporal ordering a hard gate rather than a soft preference. If $\lambda = 1$ then $\mathrm{CImp}_{O,\Delta}$ reduces to a purely extensional, precedence-gated score; if $\lambda = 0$ it reduces to a purely intensional, precedence-gated score. Thus the definition contains, as limiting cases, both a Granger-like "prediction with time-order" notion and a more structural "mechanism in the observer's vocabulary" notion.*

14.5.3 Weakness-biased causal model selection

Causal attribution is also biased by simplicity. In the Hyperseed formal core, simplicity is tracked by weakness (Section 3.7): all else equal, prefer explanations that make fewer special-case distinctions (Hyperseed-Concept 169, Hyperseed-Concept 202).

Remark 707. *This is an explicitly Russellian move: when two descriptions fit the appearances equally well, prefer the one that posits fewer independent discriminations. In Hyperseed, this preference is not only a methodological maxim but is formalized via quantale weakness measures [3, 2]. The result is that causal inference becomes a kind of model selection under a simplicity prior, rather than a mere reading-off of correlations.*

Remark 708. *Here "fewer special-case distinctions" can be read operationally as: fewer conditional branches, fewer context-specific parameters, fewer ad hoc predicates, or fewer exception clauses required to maintain predictive adequacy across the contexts recognized by O. Importantly, weakness is not merely "small cardinality" of S; it concerns the complexity of the* description *of the explanation, so that a slightly larger parent set may still be weaker if it enables a more uniform rule.*

Definition 186 (Weak causal parent selection (schematic))**.** *Fix a target event type B. Let $\mathcal{C}$ be a finite set of candidate causes. A* causal parent set *is a subset $S \subseteq \mathcal{C}$. Define a score*

$$\mathrm{Score}(S \to B) := \underbrace{\mathrm{Fit}(S \to B)}_{\textit{predictive adequacy}} \qquad +\eta \underbrace{\mathrm{Weak}(S \to B)}_{\textit{simplicity/weakness}},$$

where $\eta > 0$ is a tradeoff parameter. A weak causal explanation *for B is a parent set S^* maximizing this score.*

Remark 709. *The separation into* Fit *and* Weak *is intended to parallel standard regularization:* Fit *rewards predictive performance (e.g. likelihood, reduction in uncertainty, or improvement in $\mathrm{Cond}_{O,\Delta}$-style predictability when conditioned on S), while* Weak *acts like a simplicity prior (e.g. a penalty for representational complexity, or a reward for compressibility). The hyperparameter η therefore controls how readily the observer trades marginal predictive gains for a simpler causal story.*

Remark 710. *Although presented schematically, this parent-selection view connects back to $\mathrm{CImp}_{O,\Delta}$: one can treat* CImp *(or $\mathrm{CImp}^{\times}$) as a primitive pairwise signal used to generate $\mathcal{C}$ (screening candidates), and then use weakness-biased selection to choose a multivariate explanation that resolves redundancy among candidates (e.g. when several correlated A_i compete as apparent causes of the same B). In that role, weakness functions as a bias toward selecting upstream or more "explanatorily central" parents when multiple nearly equivalent predictors exist.*

Remark 711. *This definition is deliberately schematic: it isolates the* form *of the causal selection rule without committing to a particular* Fit *or* Weak*. Conceptually, it says that causality is not a single number but an optimization: we search for a set of antecedents that both predict B and do so without excessive complexity. In particular, the definition is meant to be read as a regularized model-selection principle: among many candidate antecedent-sets S that could be placed "before" B in the relevant sequence, we prefer those that score well under* Fit *while paying an explicit penalty (or softness constraint) measured by* Weak*. This keeps the notion of "cause" distinct from mere association, since high association achieved only by ad hoc, highly brittle conditions is treated as less causal under the same observational data. The temporal-precedence component is encoded by restricting attention to candidates that occur in the antecedent portion of* $\mathrm{Seq}(S)$ *relative to B, so that the optimization is not over arbitrary correlates but over prospective parents in the temporal (or otherwise directed) ordering.*

Remark 712. *A simple example (in outline): suppose B is `alarm(rings)`, and the candidate causes $\mathtt{C}$ include `smoke`, `steam`, and `dust`. A high-fit but overly specific rule might include a long conjunction of rare conditions; a weaker (simpler) rule might treat `smoke` as the primary parent because it captures most of the predictive signal with fewer special cases. The parameter η governs how aggressively the observer prefers such simplicity. One can view this as preferring a small, stable explanatory "core" over an arbitrarily detailed exception list: e.g. a contrived rule like `(smoke AND weekday AND sensor_A AND NOT window_open AND ...)` may fit a limited dataset extremely well while generalizing poorly, whereas `smoke` alone may capture most of the predictive mass across contexts. In this toy scenario, `steam` might be a frequent correlate in kitchens (thus sometimes predictive) but also a common benign source of false alarms, and `dust` might correlate with sensor noise in certain rooms; the weakness term is intended to suppress treating such context-fragile correlates as "the cause" unless the added distinctions genuinely buy enough predictive performance to justify the added complexity. The role of η is then analogous to a regularization strength: small η permits richly contextual causes when the fit gain is large, while large η pushes toward more parsimonious parent-sets even at some cost in fit.*

Remark 713. *This is useful for the broader theory because it harmonizes with later "Wu Wei" optimization: the same weakness bias that prefers simple causal stories can also prefer minimally contrived control policies (Section 26; Hyperseed-Concept 206, 207; see [21]). It also connects to general tradeoff-theorem thinking about balancing dependency, fit, and complexity [9]. In other words, the same mathematical knob that discourages baroque explanatory structure also discourages baroque interventions: both "overfitted explanations" and "overengineered controls" can be seen as solutions that achieve a target outcome only by relying on an excessive number of finely tuned distinctions. When the observer (or agent) is constrained to prefer weaker descriptions, it tends to select causal parents that are robust across contexts, and likewise tends to select policies that succeed without requiring a long list of special-case contingencies. This is precisely the sense in which a shared simplicity/weakness bias can provide a unifying regularity principle across prediction (which antecedents matter?), causality (which antecedents count as parents?), and control (which actions achieve outcomes without contrivance?), making the later Wu Wei criteria appear less as a separate doctrine and more as the control-theoretic face of the same selection rule.*

Remark 714 (What "Fit" and "Weak" may be)**.** *There are many concrete instantiations. For example,* Fit *may be the projected predictive implication* $\pi(\mathrm{Cond}(B \mid \mathrm{Seq}(S)))$ *or a negative log-loss; and* Weak *may be a quantale weakness of the distinctions needed to state the conditional "B depends on S" (e.g. a description-length proxy or a partition-based weakness of contexts). The point is the structure: causality is not "just statistics" but statistics plus an Occam-like bias. Concretely,* Fit *can be read as any score that rewards accurate forecasting of B from the antecedent* *sequence, including likelihood-based criteria, proper scoring rules, or information-theoretic dependence measures so long as they increase when S makes B more predictable in the intended sense. Likewise,* Weak *is intentionally permissive: it may be instantiated as an MDL-style codelength of the rule, a complexity of the partition of contexts required to make the rule true, a penalty on the number of conjuncts/clauses, or a more semantic notion of "how many distinctions the observer must track" to use the conditional reliably. The quantale phrasing is meant to allow weakness to compose and compare across heterogeneous kinds of distinctions (e.g. temporal, contextual, and representational), rather than restricting it to a single numeric proxy. Under any such instantiation, the selection principle can be read as: choose parents that are predictive* and *that can be stated and applied with a small, reusable inventory of distinctions, thereby building temporal precedence and simplicity directly into the operational meaning of "cause."*

14.6 Control, control hierarchies, and perceptual hierarchies

Hyperseed's slogan is: *control is systematic causation.* We formalize this by treating control as causal implication where the antecedent is an intervention/action variable (Hyperseed-Concept 87). In this framing, "systematic" emphasizes repeatability across relevant contexts: a controller is not defined by a single lucky coincidence but by a stable mapping from *doable* antecedents to downstream consequences. The use of causal implication rather than mere co-occurrence is meant to exclude cases where A and G happen to correlate due to a common cause, and to favor cases where actively setting or instantiating A would (in the model) make G more likely. The context parameter O and lag window Δ are therefore not incidental bookkeeping: they encode what background conditions are held fixed and what temporal scope is treated as the "effect horizon" of action.

Definition 187 (Actions, goals, and control strength)**.** *Let $\mathcal{A} \subseteq \mathcal{E}$ be a designated set of* action event types. *Let $G \in \mathcal{E}$ be a goal condition (or a conjunction/disjunction of such). For $A \in \mathcal{A}$ define the* control strength *of A over G as*

$$\mathrm{Ctrl}_{O,\Delta}(A \to G) := \mathrm{CImp}_{O,\Delta}(A, G).$$

Remark 715. *The formal move is simple: we do not invent a new scalar for control; we reuse causal implication, restricted to antecedents interpreted as actions or interventions. Philosophically, this encodes the idea that agency is not an extra substance added to the world, but an organizational stance toward certain event types as* doable *(actions) and certain event types as* desirable *(goals). A technical advantage of this reuse is that any refinements already built into causal implication (e.g. sensitivity to temporal precedence, background context O, and windowing by Δ) carry over automatically to control: what counts as "the same action" and what counts as "achieving the goal" are evaluated inside the same event-type and context machinery.*

Remark 716. *Example: if $A =$`turn(key)` and $G =$`engine(starts)`, then* $\mathrm{Ctrl}(A \to G)$ *is high precisely when turning the key differentially raises the plausibility of starting the engine, does so with temporal precedence, and (optionally) aligns with intensional property connections. This is useful because it makes control a graded quantity, allowing partial control and contested control (e.g. conflicting evidence about whether the key mechanism is functional). A further benefit of grading is comparative evaluation: if $\{A_i\}$ are alternative actions, then control strengths* $\mathrm{Ctrl}(A_i \to G)$ *provide a principled way to rank actions by their expected goal-directed causal leverage under the same context and lag assumptions. In that sense, the definition is compatible with (but does not itself impose) decision-theoretic selection rules such as choosing an A that maximizes control subject to costs or constraints.*

Remark 717. *Although the definition is written for a single antecedent A, many control situations are sequential: a policy is a temporally extended pattern of actions. One can model such cases by letting A denote a composite event type (e.g. a short action script within Δ) or by applying the definition to intermediate subgoals $G_1, G_2, \dots$ that are chained together. This keeps the basic notion of control strength intact while allowing hierarchical decomposition of complex tasks into locally controllable steps.*

Definition 188 (System-level control)**.** *Let $\mathcal{U}$ and $\mathcal{V}$ be groupings of event types (subsystems, modules, or coarse variables). We say $\mathcal{U}$* controls *$\mathcal{V}$ (in context O with lag window Δ) if there exist $A \in \mathcal{U} \cap \mathcal{A}$ and $B \in \mathcal{V}$ such that $\mathrm{Ctrl}_{O,\Delta}(A \to B)$ exceeds a chosen threshold.*

Remark 718. *This lifts control from individual event types to coarse subsystems: "$\mathcal{U}$ controls $\mathcal{V}$" means that something in $\mathcal{U}$, construed as an action, exerts sufficiently strong causal implication toward something in $\mathcal{V}$. The threshold is a modeling choice, reflecting how strict we wish to be in calling a relation "control" rather than "influence." Because the definition uses an existential quantifier, it captures the minimal claim that* some *action-like degree of freedom in $\mathcal{U}$ can steer* some *event type in $\mathcal{V}$; stronger notions (sometimes useful in engineering) would replace "there exists" with requirements like "for many $B \in \mathcal{V}$" or would aggregate via $\max_{A \in \mathcal{U} \cap \mathcal{A}} \max_{B \in \mathcal{V}} \mathrm{Ctrl}(A \to B)$ to define a graded* inter-module *control strength.*

Remark 719. *Example: let $\mathcal{U}$ be motor-command events and $\mathcal{V}$ be arm-position events. Then system-level control holds if there exists a motor command that reliably steers the arm. In more abstract cognitive systems, $\mathcal{U}$ might be an executive module and $\mathcal{V}$ a memory module; the definition then captures the idea that executive actions can gate or modulate memory states. This kind of modular control analysis is widely used in cognitive architectures (cf. [19]). In both examples, the window Δ implicitly distinguishes fast, direct effects (a command changes position within tens of milliseconds) from slower, mediated effects (a command changes posture after a sequence of reflex loops). Choosing Δ therefore selects what counts as "the controlled variable" at the scale of interest.*

Remark 720 (Asymmetry and bidirectionality)**.** *Nothing forces control to be symmetric. One may have $\mathcal{U}$ controlling $\mathcal{V}$ without $\mathcal{V}$ controlling $\mathcal{U}$. Bidirectional control corresponds to feedback coupling. In feedback-coupled systems, bidirectionality is common: $\mathcal{U}$ may act on $\mathcal{V}$ while $\mathcal{V}$ supplies observations or error signals that modulate subsequent actions in $\mathcal{U}$. The present definition is deliberately agnostic about stability and optimality: it identifies the presence of causal leverage, not whether the resulting closed-loop dynamics converge, oscillate, or diverge. Those dynamical questions can be layered on top by analyzing control strengths across multiple lags or across recurrent cycles.*

Definition 189 (Control hierarchy)**.** *A* control hierarchy *is a partial order $(\mathcal{M}, \succcurlyeq)$ on a family of modules $\mathcal{M}$ such that $M_1 \succcurlyeq M_2$ is aligned with "M_1 has (potentially asymmetric) control over M_2."*

Remark 721. *The term "hierarchy" is used in the order-theoretic sense: $\succcurlyeq$ is a partial order, so it need not compare every pair of modules. This accommodates heterarchical organization (Hyperseed-Concept* **??***) where some modules are incomparable or form local loops, while still capturing a global tendency for some modules to sit "above" others in the sense of exerting more control (Hyperseed-Concept 88). Operationally, one can imagine estimating pairwise system-level control relations (possibly at different thresholds or different Δ) and then taking the transitive closure to obtain an ordering over modules. When mutual control is pervasive, it is often useful to treat strongly mutually controlling clusters as equivalence classes, so that the partial order applies between clusters rather than insisting on antisymmetry between tightly coupled components.*

Remark 722. *A simple example is a two-level robot controller: a high-level planner module M_{plan} chooses goals and sequences, and a low-level motor module M_{motor} executes them. Then $M_{\text{plan}} \succcurlyeq M_{\text{motor}}$. In biological or cognitive settings, such a clean order may not exist globally; using a partial order rather than a total order respects this. One also frequently encounters multi-level cases where M_{plan} controls not the motor plant directly but the* parameters *of lower controllers (gains, setpoints, task constraints), while lower controllers control moment-to-moment actuator outputs. The partial-order notion is intended to cover both "direct command" and "parameter-setting" as varieties of control, so long as they show up as strong causal implication from action-like events in the higher module to state changes in the lower one.*

Remark 723. *This definition is useful because it gives a formal handle on a pervasive explanatory motif: many systems are organized so that some processes constrain or parameterize others. Later sections revisit this motif under attention allocation and cognitive synergy, where control of resource flow is as important as control of external actions. A further motif is* abstraction*: higher modules often act over coarser variables and longer time horizons, while lower modules act over finer variables and shorter time horizons. The parameters (O, Δ) can be chosen to reflect this scale separation, so that "higher controls lower" is not merely a metaphor but corresponds to measurable differences in what kinds of event types are treated as actions, what kinds of event types are treated as goals, and over what temporal windows the causal implications are evaluated.*

Definition 190 (Perceptual hierarchy)**.** *A* perceptual hierarchy *is a control hierarchy in which the relevant control events are instances of pattern recognition (Section 13): controlling a module consists in selecting, stabilizing, or transforming the patterns it registers.*

Remark 724. *This definition treats perception as a special case of control: higher levels "control" lower levels by constraining what patterns are recognized, amplified, or suppressed. It thereby links representation (Section 13) with action: to perceive is to enact a selection among possible organizations of the incoming stream (Hyperseed-Concept 133). Concretely, "control" here can be realized by mechanisms such as attentional gating, adaptive thresholding, top-down priming, or predictive templates that bias which hypotheses the lower module considers. On this view, a higher perceptual level does not merely* read *a fixed set of features; it can actively shape the feature space and the salience landscape, thereby changing what the lower level will count as a match on subsequent inputs. This is especially clear in ambiguous stimuli, where stabilizing one interpretation over another is itself a form of goal-directed regulation of internal state, even if no overt motor action is taken.*

Remark 725. *Example: in vision, a high-level hypothesis like `face-present` can bias lower-level feature detectors to stabilize edge/texture patterns consistent with a face; conversely, ambiguous low-level features may fail to stabilize any high-level pattern. In the present formalism, such biasing is represented abstractly as control relations among modules whose event types include recognition events. This is consonant with active-perception and predictive-processing intuitions, while not committing to a particular neural implementation.*

The point of phrasing this as a control relation *is that the "top–down" influence is treated as a directional constraint on which downstream events are made more (or less) likely to occur in a stable way, rather than as a mere correlation. In particular, a recognition event at a higher layer functions as a context-setting signal: it changes which lower-level event sequences are admissible (or evidentially supported) as the system settles into an interpretation. Conversely, persistent instability at the lower layer can be read as a failure to supply sufficient evidential support for any higher-level recognition event to become dominant, which explains why the overall percept remains indeterminate in ambiguous stimuli.*

Remark 726 (Perception as action). *In this view, perception is not passive "taking in data" but an active control process that modulates which patterns become salient and how they are organized. This aligns naturally with predictive-processing and active-inference perspectives, but remains agnostic about particular neuroscience.*

More concretely, the "action" here need not be overt motor behavior; it can also be internal action in the space of hypotheses, such as adjusting attention, gain, precision, or other modulatory knobs that determine which prediction errors are amplified and which are attenuated. The formal upshot is that perceptual outcomes are treated as controlled *equilibria: what is perceived is whatever interpretation the system can stably maintain under its current control policy and evidential constraints, rather than a direct readout of raw sensory input.*

14.7 Planning and optimal control: integration hooks

14.7.1 Event calculus hook

The Event Calculus represents temporally extended domains using predicates such as $\text{Happens}(a,t)$, $\text{Initiates}(a,f,t)$, $\text{Terminates}(a,f,t)$, and $\text{HoldsAt}(f,t)$. In a Hyperseed-style uncertain setting, one can attach p-bit evidence values to these predicates and treat planning as search for action sequences whose composed predictive implication toward the goal is high. The sequential composition operator from Section 14.4 is designed to match the temporal compositionality required by planning.

The intended reading is that each of these predicates can be treated as an *evidential claim* rather than a Boolean fact: an agent may have partial support that an action occurred, mixed support that it initiates a fluent, or even contradictory support due to noisy sensing, conflicting reports, or model mismatch. Planning then becomes an evidential optimization problem: instead of searching for a single logically consistent narrative, one searches for trajectories whose chained, time-respecting implications make the goal fluent more strongly supported at the relevant horizon. The sequential operator is the mechanism that turns per-step evidential implications into an aggregate multi-step assessment while respecting temporal order (i.e. earlier actions can only influence later holds).

Remark 727. *This paragraph is an interface point rather than a full development: it says that one may take a classical event/process calculus (Hyperseed-Concept* **??***) and replace its crisp truth values with* p-bit *evidence values, thereby allowing plans to be assessed under contradictory and incomplete information. The quantale-composition rule then supplies an algebra for aggregating multi-step plan reliability without leaving the evidential domain.*

In particular, the "interface" claim is that existing symbolic planning infrastructure can be reused at the level of syntax and temporal structure (events, fluents, and their persistence), while the semantics of entailment is softened into evidential support. This makes it possible to speak meaningfully about plans that are good enough *even when no plan can be proven correct in the classical sense, and it clarifies how plan refinement can proceed: one improves a plan either by strengthening the evidential links between steps (better predictive implication) or by inserting actions whose main role is epistemic, i.e. to reduce contradiction and increase the stability of later inferences about* $\text{HoldsAt}(f,t)$.

14.7.2 Wu Wei preview

Section 26 introduces Wu Wei dynamics: a bias toward minimal contrivance, i.e. achieving goals via the weakest (least special-case) control policies that still work. In the present terms, Wu Wei is a global optimization principle layered on top of the local notions of attraction/causality/control. Roughly: among plans that achieve high projected predictive implication toward the goal, prefer those that maximize weakness (simplicity) and minimize experienced effort (Section 8) (Hyperseed-Concept 206, Hyperseed-Concept 100; see [21]).

The integration hook to optimal control is that "weakness" plays a role analogous to regularization or complexity penalties: it biases the solution set toward policies that are robust under model error and that do not rely on brittle coincidences in the environment. Meanwhile "effort" functions like a cost functional over control signals, including both overt energy expenditure and internal computational or attentional load. The resulting preference ordering is thus not merely about whether a goal can be reached, but about whether it can be reached in a way that remains stable under the agent's limited resources and imperfect knowledge.

Remark 728. *The philosophical tenor here is that of "least action," but translated from physics to agency: do not seek maximal domination of the world, but maximal alignment with the world's own tendencies, so that small interventions suffice. Formally, this becomes a multi-objective optimization over (i) plan success (predictive implication), (ii) simplicity/weakness, and (iii) effort. This is also where control theory (in the engineering sense) and weakness theory (in the Hyperseed sense) meet.*

One can also read this as a constraint on control hierarchies*: higher layers should prefer to set broad, low-commitment goals or biases that allow lower layers to exploit existing attractors in the environment, rather than micromanaging every degree of freedom. In that sense, Wu Wei is not a rejection of control but a discipline of control: intervene at the level where a small informational or policy change yields a large shift in downstream trajectories, and avoid interventions that must be continually "propped up" against the system's natural dynamics.*

Hyperseed concepts covered

- Attraction, PredictiveImplication, PredictiveAttraction; sequential temporal operators (SequentialAND, SimultaneousAND, SimultaneousOR) at a formal level.
- Cause, CausalImplication, SimpleCausalImplication; extensional vs intensional predictive attraction; temporal precedence; weakness/simplicity bias.
- Control, asymmetric/symmetric control; Control Hierarchy; Perceptual Hierarchy.
- Planning hook (Event Calculus) and connection to later Wu Wei optimal control.

15 Attention and cognitive synergy

15.1 From control to attention

Section 14 introduced prediction, attraction, and control. For bounded systems, however, "control" is always exercised through a bottleneck: only a small fraction of the system's internal processes can be actively updated at any moment. This bottleneck can be read quite literally as a limit on concurrently maintainable state, updatable parameters, searchable hypotheses, or executable action plans—and, more abstractly, as the simple fact that any physical mechanism has finite throughput. Hyperseed calls the structured management of this bottleneck *attention.* In other words, attention is not an optional add-on to control; it is the mechanism by which control becomes realizable under finite capacity.

Informally, attention is not (only) a spotlight on sensory data. It is the system's allocation of its limited resources (time, energy, computation, bandwidth) across the recognition, inference, simulation, and action processes that operate on patterns. This includes not only *which* patterns are processed, but also *how deeply* they are processed: e.g., whether a hypothesis is merely queued, weakly checked, or iteratively refined until it becomes a stable, reusable chunk in the system's pattern inventory. When the allocation becomes highly concentrated, the system has an *attentional focus*. When the system's self-model lies inside the focus, it has *self-reflective attention*, a key ingredient in Hyperseed's later notion of reflective consciousness (Section 17). Equivalently, self-reflective attention can be viewed as the case where the system treats parts of its own modeling-and-control loop as objects of ongoing inference and revision, rather than as fixed machinery.

A useful way to read the above is that attention defines an *attentional policy* over internal processes: it determines which inference chains get additional compute, which simulations get extended time horizons, which sensors are sampled at higher fidelity, and which candidate actions are evaluated with higher resolution. Since these choices affect what the system learns and what it can do next, attention couples short-term performance to long-term capability: the system that repeatedly allocates effort to the same limited set of patterns may become very efficient there, but risks neglecting alternative explanations or actions. This trade-off between exploitation (deepening a current focus) and exploration (shifting focus to new patterns) will reappear later when we discuss synergy across processes and the conditions under which collections of patterns become mutually supportive rather than mutually distracting.

Remark 729. *The guiding idea is that agency is never merely about possessing a good model; it is also about* deciding which parts of the model to refine now*. This is a resource-theoretic thought in the style of bounded rationality, but expressed in the native Hyperseed vocabulary of patterns and genenergy. In this sense, attention is the operative bridge between the "can in principle" of prediction/control and the "can right now" of a finite mechanism [19, 1]. One concrete implication is that even an accurate generative model may fail to yield effective control if the system cannot reliably route effort to the model components that matter for the present context (e.g., the causal variables relevant to a current goal, or the uncertainty sources that dominate expected loss).*

Remark 730. *When we later refer to the Hyperseed core-concept set, the notions of attention and focus here should be read alongside Hyperseed-Concept 60 and the more general resource/effort notions (Hyperseed-Concept 100) that implicitly underwrite the formal budget constraints below. In particular, "effort" can be interpreted as the accounting unit that allows different internal activities (updating beliefs, running simulations, searching memories, selecting actions) to be compared and traded off within a single bounded budget, even when their concrete computational substrates differ.*

Remark 731. *It is also helpful to distinguish the* target *of attention (which patterns or processes are selected) from the* mode *of attention (how selection is enforced). In engineered systems this mode might look like explicit scheduling, priority queues, or dynamic resource allocation; in biological systems it may appear as gating, inhibition, or neuromodulatory gain control. Hyperseed abstracts away from these implementations and treats attention primarily as the functional role of reliably concentrating limited genenergy on the pattern-transformations most relevant to the current trajectory of inference and action.*

15.2 Genenergy budgets and attention measures

Hyperseed measures attention in terms of "genenergy": any fungible resource that gates what the system can do (metabolic energy, compute cycles, working memory bandwidth, time-on-task, etc.). Section 19 gives a broader treatment of energy/genenergy; here we only need a minimal accounting formalism.

Definition 191 (System, modules, and genenergy flow)**.** *A* system S *is assumed to have:*

(a) a finite set of modules $\mathcal{M} = \{1, \dots, n\}$ *(subsystems/process bundles);*

(b) a finite (or countable) set of patterns $\mathcal{P}$ *(Section 9);*

(c) an association map $\mathrm{Assoc} : \mathcal{M} \to 2^{\mathcal{P}}$ *indicating which patterns each module is currently "about" (recognizes, maintains, manipulates);*

(d) a time index set T (Section 7);

(e) a genenergy expenditure *function*

$$g : T \times \mathcal{M} \to [0, \infty), \qquad (t, i) \mapsto g_t(i),$$

where $g_t(i)$ is the amount of genenergy spent by module i during the interval around t.

The total genenergy spent at time t is

$$G_t := \sum_{i \in \mathcal{M}} g_t(i).$$

Remark 732. *Intuitively, the definition separates* what the system is *(a collection of modules that can spend resources) from* what the system is about *(the patterns those modules are currently tracking or manipulating). The association map* Assoc *is intentionally coarse: it is not a semantic truth-condition, only a bookkeeping relation indicating which patterns are in the working ambit of which processes (Hyperseed-Concept 59; Hyperseed-Concept 130).*

Remark 733. *A simple example is a toy architecture with three modules: vision ($i = 1$), planning ($i = 2$), and motor control ($i = 3$). At time t, we might have $g_t(1) = 5$, $g_t(2) = 2$, $g_t(3) = 1$, so $G_t = 8$. Even in this minimal case, attention is already present as the uneven allocation of genenergy across modules (Hyperseed-Concept* **??***).*

Remark 734. *The notation $g_t(i)$ follows a standard convention: g is the underlying function, while the subscript t indicates we freeze time and view g_t as a function of the module index i. Similarly, G_t is the scalar total expenditure at time t. This small notational discipline matters later, when we push forward module-level allocations to pattern-level distributions.*

Remark 735. *Nothing in the definitions requires genenergy to be conserved or fixed across time. If $G_t = 0$ we interpret S as effectively inactive at time t.*

15.2.1 Attention to a pattern class

Hyperseed defines attention to a class of patterns as genenergy spent on processes associated with those patterns. To avoid double-counting when modules touch multiple patterns, we distribute each module's expenditure over its associated pattern set.

Definition 192 (Pattern-level attention)**.** *Assume each module i comes with a nonnegative weighting*

$$w_i : \mathcal{P} \to [0, 1], \qquad \sum_{p \in \mathcal{P}} w_i(p) = 1,$$

with $w_i(p) = 0$ unless $p \in \mathrm{Assoc}(i)$. Define the attention mass *on pattern p at time t by*

$$\mathrm{Attn}_t(p) := \sum_{i \in \mathcal{M}} g_t(i)\, w_i(p).$$

For a class of patterns $X \subseteq \mathcal{P}$ define

$$\mathrm{Attn}_t(X) := \sum_{p \in X} \mathrm{Attn}_t(p).$$

When $G_t > 0$, define the normalized attention distribution

$$\alpha_t(p) := \frac{\mathrm{Attn}_t(p)}{G_t}, \qquad \sum_{p \in \mathcal{P}} \alpha_t(p) = 1.$$

Remark 736. *The intent is to get a clean quantitative proxy for the intuitive claim "pattern p is in the spotlight." Each module spends genenergy, and each module spreads its expenditure over the patterns it is currently engaging. The weights $w_i(p)$ can be read as a soft assignment: how much of module i's work is effectively "about" p rather than something else.*

Remark 737. *A concrete example: suppose a planning module i is simultaneously considering two candidate subgoals, represented by patterns p_1 and p_2. One might set $w_i(p_1) = 0.7$, $w_i(p_2) = 0.3$. Then if $g_t(i) = 10$, this module contributes 7 units of attention mass to p_1 and 3 to p_2. Summing across modules yields a global pattern-level allocation.*

Remark 738. *The distribution $\alpha_t \in \Delta(\mathcal{P})$ is the normalized version of attention mass. Here $\Delta(\mathcal{P})$ denotes the probability simplex on $\mathcal{P}$: the set of functions $\alpha : \mathcal{P} \to [0,1]$ summing to 1. We use probabilistic notation not because attention is always stochastic, but because normalization turns "share of resources" into a form that can be compared across times and systems, and connected to entropy-like concentration measures.*

Remark 739 (Module-level vs pattern-level)**.** *One can also work directly with the module allocation vector $\hat{\alpha}_t(i) := g_t(i)/G_t$. The pattern-level distribution α_t is a pushforward of $\hat{\alpha}_t$ along the weights w_i.*

Remark 740. *The pushforward comment can be read categorically: $\hat{\alpha}_t$ lives on modules, while α_t lives on patterns; the weights w_i implement a (time-dependent) stochastic map from modules to patterns. In the philosophical idiom, this is how the system's internal economy of effort becomes a distribution over what is* present to its cognition *(Hyperseed-Concept **??**).*

15.2.2 Attentional focus and self-reflective attention

Hyperseed's notion of attentional focus is a *concentration* condition: a relatively small subset of the system absorbs a relatively large fraction of genenergy. In this section we treat the attention weights $\alpha_t(p)$ as an abstract accounting device for how much of the system's limited update capacity is effectively routed through pattern p at time t. In particular, one can read α_t as a probability distribution over $\mathcal{P}$ (hence $\sum_{p \in \mathcal{P}} \alpha_t(p) = 1$), but the intended interpretation is budgetary: the mass is a normalized proxy for "genenergy share" rather than a claim about any specific implementation.

Definition 193 (Attentional focus)**.** *Fix parameters $\theta \in (0,1)$ (mass threshold) and $k \in \mathbb{N}$ (size bound). We say S has an* attentional focus *at time t (at level (θ, k)) if there exists a subset $F_t \subseteq \mathcal{P}$ with $|F_t| \le k$ such that*

$$\alpha_t(F_t) := \sum_{p \in F_t} \alpha_t(p) \ge \theta.$$

Equivalently, if $\alpha_t^{\downarrow}$ is the nonincreasing rearrangement of the weights $(\alpha_t(p))_{p \in \mathcal{P}}$, then focus holds iff $\sum_{j=1}^{k} \alpha_t^{\downarrow}(j) \ge \theta$.

Remark 741. *The definition formalizes an old introspective fact: at any moment, a mind is usually "mostly doing one thing," perhaps with a few side computations. The parameters (θ, k) let us tune what we mean by "mostly" and "few." The nonincreasing rearrangement $\alpha_t^{\downarrow}$ is simply the list of attention weights sorted from largest to smallest; the criterion then says: the top k patterns together carry at least θ fraction of the attention mass. It is also useful to keep in mind that the set F_t is typically* not *unique: whenever there are ties among the largest weights, multiple choices of F_t witness the same level of focus. Nothing in later arguments depends on a canonical choice; only the existence of some small set with large mass matters.*

Remark 742. *A simple example: if $\mathcal{P}$ has* 100 *patterns and the top $k = 5$ patterns carry* 85% *of the mass, then the system has focus at $(\theta, k) = (0.85, 5)$. Conversely, if attention is spread nearly uniformly, then no small subset can reach a high threshold and focus fails. This aligns with the intuition that "diffuse attention" is the absence of a narrow bottleneck. Note that this is sensitive to* how *nonuniformity is distributed: e.g. two medium-sized clusters can each be salient without either cluster alone clearing a large θ for small k, which matches the everyday phenomenon of "split attention" (two active tasks) as distinct from either single-task focus or fully uniform diffusion.*

Remark 743. *The usefulness of this definition is pragmatic: it lets later sections talk about focus-dependent phenomena (e.g. workspace access, self-reference, and stable control loops) without committing to a specific psychological or neural mechanism. It is thus a minimal mathematical hook for Hyperseed-Concept 60. A further pragmatic benefit is that the condition is scale-free: only the* relative *genenergy shares matter. This is helpful when comparing subsystems or agents whose absolute compute budgets differ, since attentional bottlenecks are often about allocation rather than total capacity.*

Remark 744 (Basic monotonicities)**.** *The definition behaves monotonically in the expected way: if focus holds at (θ, k), then it holds at (θ', k') for any $\theta' \leq \theta$ and any $k' \geq k$. Conversely, increasing θ or decreasing k makes the test strictly harder. This lets one speak of "strong" focus (high θ with small k) versus "weak" focus (lower θ and/or larger k) without changing the underlying concept.*

Remark 745 (Canonical witnessing set via top-k)**.** *Given α_t, one can always witness the maximal attainable mass under a size bound k by choosing F_t to be any set of k patterns achieving the k largest weights (ties arbitrary). Then $\alpha_t(F_t) = \sum_{j=1}^{k} \alpha_t^{\downarrow}(j)$, which shows that the "existence of F_t" phrasing and the rearrangement criterion are not merely equivalent but operationally the same test: compute the top-k share and compare to θ.*

Definition 194 (Self-model and self-reflective attention)**.** *Let $\mathcal{P}_{\mathrm{self}} \subseteq \mathcal{P}$ be the set of patterns that constitute the system's current self-model (Section 16). We say S has* self-reflective attention *at time t if*

$$\alpha_t(\mathcal{P}_{\mathrm{self}}) \geq \theta_{\mathrm{self}}$$

for some chosen threshold $\theta_{\mathrm{self}} \in (0, 1)$. More strongly, S has focused self-reflective attention *at time t if F_t can be chosen so that $F_t \cap \mathcal{P}_{\mathrm{self}} \neq \emptyset$.*

Remark 746. *Here the point is not metaphysical privilege but routing: self-model patterns are those whose update affects how the system predicts, controls, and narrates itself. When a significant share of attention mass is allocated to $\mathcal{P}_{\mathrm{self}}$, the system is spending real resources on maintaining or revising its self-description (Hyperseed-Concept* **??***; Hyperseed-Concept 165). The two thresholds θ (general focus) and θ_{self} (self allocation) need not coincide: one may want to detect self-involvement even when overall focus is weak (e.g. rumination spread across many self-related fragments), or conversely require that self-related patterns occupy a significant fraction of a very tight focus set.*

Remark 747. *A typical example is a learning agent that allocates attention to error-monitoring patterns such as "I am failing" or "my model is uncertain." These are self-model patterns in the present sense, and when they enter the focus set F_t, one gets a crisp formal correlate of the everyday report "I noticed that I was confused." This is a small but essential ingredient for the later consciousness interface (Section 17) and resonates with empirical discussions of self-related processing (Hyperseed-Concept 85). It is worth emphasizing that the stronger condition (intersection with F_t) captures a difference between (i) dedicating some background mass to self-maintenance and (ii) having self-model content be among the currently dominant patterns. The latter is the mathematically clean version of the phenomenological distinction between "the self is in the foreground" and "the self is merely implicitly present."*

Remark 748 (Focus is graded)**.** *The parameters (θ, k) provide a simple family of "focus tests." Other concentration measures can be used (entropy, Gini coefficient, top-k share), but the above definition is adequate for connecting to later sections. In practice, one may also care about* temporal *aspects (how long a focus persists): a brief spike where $\sum_{j=1}^{k} \alpha_t^{\downarrow}(j) \geq \theta$ may have different functional consequences than a sustained interval on which the inequality holds. Later when we discuss stable control loops, it will be natural to consider not only instantaneous focus but also its persistence under small perturbations of α_t.*

15.3 Attention as a bounded control policy

Attention is itself an action: it chooses which parts of the internal model are updated, refined, or queried. Formally, we treat attention as a policy that selects a distribution over internal update actions. This framing makes "what to think about next" a first-class control variable, rather than a side-effect of perception or representation: the system can actively steer its own computational trajectory by deciding which internal transformation to apply next.

Definition 195 (Internal update actions)**.** *Let $\mathcal{U}$ be a set of* internal update actions*. An element $u \in \mathcal{U}$ may represent:*

(a) refining a distinction (Section 3);

(b) updating a pattern intensity estimate (Section 9);

(c) querying memory or a submodule (Section 20);

(d) simulating a causal consequence (Section 14);

(e) reweighting or re-indexing representations (Section 13).

Assume each update action u has a genenergy cost $c(u) \geq 0$.

Remark 749. *The philosophical move here is to treat attention not as a passive "light" but as an internal intervention: an update action u changes the system's internal state, and thus changes what future actions are possible. This matches the control-theoretic reading of attention used in engineered AGI systems, where "choosing what to compute next" is itself a crucial policy decision [19].*

Remark 750. *It is useful to emphasize that $\mathcal{U}$ can mix heterogeneous operations that live at different algorithmic levels. For example, "refine a distinction" may change the representational vocabulary, while "retrieve one memory" may only change the active context, and "simulate a consequence" may instantiate a temporary forward model. Treating all of these as elements of a single action set is a deliberate unification: the attention mechanism need not commit in advance to a single computational paradigm, and can instead arbitrate among many possible internal moves.*

Remark 751. *Examples of $u \in \mathcal{U}$ include: running one step of a planner; performing a memory retrieval; updating a Bayesian posterior; or running a short roll-out simulation. The cost $c(u)$ is deliberately abstract so it can stand in for time, energy, FLOPs, bandwidth, or any conserved-or-not resource (Hyperseed-Concept 87; Hyperseed-Concept 100).*

Remark 752. *The cost function $c(u)$ can also be interpreted as a* capacity consumption *measure: two update actions may both be fast, but one may monopolize scarce working memory or interfere with concurrent processes. In that sense, bounded attention is not only a time-budget story; it can represent any constraint that forces internal computation to be selectively scheduled rather than globally applied.*

Definition 196 (Attention policy with budget)**.** *Fix a budget $B_t \geq 0$ for time t. An* attention policy *is a map*

$$\pi_t : \Omega_t \to \Delta(\mathcal{U}),$$

where Ω_t is the system's internal state space at time t and $\Delta(\mathcal{U})$ is the set of probability distributions over $\mathcal{U}$. A draw $u \sim \pi_t(\omega)$ is feasible if $c(u) \leq B_t$.

Remark 753. *One can equivalently define, for each (t, ω), a feasible subset*

$$\mathcal{U}_t(\omega) := \{u \in \mathcal{U} \ : \ c(u) \leq B_t\},$$

and view $\pi_t(\omega)$ as a distribution supported on $\mathcal{U}_t(\omega)$. This highlights that the budget may be context-dependent in practice: the same nominal update action might be cheap in one internal configuration (e.g., when a relevant cache is warm) and expensive in another (e.g., when a submodule must be re-initialized).

Remark 754. *The notation $\pi_t : \Omega_t \to \Delta(\mathcal{U})$ is standard in decision theory: given an internal state $\omega \in \Omega_t$, the policy π_t returns a distribution over actions. The only twist is that actions here are internal computations or updates rather than external motor moves. The feasibility condition $c(u) \leq B_t$ makes the resource constraint explicit, so that attention is a bounded-control problem rather than a purely epistemic one.*

Remark 755. *In this language, "attention failure" can be described without invoking any special pathology: it is simply the selection (perhaps repeatedly) of update actions that are locally feasible but globally unhelpful, e.g., over-investing in cheap but low-value computations, or repeatedly applying an update rule that no longer improves internal predictions. Conversely, "skilled attention" is a policy π_t that reliably selects update actions whose downstream effects improve later decision quality under budget constraints.*

Remark 756. *A simple example: if B_t is small, the policy may assign high probability only to cheap actions like "retrieve one memory" rather than expensive ones like "run a long simulation." This gives a clean way to formalize attentional phenomena such as shallow vs. deep reasoning under time pressure, without altering the underlying pattern semantics.*

Remark 757. *The budgeted-policy view also clarifies how attentional allocation can couple to external action. If an external decision must be made imminently, B_t effectively shrinks, shifting π_t toward quick diagnostic updates; if the system is in a deliberative regime, B_t can expand, permitting costly counterfactual simulation and deeper representational refinement. In both cases, the same internal machinery can be used; only the feasible set and the policy's trade-offs change.*

The definitions above are intentionally abstract: Hyperseed is compatible with many concrete attention mechanisms. One common form is "soft" allocation by expected value-of-information or expected control benefit. In particular, we can separate (i) a mechanism that scores candidate foci (e.g., patterns) for their relevance to control, from (ii) a mechanism that turns those scores into a bounded allocation that respects the need to diversify across multiple competing opportunities for improvement.

Definition 197 (Priority scores from predictive attraction)**.** *Let $\mathcal{G}$ be a set of goal conditions (Section 18). For each pattern $p \in \mathcal{P}$ assume there is an associated event type A_p meaning "pattern p is currently active/salient" (Section 14). Define a* priority score *at time t by*

$$\mathrm{Prio}_t(p) := \max_{G \in \mathcal{G}} \left|\mathrm{Att}_{O,\Delta}(A_p, G)\right|,$$

where $\mathrm{Att}_{O,\Delta}$ is the attraction operator from Section 14.3.

Remark 758. *This definition is the promised "differential" idea in miniature: a pattern is prioritized if its presence makes a significant difference to what the system expects about its goals. The absolute value allows both positive and negative attraction to matter: either "this pattern tends to bring about the goal" or "this pattern tends to prevent the goal" can warrant attention, because both can guide effective control.*

Remark 759. *The use of $\max_{G \in \mathcal{G}}$ encodes a conservative, goal-sensitive criterion: a pattern is high-priority if it substantially affects at least one goal condition, even if it is irrelevant to others. Alternative aggregations are possible (e.g., expectation under a goal-importance distribution, or a weighted sum), but the max operator cleanly captures the idea of "whatever is most at stake right now" without committing to a particular utility encoding beyond the existence of $\mathcal{G}$.*

Remark 760. *One may read $\mathrm{Prio}_t(p)$ as a bridge between prediction/control (Section 14) and resource allocation: it converts the attraction relation into a scalar that can be traded off against entropy-regularization or other concentration penalties. This is a typical move in architectures emphasizing cognitive synergy and integrated attention allocation [19].*

Remark 761. *To connect the pattern-level priority score back to the update-action view, one may imagine that many update actions $u \in \mathcal{U}$ are* pattern-indexed *(e.g., "update intensity of p", "refine distinction involving p", "retrieve memories associated with p"). In that case, $\mathrm{Prio}_t(p)$ induces a natural family of heuristics for scoring update actions: an action is valuable insofar as it is expected to reduce uncertainty, sharpen distinctions, or improve control predictions for high-priority patterns. This is one concrete route from attraction-based semantics to implementable attention scheduling.*

Proposition 23 (Entropy-regularized attention allocation)**.** *Fix $\beta > 0$ and suppose $\mathcal{P}$ is finite. Among all distributions $\alpha \in \Delta(\mathcal{P})$, the maximizers of*

$$J(\alpha) := \sum_{p \in \mathcal{P}} \alpha(p)\, \mathrm{Prio}_t(p) \;-\; \frac{1}{\beta} \sum_{p \in \mathcal{P}} \alpha(p) \log \alpha(p)$$

are exactly the softmax distributions

$$\alpha^*(p) = \frac{\exp(\beta\, \mathrm{Prio}_t(p))}{\sum_{q \in \mathcal{P}} \exp(\beta\, \mathrm{Prio}_t(q))}.$$

Remark 762. *A standard proof uses Lagrange multipliers: optimize $J(\alpha)$ subject to $\sum_p \alpha(p) = 1$ and $\alpha(p) \geq 0$. Differentiating yields*

$$\mathrm{Prio}_t(p) - \frac{1}{\beta}(1 + \log \alpha(p)) + \lambda = 0,$$

so $\alpha(p) \propto \exp(\beta \, \mathrm{Prio}_t(p))$, and normalization gives the stated form. The entropy term is strictly concave in α (on the simplex interior), so the optimizer is unique when all $\alpha(p) > 0$.

Remark 763. *This proposition says: if you want to allocate attention to maximize expected priority, but you also penalize excessively peaky allocations using Shannon entropy, then the optimal allocation has the familiar exponential form. In other words, "soft attention" is not an arbitrary heuristic; it is the exact optimizer of a simple and interpretable objective.*

Remark 764. *The parameter β plays the role of an inverse temperature. As $\beta \to \infty$, the entropy penalty vanishes and α^* concentrates on patterns with maximal $\mathrm{Prio}_t(p)$, yielding a nearly greedy attentional focus; as $\beta \to 0^+$, the entropy term dominates and α^* tends toward a uniform allocation over $\mathcal{P}$, representing highly diffuse or exploratory attention. Thus, β provides a compact handle on the sharpness of attentional selection, independent of the underlying semantics of priority.*

Remark 765. *The result matters here because it gives a canonical mathematical mechanism for turning attraction scores into a distribution α_t that can be compared to the earlier focus definition. It therefore makes contact between the qualitative Hyperseed narrative about attention and a quantitative optimization principle common in both cognitive modeling and machine learning. In particular, it turns an* ordinal *ranking of patterns (what is more or less attractive) into a* cardinal *allocation rule (how much attention each pattern receives), which is necessary if attention is later treated as a measurable bottleneck. The same mechanism also clarifies what it means for attention to be "bounded": the entropy term encodes a soft resource constraint that penalizes overly concentrated allocations unless the priorities justify them.*

Remark 766. *The connection to the rest of the document is direct: predictive attraction (Section 14.3) feeds Prio_t, which feeds an attention distribution α_t, which then gates which patterns and knowledge types can participate in cognitive synergy (Section 15.6). This makes α_t a control-like interface between evaluation and participation: it is computed from internal scores, but it has externally visible consequences for which inference steps, memory retrievals, and action proposals are even available to be composed. Seen this way, Prio_t plays the role of an energy landscape over patterns, while α_t is the induced sampling or allocation policy used by downstream cognitive processes.*

Proof. This is the standard Lagrange-multiplier calculation for maximizing a linear functional with an entropy regularizer under the simplex constraint $\sum_p \alpha(p) = 1$. Differentiating the Lagrangian yields $\mathrm{Prio}_t(p) - \frac{1}{\beta}(1 + \log \alpha(p)) = \lambda$ for all p, which implies $\alpha(p) \propto \exp(\beta \, \mathrm{Prio}_t(p))$. To make the dependence explicit, one may start from an objective of the form $J(\alpha) = \sum_p \alpha(p) \, \mathrm{Prio}_t(p) + \frac{1}{\beta} H(\alpha)$ with $H(\alpha) = -\sum_p \alpha(p) \log \alpha(p)$, and impose $\alpha(p) \geq 0$ with $\sum_p \alpha(p) = 1$. The stationarity condition above holds on the interior (where $\alpha(p) > 0$); at the optimum one indeed gets strictly positive weights whenever β is finite and the priorities are finite, so the interior calculation is self-consistent. Solving the first-order condition gives $\alpha(p) = \exp(\beta(\mathrm{Prio}_t(p) - \lambda) - 1)$, and the scalar λ is fixed by the normalization constraint, yielding the familiar normalized softmax form. □

Remark 767. *At a high level, the proof works because the objective $J(\alpha)$ is strictly concave in α on the interior of the simplex: a linear term plus (negative) entropy. Strict concavity guarantees a* *unique optimum (up to degeneracies when priorities tie), and the first-order condition characterizes it. Equivalently, one can view the optimization as minimizing a Kullback–Leibler divergence to a Gibbs distribution: maximizing* $\sum_p \alpha(p)\mathrm{Prio}_t(p) + \frac{1}{\beta}H(\alpha)$ *is the same as minimizing* $\mathrm{KL}(\alpha \,\|\, \pi_\beta)$ *where* $\pi_\beta(p) \propto \exp(\beta\,\mathrm{Prio}_t(p))$*. This perspective makes clear why the solution has full support for finite* β *(no pattern is given exactly zero attention unless forced by infinite negative priority), and why ties in* Prio_t *can yield symmetry-induced degeneracies only in the limiting cases where the objective effectively becomes linear.*

Proof sketch. Introduce a Lagrange multiplier λ to enforce $\sum_p \alpha(p) = 1$. Taking derivatives with respect to each coordinate $\alpha(p)$ yields an equation of the form $\log \alpha(p) = \beta(\mathrm{Prio}_t(p) - \lambda) - 1$. Exponentiating gives an unnormalized exponential distribution, and the normalization constant is the partition function $\sum_q \exp(\beta\,\mathrm{Prio}_t(q))$. In other words, the multiplier λ is nothing but (a shifted version of) the log-partition function that ensures the simplex constraint is satisfied, and it couples all coordinates of α through a single global normalization. The same algebra also shows the invariance under shifting priorities by a constant: replacing $\mathrm{Prio}_t(p)$ by $\mathrm{Prio}_t(p) + c$ multiplies all unnormalized weights by $e^{\beta c}$, which cancels after normalization, so only relative priority differences matter. □

Remark 768. *Geometrically, one may picture the simplex* $\Delta(\mathcal{P})$ *as a polytope and the entropy term as a barrier that discourages sliding onto its faces. As* $\beta \to \infty$*, the barrier weakens and the optimum approaches a hard argmax (full focus on the best pattern). As* $\beta \to 0$*, the barrier dominates and the optimum approaches uniform attention. Thus* β *is a temperature-like knob interpolating between exploration and exploitation, but now phrased as an internal allocation of genenergy. A complementary interpretation is that* β *sets the* sensitivity *of allocation to priority gaps: for moderate* β*, small differences in* Prio_t *produce gently varying weights, while for large* β *the distribution becomes sharply peaked and effectively implements winner-take-most selection. This matters for cognitive synergy because it controls how many distinct pattern types can remain active enough to interact; overly large* β *risks premature single-pattern lock-in, whereas overly small* β *disperses genenergy so widely that no pattern is sufficiently amplified to contribute strongly.*

Remark 769. *Proposition 23 does* not *claim Hyperseed requires softmax attention. It only shows one clean way to connect the earlier notion of predictive attraction to a concrete bounded-resource allocation rule. More broadly, the proposition functions as an existence proof that "attraction* $\to$ *gated participation" can be implemented by a principled optimization criterion, rather than by an ad hoc mapping. Alternative mechanisms (e.g., sparsemax/entmax variants, thresholded mixtures, or constraint-based allocations) could be substituted if they better match the desired phenomenology, but the softmax case provides a simple baseline with a clear control parameter and well-understood limiting behavior.*

15.4 Varieties of knowledge as typed pattern structures

Hyperseed treats "knowledge" as a family resemblance notion: multiple distinct types of stored content play different roles in prediction and control. The ontology offers a pragmatic classification for human-like minds; we formalize it as a family of typed stores. In this framing, a "store" is not merely a container of propositions, but a structured substrate whose items behave like *typed pattern constraints*: each type comes with characteristic generalization behavior, characteristic forms of evidence, and characteristic ways it can be brought to bear on ongoing perception/action loops.

Definition 198 (Knowledge type)**.** *A* knowledge type T *for a system* S *consists of:*

(a) a carrier set (or space) K_T of knowledge items;

(b) a semantics map $\mathrm{Sem}_T : K_T \to \mathcal{S}$ that interprets items as constraints on patterns, processes, or goals;

(c) an update operator (or family of operators) Upd_T specifying how items are learned, revised, or forgotten;

(d) an interface specifying which other types it can exchange information with.

Remark 770. *One can make the "update operator" more explicit as a rule family of the form*

$$\mathrm{Upd}_T : K_T \times \mathcal{E}_T \to K_T,$$

where $\mathcal{E}_T$ denotes the space of admissible evidential inputs for type T (e.g. sensory episodes, counterexamples, rewards, demonstrations, proofs, or internal audit signals). What matters for the present section is that different knowledge types have different $\mathcal{E}_T$ and different invariants under update (for example, exemplar memories may be capacity-limited while declarative stores may be consistency-limited only by attention and time).

Remark 771. *The point of calling these "types" is not to reify a metaphysical taxonomy, but to mark distinct* update dynamics *and distinct* failure modes*. A knowledge item is not only something that can be true or false; it is something that can be learned, revised, forgotten, communicated, and used for control. These verbs differ across types, and this difference is precisely what makes cross-type synergy possible [19].*

Remark 772. *The "interface" component (d) is where cognitive synergy becomes operational: it specifies what queries a store can answer, what messages it can accept, and what it can emit to other stores. Concretely, an interface may include (i) a set of accessors (e.g. retrieve-by-key, retrieve-by-similarity, retrieve-by-goal), (ii) a set of translators into other representational formats, and (iii) gating conditions (e.g. only export high-confidence items, or only import items when attention flags a relevant context boundary). In practice, interfaces are also where resource constraints show up: two knowledge types may be semantically compatible but interface-incompatible because translation is too expensive under current genenergy/attention budgets.*

Remark 773. *One can view Sem_T as a disciplined way of saying "what does this store constrain?" For declarative knowledge it constrains beliefs about events; for procedural knowledge it constrains the space of policies; for attentional knowledge it constrains how the system searches its own computations. In each case the semantics map ties a symbolic or stored item back to patterns and processes (Hyperseed-Concept 157; Hyperseed-Concept* **??***). A useful way to read Sem_T is as a* bridge *from a compact stored token to a (possibly large) set of permitted pattern instantiations: the token is small, but its denotation is a constraint over the system's pattern space.*

15.4.1 Declarative knowledge

Definition 199 (Declarative knowledge)**.** *Declarative knowledge is a store of* pattern beliefs*, often (but not necessarily) linguistically expressible. Formally, let $\mathcal{L}$ be a language for talking about events/patterns. A declarative state is a valuation*

$$K_{\mathrm{dec}} : \mathcal{L} \to \mathbb{V} = [0, 1]^2,$$

assigning each formula a p-bit *degree of positive/negative evidence (Section 3.2).*

Remark 774. *Although $\mathcal{L}$ can be taken as a linguistic/propositional language, nothing in the definition requires natural language; $\mathcal{L}$ may equally be a structured pattern description language (e.g. relational templates over perceived entities, temporal claims, or causal sketches). The essential ingredient is that formulas in $\mathcal{L}$ are the kind of objects that can be* queried *by other subsystems (e.g. planning, explanation, counterfactual reasoning), and that their evidence values can be updated by a mix of perception, testimony, and internal consistency checks.*

Remark 775. *Intuitively, $K_{\mathrm{dec}}(\varphi)$ is the system's present evidential stance toward the claim φ: not merely "how likely," but "how supported" and "how refuted," separately. This is a natural fit for observer-relative and potentially inconsistent boundaries, where one can have both substantial evidence for and against the same proposition without collapse (Hyperseed-Concept 65; see also paraconsistent motivations in [23, 24]).*

Remark 776. *Update for declarative knowledge typically consists of accumulating or discounting evidence while preserving the separation between positive and negative support. For example, a single observation may increase the first coordinate without decreasing the second, while a debunking argument may increase the second coordinate without forcing the first to vanish. This is relevant to attention because conflict (high support and high refutation) is a natural trigger for targeted information gathering: attention can treat such formulas as "open loops" whose resolution is valuable but not always urgent.*

Remark 777. *A simple example is a vague predicate like "the room is quiet." A system might store $K_{\mathrm{dec}}(quiet) = (0.7, 0.4)$, reflecting positive evidence from a low sound meter and negative evidence from intermittent noise. The usefulness is that later inference can proceed without forcing premature consistency; attention can then decide whether to spend genenergy resolving the conflict or to act under it.*

15.4.2 Procedural knowledge

Definition 200 (Procedural knowledge)**.** *Procedural knowledge consists of "if in context C, doing procedure π tends to achieve goal G." Let $\mathcal{C}$ be a set of contexts and $\mathcal{G}$ a set of goals. Let Π be a set of procedures (policies, programs, controllers). A procedural knowledge item is a triple (C, π, G) together with an evidence value $\mathrm{ProcEvd}(C, \pi, G) \in \mathbb{V}$.*

Remark 778. *Here "context" C should be read broadly: it may denote an external situation (terrain type, social setting), an internal state (fatigue, low battery), or a conjunction of both, and it may be crisp or fuzzy depending on the system's perceptual and conceptual granularity. In particular, procedural knowledge can be indexed by* attentionally constructed *contexts: the system may only carve out a context boundary (and thus create a stable key C) once attention has repeatedly found that a certain cluster of features predicts procedure success/failure.*

Remark 779. *Procedural knowledge is "knowing how" rather than "knowing that." The evidence value $\mathrm{ProcEvd}(C, \pi, G)$ plays the same paraconsistent role as in declarative knowledge, but now attached to a claim about the efficacy of a procedure. This lets a system represent, for instance, that a policy often works but has known failure modes, without reducing everything to a single success probability (Hyperseed-Concept **??**; Hyperseed-Concept **??**).*

Remark 780. *Procedural update is typically driven by rollouts, trial-and-error, imitation, and counterfactual evaluation: a single attempted execution of π under an estimated C contributes evidence to $\mathrm{ProcEvd}(C, \pi, G)$, while diagnosis of why an attempt failed can refine the context key* *(the system may split C into subcontexts where the procedure behaves differently). This is one of the primary points of interaction with attention: attention determines which trials to run, which failures to analyze deeply, and which context splits are worth the representational complexity.*

Remark 781. *As an example, C might be "slippery ground," π might be "walk slowly," and G might be "reach destination without falling." The system may have positive evidence from past successes and negative evidence from rare but salient failures. Such items feed directly into control selection (Section 14) and can be prioritized by attention when a context boundary becomes active.*

15.4.3 Sensory knowledge

Definition 201 (Sensory knowledge)**.** *Sensory knowledge is memory enabling discrimination: after sensing an item s, the system can later distinguish a copy/recurrence of s from similar non-copies. Formally, let $\mathcal{S}$ be a stimulus space and let d be a similarity (pseudo)metric. A sensory memory state is a finite set of stored exemplars $\{s_j\}$ together with an embedding $\phi : \mathcal{S} \to Y$ such that discrimination is performed by thresholding distances $d_Y(\phi(s), \phi(s_j))$.*

Remark 782. *This definition abstracts over many implementations (template matching, nearest-neighbor retrieval, metric learning, associative memories) by highlighting the functional role: a* discrimination operator *induced by storing exemplars and comparing them in an internal space. The finiteness of $\{s_j\}$ is not merely technical: it encodes the idea that sensory memory is usually capacity-limited, so forgetting (or prototype compression) is a normal and often desirable update dynamic.*

Remark 783. *This definition captures the bare bones of recognition by similarity: store a few exemplars, map stimuli into an internal space Y, and then declare "match" when the embedded distance is small. The pseudo-metric d allows the usual flexibility: different stimuli may be deemed zero-distance by the system because it cannot or does not care to distinguish them at the current resolution.*

Remark 784. *The embedding ϕ can be fixed, learned, or attention-modulated. In particular, attentional control can act by temporarily changing the effective metric (or the threshold) so that, for the current task, some distinctions are sharpened while others are collapsed. This gives one route to cognitive synergy between sensory and declarative/procedural stores: declarative hypotheses can cue which sensory dimensions should matter, and procedural demands can cue which discriminations are worth allocating representational capacity to.*

Remark 785. *A simple example is face recognition: $\mathcal{S}$ is the space of face images, Y is an embedding space learned by a neural network, and the exemplars $\{s_j\}$ are stored reference faces. The utility of formalizing sensory knowledge this way is that it makes explicit where genenergy is spent: improving ϕ, storing more exemplars, or changing thresholds are all internal update actions (Section 15.3).*

Remark 786. *The same schematic separation also clarifies what can be held fixed while something else is adapted. For instance, if ϕ is treated as stable (a "frozen" encoder), then sensory improvement must occur via exemplar management (adding, pruning, reweighting, or clustering $\{s_j\}$) and via decision rules (thresholds, rejection options, abstention policies). Conversely, if exemplar memory is constrained, genenergy can be redirected toward learning a more invariant ϕ so that fewer exemplars suffice. Making these tradeoffs explicit is useful when diagnosing failure: poor recognition might come from an inadequate embedding, from stale exemplars, or from a miscalibrated acceptance criterion, and these correspond to distinct internal actions and costs.*

15.4.4 Attentional knowledge

Hyperseed highlights a specific meta-knowledge type: learned regularities of attention shift.

Definition 202 (Attentional knowledge)**.** *Let $\mathcal{X}$ be a set of "attention targets" (pattern classes, module clusters, or questions). Attentional knowledge consists of regularities of the form: "when attention is on X, it often shifts to Y, and this shift is associated with goal success." Formally, an attentional knowledge state may be represented as a family of kernels*

$$K_{\mathrm{att}}(Y \mid X, G) \in \mathbb{V}, \qquad X, Y \in \mathcal{X},\ G \in \mathcal{G},$$

encoding (paraconsistent) evidence that shifting focus from X to Y tends to support G.

Remark 787. *This is knowledge about the system's own search procedure: it stores which transitions of attentional focus have historically been fruitful. The notation $K_{\mathrm{att}}(Y \mid X, G)$ is deliberately reminiscent of a conditional probability kernel, but valued in $\mathbb{V} = [0,1]^2$ to permit mixed evidence. The targets $\mathcal{X}$ can be pattern sets, modules, or even explicit questions (Hyperseed-Concept* **??***).*

Remark 788. *Interpreting K_{att} as a kernel emphasizes that it can be many-to-many and contextually gated by goals: from the same X there may be several productive next foci Y, and the ranking can depend strongly on G. The paraconsistent valuation $\mathbb{V} = [0,1]^2$ can be read as separately tracking evidence-for and evidence-against a shift, so that the system may represent both (i) that a transition is often helpful in some regimes, and (ii) that it is also often harmful or distracting in others, without collapsing this tension into a single scalar. This matters for attention control, since overly aggressive "always shift to Y" habits are a common pathology in bounded systems.*

Remark 789. *One can also regard K_{att} as an internal, learned "operator selection" map: X names a current representational neighborhood (e.g., a memory store, a perception stream, a planning module), and Y names which neighborhood to query next. In this reading, attentional targets are not only semantic objects but also* interfaces *to computational resources, so the kernel summarizes regularities about which interface-switches pay off under which goals. This makes attentional knowledge a natural site for genenergy expenditure: updating K_{att} changes how future computation is allocated even when the underlying declarative beliefs remain unchanged.*

Remark 790. *A simple example: when debugging code (target X), shifting attention to "construct a minimal reproducible example" (target Y) often supports the goal G of fixing the bug. The system may not be able to justify why this works declaratively, yet it can learn the attentional transition as a useful habit. This is one of the clearest loci where cognitive synergy manifests in practice: the system uses one knowledge type (attentional) to orchestrate updates in others.*

Remark 791. *In that debugging example, the shift $X \to Y$ is valuable partly because it* changes the data distribution *seen by other subsystems: a minimal reproducible example compresses the search space, reduces confounds, and yields cleaner counterfactual tests. Thus attentional knowledge can be viewed as knowledge about which transformations of the agent's own input streams make downstream learning or inference cheaper. This perspective also clarifies why attentional habits can remain useful even when they are not explicitly articulated: the relevant regularity may be procedural and distributed across modules rather than available as a compact declarative rule.*

15.4.5 Intentional knowledge

Definition 203 (Intentional knowledge)**.** *Intentional knowledge captures goal specialization: "when pursuing goal G in context C, it is appropriate to switch to a specialized goal G_1." Formally, represent intentional knowledge as a relation*

$$K_{\mathrm{int}}(G_1 \mid G, C) \in \mathbb{V}, \qquad G, G_1 \in \mathcal{G},\ C \in \mathcal{C}.$$

Remark 792. *This is knowledge about the* internal goal topology *of the agent: how abstract goals refine into more concrete subgoals when contexts shift. It is not merely planning, but a learned mapping of which refinements tend to be appropriate. In Hyperseed terms, it is a pattern of goal-development (Hyperseed-Concept 95; Hyperseed-Concept* **??***).*

Remark 793. *The emphasis on topology is meant literally: the agent's goal system can be treated as a graph (or hypergraph) where edges correspond to refinement, decomposition, or constraint addition. Then $K_{\text{int}}(G_1 \mid G, C)$ plays a role analogous to a context-sensitive adjacency relation, encoding which outgoing refinements are supported or discouraged by experience. Because it is $\mathbb{V}$-valued, the representation can capture that a refinement is plausible yet risky, or that it is appropriate only when further conditions (not yet represented in C) hold. This allows the agent to maintain multiple candidate specializations without premature commitment.*

Remark 794. *An example: for a general goal G = "be healthy," and context C = "winter," a specialized goal might be G_1 = "get vitamin D." The system may have mixed evidence about the appropriateness of this specialization depending on other latent factors, hence the* p-bit*-valued relation. Formalizing K_{int} is useful because it provides a precise target for attentional update actions: one can spend genenergy revising not only beliefs and policies but also the mapping from goals to subgoals.*

Remark 795. *The "appropriate to switch" phrasing is intentionally compatible with several control regimes. In a strict regime, K_{int} may be used to* replace *G by G_1 (commitment); in a softer regime, it may* spawn *G_1 as a concurrent subgoal (branching); and in a reflective regime, it may be treated as a prompt for information gathering (e.g., attend to whether latent conditions hold before specializing). These distinctions matter operationally because they correspond to different resource commitments and different ways of recovering from a poor specialization.*

Remark 796 (Why multiple knowledge types)**.** *Different types have different update dynamics and different failure modes. Procedural knowledge can be robust without being explainable; declarative knowledge can be communicable without being actionable; attentional knowledge can guide search even when the system cannot articulate why the guidance works. This plurality is one of Hyperseed's motivations for cognitive synergy.*

Remark 797. *The failure-mode differences are not merely philosophical; they induce different diagnostics and different interventions. When procedural knowledge fails, the symptom may be brittle performance under distribution shift; when declarative knowledge fails, the symptom may be contradiction or confabulation under questioning; when attentional knowledge fails, the symptom may be wasted compute on unproductive loci even if the necessary facts are present somewhere in memory. Treating these as distinct knowledge types supports targeted repair: e.g., revise a kernel like K_{att} to change where the system looks, rather than trying to directly patch the content it will eventually retrieve or infer.*

Remark 798. *In the Hyperseed framing, the plurality is not a defect but a structural response to finitude: because a bounded system cannot maintain one perfect, unified representational format, it maintains several partially overlapping ones. Synergy is then the disciplined practice of translating between them, so that the weaknesses of one type are compensated by the strengths of another (Hyperseed-Concept* **??***; [19]).*

Remark 799. *On this view, cognitive synergy is implemented by concrete cross-type couplings: attentional knowledge decides which declarative store to consult; declarative knowledge can propose new attention targets (e.g., a hypothesis suggests a test); procedural knowledge can supply fast* *heuristics that seed deliberate reasoning; and intentional knowledge can reshape the very criteria by which attention shifts are judged successful. The point of explicitly typing these structures (kernels over $\mathcal{X}$, relations over $\mathcal{G}\times\mathcal{C}$, etc.) is to make such couplings engineerable: each type exposes specific "handles" for internal update actions, and genenergy can be budgeted among them rather than being spent implicitly and opaquely.*

15.5 Cognitive synergy as cross-type weakness improvement

Hyperseed's term *cognitive synergy* names a ubiquitous architectural fact: complex cognition typically requires frequent exchange of intermediate products between distinct knowledge processes (not merely "final answers"). We now give a weakness-based formalization. In particular, the guiding hypothesis is that many of the practical benefits of "integrated cognition" can be expressed as *improved explanation quality at lower contrivance* when multiple knowledge types are allowed to interact, i.e. when one representational mode can supply constraints, priors, candidate structures, or abstractions to another.

Remark 800. *The motivating intuition is that "the whole is more than the sum of its parts" becomes operational when translations between representational modes yield new compressions. This is the same spirit in which pattern discovery is a compression phenomenon (Section 9; [5]), but now lifted to an architectural level: the compression is enabled by cross-type interaction rather than by a single homogeneous inference engine (Hyperseed-Concept 73). One may read "translation" broadly: it can be an explicit encoder/decoder, a shared latent space, a symbolic labeling of subsymbolic states, a compilation of rules into a policy prior, or any other mechanism by which structure found in one knowledge store reduces the search burden in another.*

15.5.1 Usefulness of a learning algorithm for a knowledge type

Definition 204 (Learning algorithms indexed by knowledge type)**.** *For each knowledge type T, let $\mathsf{Alg}(T)$ denote a family of learning/update algorithms appropriate to T (e.g. logical inference for declarative, reinforcement learning for procedural, metric learning for sensory). An algorithm $A \in \mathsf{Alg}(T)$ induces an update map $\mathrm{Upd}_{T,A} : K_T \to K_T$.*

Remark 801. *This definition is a modest piece of type discipline: it says that not every learning method is appropriate for every store. One does not typically update a sensory embedding ϕ by syllogistic inference, nor update a logical theory by gradient descent—though hybrid methods exist. By making $\mathsf{Alg}(T)$ explicit, we can later speak precisely about cross-type communication: outputs of one type become inputs to algorithms of another. A convenient side effect is that it lets us talk about* where *an intervention occurs: an update that changes K_{dec} but leaves K_{proc} fixed is a different kind of cognitive act than one that changes both, even if both ultimately serve the same downstream goal.*

Remark 802. *A simple example is: $T = \mathrm{proc}$, $\mathsf{Alg}(T)$ includes Q-learning, and $\mathrm{Upd}_{T,A}$ takes a table of action values and updates it after an episode. For $T = \mathrm{dec}$, $\mathsf{Alg}(T)$ might include a paraconsistent inference procedure (Section 3.2). The usefulness of writing $\mathrm{Upd}_{T,A}$ is that it lets us treat learning steps as internal update actions in the sense of Section 15.3. It also makes iteration explicit: repeated application $\mathrm{Upd}^{(n)}_{T,A} := \underbrace{\mathrm{Upd}_{T,A} \circ \cdots \circ \mathrm{Upd}_{T,A}}_{n\ times}$ is the formal proxy for "training for n steps" or "performing n rounds of inference," and so properties like convergence, brittleness, or sensitivity to initialization can be attached to the map rather than left implicit.*

Definition 205 (Usefulness)**.** *Fix a goal set $\mathcal{G}$ and a success predicate* $\mathrm{Succ}(G)$*. An algorithm* $A \in \mathsf{Alg}(T)$ *is* useful for knowledge type T *if, across the contexts of interest, repeatedly applying* $\mathrm{Upd}_{T,A}$ *tends (in expectation) to increase the probability of achieving some goals in $\mathcal{G}$. Equivalently, "invoking A to learn T-knowledge" forms a valuable pattern in the system's activity (Section 9).*

Remark 803. *The definition says: a learning algorithm is not judged by elegance but by teleology—by whether it improves goal achievement in the contexts that matter. This is a deliberately pragmatic stance in the spirit of Hyperseed's observer-relative epistemology (Hyperseed-Concept* **??***; Hyperseed-Concept 160). Here "contexts of interest" can be understood as a (possibly implicit) distribution over task situations, sensory histories, internal states, and resource constraints; the expectation is taken with respect to that distribution together with any stochasticity in the algorithm or environment. This framing also makes room for bounded rationality: an algorithm may be "useful" because it improves* timely *success under limited compute, even if an idealized unbounded method would eventually do better.*

Remark 804. *As an example, a memory consolidation method might be "useful" if it increases the probability of later successful recognition or planning, even if it occasionally strengthens some false declarative beliefs. The paraconsistent setting makes room for such tradeoffs: usefulness is an expected-value criterion rather than a demand for global consistency. In the same vein, a heuristic that increases success on a target regime while slightly degrading performance on rare corner cases can still qualify as useful—and such regime-dependence will later be important when we discuss synergy, since cross-type information flow often acts as a mechanism for shifting the system toward the regimes where its individual methods are strongest.*

15.5.2 Explanations, weakness, and contrivance cost

We measure the "simplicity" or "generality" of an explanatory construct by a scalar weakness. This is a specialization of the quantale weakness ideas from Section 3.7. Intuitively, "weak" explanations are permissive (they rule out fewer possibilities), while "strong" ones are more committal (they encode many fine distinctions); contrivance cost is then the currency in which committal structure is paid for.

Definition 206 (Explanations and weakness)**.** *Fix a behavior (or dataset) b. Let $\mathcal{E}(b)$ be a set of candidate* explanations *of b (models, hypotheses, plans, proofs, causal graphs, etc.). Assume each explanation $E \in \mathcal{E}(b)$ comes with:*

(a) an adequacy score $\mathrm{Fit}(E) \in [0,1]$ *(how well it predicts/explains/controls b);*

(b) a weakness $\mathrm{Weak}(E) \in (0,1]$ *(how few distinctions it makes; larger is weaker).*

Define the contrivance cost *(description-length proxy)*

$$\mathrm{Con}(E) := -\log \mathrm{Weak}(E) \in [0,\infty).$$

Remark 805. *Weakness is a formal proxy for a familiar epistemic virtue: an explanation that makes fewer distinctions is, other things equal, more general and less brittle. In the Hyperseed development, weakness is not mere vagueness; it is a structured notion built to live in quantale settings where composition and partial order matter (Hyperseed-Concept 202; Hyperseed-Concept* **??***; [3, 2]). At a purely scalar level, one can read* $\mathrm{Weak}(E)$ *as measuring "how large a set of worlds" (or latent configurations) remain compatible with E; then larger* $\mathrm{Weak}(E)$ *corresponds to a coarser partition of possibilities, hence fewer encoded distinctions.*

Remark 806. *A simple example: suppose b is a dataset generated by a linear relation plus noise. A linear model may have high* $\mathrm{Weak}(E)$ *(few degrees of freedom, fewer distinctions) and decent* $\mathrm{Fit}(E)$*, while a high-degree polynomial can achieve higher fit but lower weakness (more contrivance). The cost* $\mathrm{Con}(E) = -\log \mathrm{Weak}(E)$ *then behaves like a description length in the spirit of algorithmic information theory [16]. One may also view this as a minimal-description-length style tradeoff: among explanations with comparable adequacy, those with larger weakness (smaller* Con*) are preferred because they are less likely to be overfit to incidental structure in b.*

Remark 807. *The usefulness of* Con *is that it makes the Russellian demand for clarity operational: to explain is to compress, and to compress is to pay for distinctions. The logarithm converts multiplicative weakness comparisons into additive costs, which is exactly the currency in which tradeoffs and budgets are most naturally expressed. Because* $\mathrm{Weak}(E) \in (0, 1]$*, the sign convention ensures* $\mathrm{Con}(E) \geq 0$ *and assigns infinite penalty only to the limiting case of* $\mathrm{Weak}(E) \to 0$*, i.e. to explanations so highly contrived that they are maximally distinction-heavy. The choice of logarithm base merely selects units (e.g. natural nats versus bits with* $\log_2$*), and the additive form is what matters for comparing composite explanations built from multiple sub-structures.*

Remark 808. *It is often helpful to interpret the pair* $(\mathrm{Fit}(E), \mathrm{Con}(E))$ *as defining a Pareto-style frontier: improving fit typically requires paying additional contrivance, while reducing contrivance may reduce fit. In that light, "weakness improvement" refers to moving to an explanation E' with comparable (or higher) adequacy but lower cost, e.g.* $\mathrm{Fit}(E') \geq \mathrm{Fit}(E)$ *and* $\mathrm{Con}(E') < \mathrm{Con}(E)$*. This is the axis along which cross-type interaction will be cast as synergistic: a translation from one representational mode to another can supply constraints or latent variables that let the second mode reach the same adequacy with fewer ad hoc distinctions.*

Remark 809. *The use of* $-\log$ *is optional but convenient: multiplicative weakness becomes additive cost. Any monotone transform would serve similarly.*

Definition 207 (Best achievable contrivance under a fit threshold)**.** *Fix $\tau \in (0, 1]$. For a collection of knowledge types $\mathcal{T}$ (e.g. a subset of the full architecture), let $\mathcal{E}_{\mathcal{T}}(b)$ be the explanations constructible using only those types. Define*

$$\mathrm{Con}^*(\mathcal{T}; \tau) := \inf\{\mathrm{Con}(E) : E \in \mathcal{E}_{\mathcal{T}}(b),\ \mathrm{Fit}(E) \geq \tau\}.$$

Equivalently, $\mathrm{Con}^*(\mathcal{T}; \tau)$ *is the minimal contrivance needed to reach fit τ using the knowledge in $\mathcal{T}$.*

Remark 810. *The quantity* $\mathrm{Con}^*(\mathcal{T}; \tau)$ *is a performance frontier: it asks for the least contrived (most weak/general) explanation that still meets an adequacy demand τ. The infimum allows that the best tradeoff might be approached by a sequence of explanations even if not attained exactly, which is important when the space of explanations is large or continuous.*

Remark 811. *In practice, one may think of τ as a required success rate, prediction accuracy, or control competence. Then* $\mathrm{Con}^*(\mathcal{T}; \tau)$ *is the minimal "model complexity" that the architecture fragment $\mathcal{T}$ must deploy to achieve that competence. This creates a clean interface to later "intelligence under budget" notions (Section 21).*

15.5.3 Synergy as strict subadditivity of contrivance

Definition 208 (Cognitive synergy between knowledge sets)**.** *Let $\mathcal{T}_1, \mathcal{T}_2$ be two disjoint sets of knowledge types and fix $\tau \in (0, 1]$. We say there is* cognitive synergy at level τ *between $\mathcal{T}_1$ and $\mathcal{T}_2$ if*

$$\mathrm{Con}^*(\mathcal{T}_1 \cup \mathcal{T}_2; \tau) \ < \ \mathrm{Con}^*(\mathcal{T}_1; \tau) + \mathrm{Con}^*(\mathcal{T}_2; \tau).$$

The synergy gain *is the positive part*

$$\Sigma(\mathcal{T}_1, \mathcal{T}_2; \tau) := \Big(\mathrm{Con}^*(\mathcal{T}_1; \tau) + \mathrm{Con}^*(\mathcal{T}_2; \tau) - \mathrm{Con}^*(\mathcal{T}_1 \cup \mathcal{T}_2; \tau)\Big)_+.$$

Remark 812. *In plain terms: synergy means that letting the two knowledge sets interact yields an explanation meeting the same adequacy threshold with strictly less contrivance than one could achieve by using each set in isolation and then "adding" the results. The positive-part operator $(\cdot)_+$ ensures Σ is always nonnegative, so it behaves like a measurable gain rather than a signed difference.*

Remark 813. *A simple example is a system where declarative knowledge supplies a compact causal rule that lets procedural learning drastically reduce exploration. Separately, each subsystem must encode many exceptions; together, one subsystem supplies a compression that the other can exploit, lowering the overall contrivance needed for fit. This is precisely the kind of architectural phenomenon discussed under the name "cognitive synergy" in [19] (Hyperseed-Concept 73).*

Remark 814. *The definition captures Hyperseed's informal criterion: exchanging intermediate representations is useful when it enables a* less contrived *(weaker, more general) explanation to achieve the same level of adequacy.*

15.5.4 A sufficient condition: monoidal compositionality of weakness

The simplest theorem states that if weakness is compositional across independent subsystems, then combining subsystems cannot be worse (in contrivance cost) than treating them separately.

Definition 209 (Multiplicative weakness model)**.** *Assume that when two explanations E_1, E_2 are combined (e.g. run in parallel, or glued along an interface) to form $E_1 \otimes E_2$, their weakness satisfies*

$$\mathrm{Weak}(E_1 \otimes E_2) \geq \mathrm{Weak}(E_1)\,\mathrm{Weak}(E_2).$$

Remark 815. *This condition says that composing explanations does not force additional distinctions beyond those already made by the parts. Since weakness is larger when fewer distinctions are made, the inequality* $\mathrm{Weak}(E_1 \otimes E_2) \geq \mathrm{Weak}(E_1)\mathrm{Weak}(E_2)$ *asserts that the composed system is at least as "weak" as the multiplicative baseline. This is a natural monoidal-style assumption consistent with the quantale flavor of weakness developed earlier [3] (Hyperseed-Concept* **??***).*

Remark 816. *A concrete example is when E_1 and E_2 explain disjoint aspects of the data b and are glued without sharing parameters. Then the combined description length is roughly additive, corresponding to multiplicative weakness. The reason to formalize this is not because independence always holds, but because it gives a clean baseline against which emergent (strict) synergy can later be measured.*

Proposition 24 (Subadditivity of contrivance under multiplicative weakness)**.** *If* $\mathrm{Weak}(E_1 \otimes E_2) \geq \mathrm{Weak}(E_1)\mathrm{Weak}(E_2)$ *for all composable E_1, E_2, then for all disjoint knowledge sets $\mathcal{T}_1, \mathcal{T}_2$ and all τ,*

$$\mathrm{Con}^*(\mathcal{T}_1 \cup \mathcal{T}_2; \tau) \;\leq\; \mathrm{Con}^*(\mathcal{T}_1; \tau) + \mathrm{Con}^*(\mathcal{T}_2; \tau).$$

In particular, the synergy gain $\Sigma(\mathcal{T}_1, \mathcal{T}_2; \tau)$ is well-defined and nonnegative.

Remark 817. *The proposition says that, under the multiplicative weakness model, there is never a* penalty *(in minimal contrivance) for allowing two disjoint knowledge sets to be used together. Even if they do not yield strict synergy, they can at least be composed without worsening the best achievable tradeoff.*

Remark 818. *This result is important mainly as a sanity check: it ensures that the synergy gain defined earlier behaves as a nonnegative quantity under a natural compositionality assumption. It thereby connects the architectural idea of cross-type interaction to the algebraic idea that weakness behaves well under composition (a theme running through the weakness/pattern layers of the document). In particular, the inequality can be read as saying that "having access to more explanation types" cannot make the best achievable contrivance frontier worse, provided that the architecture admits a way of juxtaposing explanations without destroying their adequacy. This is the minimal monotonicity one expects from any notion of joint modeling capacity: if it were violated, then the definitions of* Weak, Con, *and the admissible explanation classes would be misaligned with the intended semantics of "adding representational degrees of freedom."*

Remark 819. *The link to later sections is that attention (as a gating mechanism) determines whether compositions like $E_1 \otimes E_2$ are actually realized in time. The inequality here is about representational possibility; Section 15.6 is about resource-mediated actuality. Said differently, Proposition 24 is "offline": it assumes the agent is permitted to form the composite explanation and then measures what cost is achievable in principle. Attention introduces an "online" constraint: even if E_1 and E_2 exist and can be composed, the system may fail to instantiate $E_1 \otimes E_2$ because the gating policy does not co-activate the relevant pathways, or because partial activation yields an effectively degraded fit that falls below τ.*

Proof. Let $\varepsilon > 0$. Choose explanations $E_1 \in \mathcal{E}_{\mathcal{T}_1}(b)$ and $E_2 \in \mathcal{E}_{\mathcal{T}_2}(b)$ with $\mathrm{Fit}(E_i) \geq \tau$ and $\mathrm{Con}(E_i) \leq \mathrm{Con}^*(\mathcal{T}_i;\tau) + \varepsilon$. (Here we use that $\mathrm{Con}^*(\mathcal{T}_i;\tau)$ is an infimum: for any $\varepsilon > 0$ there exists an admissible explanation whose contrivance lies within ε of the optimum.) Combine them to form $E := E_1 \otimes E_2$. Assuming the combination preserves fit at level τ (e.g. the two parts address disjoint aspects of b), we have $E \in \mathcal{E}_{\mathcal{T}_1\cup\mathcal{T}_2}(b)$. The "disjoint aspects" condition is one sufficient way to guarantee that the joint explanation does not introduce interference; more generally, any architectural condition ensuring that the composite retains $\mathrm{Fit} \geq \tau$ is enough for the argument. Then

$$\begin{aligned} \mathrm{Con}(E) &= -\log \mathrm{Weak}(E) \leq -\log(\mathrm{Weak}(E_1)\mathrm{Weak}(E_2)) \\ &= \mathrm{Con}(E_1) + \mathrm{Con}(E_2) \leq \mathrm{Con}^*(\mathcal{T}_1;\tau) + \mathrm{Con}^*(\mathcal{T}_2;\tau) + 2\varepsilon. \end{aligned}$$

The first inequality is exactly where the multiplicative weakness hypothesis enters; it is also where one implicitly uses that the relevant weakness quantities lie in $(0,1]$ so that $-\log$ is well-defined and order-reversing in the expected way. Taking the infimum over admissible E and then letting $\varepsilon \to 0$ yields the inequality. Equivalently, the construction shows that for each ε one can exhibit a feasible joint explanation whose cost is within 2ε of the sum of the separate optima, which forces the joint optimum not to exceed that sum in the limit. $\square$

Remark 820. *The proof is a standard ε-approximation argument: one takes nearly optimal explanations from each side, composes them, and then uses the multiplicative weakness hypothesis to show the cost of the composite is no more than the sum of the costs. The passage to the infimum and the limit $\varepsilon \to 0$ then yields the stated inequality for the optimal frontiers. Conceptually, this is the same pattern as "subadditivity" arguments in coding and complexity: once a candidate composite description is written down, optimality can only improve upon it, never worsen relative to that explicit construction.*

Proof sketch. Pick E_1 and E_2 within ε of their respective optima. Form the composite $E = E_1 \otimes E_2$. Multiplicative weakness turns into additive cost because of the $-\log$. This gives an upper bound on $\mathrm{Con}^*(\mathcal{T}_1 \cup \mathcal{T}_2;\tau)$, and letting $\varepsilon \to 0$ removes slack. One can interpret the "slack" as coming solely from the choice of near-optimal witnesses rather than exact minimizers; no special convexity or continuity assumptions are required beyond the basic ability to approximate an infimum. □

Remark 821. *The key step is exactly why the logarithm was chosen: it converts the structural hypothesis about weakness under composition into the familiar subadditivity inequality for costs. Visually, if one thinks of weakness as a kind of "volume" of indistinction, then composing independent explanations multiplies volumes; contrivance cost is then the negative log-volume, hence additive. This is also the sense in which "independence" (or sufficiently weak interaction) is the baseline case: when the two explanations do not share compressive structure, one expects multiplication of volumes and hence mere additivity of costs, leaving no room for strict gains.*

15.5.5 When does synergy become *strict*?

Proposition 24 only guarantees "no penalty" for combining knowledge types. Hyperseed's intended phenomenon is stronger: *strict* improvement, driven by cross-type emergent patterns (Section 9). The strict case corresponds to the presence of shared structure that is representable once in the joint space but would have to be redundantly encoded (or simulated) in each type-specific space if one enforced modularity.

Definition 210 (Cross-type emergent compression)**.** *Let $\mathcal{T}_1, \mathcal{T}_2$ be disjoint knowledge sets. We say there is a* cross-type emergent compression pattern *for b if there exists an explanation $E \in \mathcal{E}_{\mathcal{T}_1 \cup \mathcal{T}_2}(b)$ with $\mathrm{Fit}(E) \geq \tau$ such that for every decomposition $E \approx E_1 \otimes E_2$ with $E_i \in \mathcal{E}_{\mathcal{T}_i}(b)$ and $\mathrm{Fit}(E_i) \geq \tau$, one has*

$$\mathrm{Con}(E) < \mathrm{Con}(E_1) + \mathrm{Con}(E_2).$$

In this formulation, the strict inequality is uniform over all admissible factorizations: it is not enough that some *particular split is inefficient; rather,* every *attempt to realize the same explanatory content via separate type-restricted components incurs additional contrivance.*

Remark 822. *This definition formalizes the intuitive notion of emergence as* irreducible compression*: the joint explanation achieves a description-length advantage that cannot be recovered by any attempt to factor it into separate explanations for the two subsystems. The approximate equality $E \approx E_1 \otimes E_2$ is intentionally informal: it stands for any decomposition notion appropriate to the architecture (e.g. separable parameterizations, modular pipelines, or independent subgraphs). The intent is that $E \approx E_1 \otimes E_2$ should range over all "reasonable" ways of enforcing a two-part modular interpretation; the strict inequality then says that the best such modular account still fails to match the compression achieved by a genuinely cross-type representation.*

Remark 823. *A simple example is when a shared latent variable simultaneously explains sensory regularities and guides procedural choices; representing it once in a cross-type structure is less contrived than duplicating its effect separately in each module. In pattern language, the latent variable is an emergent pattern spanning multiple representational strata [5] (Hyperseed-Concept* **??***). One can also view this as a coordination advantage: a single latent factor couples prediction and control constraints, so that the same degrees of freedom satisfy both simultaneously, whereas separate modules must "rediscover" compatible structure through additional parameters or ad hoc interface conventions.*

Remark 824. *The usefulness of naming emergent compression explicitly is that it makes "synergy" empirically testable in principle: one can compare minimal contrivance frontiers under enforced modularization versus allowed interaction, and ask whether a strict gap appears. Operationally, this suggests experimental protocols where the architecture is trained under different constraints* *(e.g. blocked cross-attention, frozen communication channels, or enforced factorizations) and the resulting best-achievable* Con* *curves are compared at matched fit thresholds.*

Proposition 25 (Emergent compression implies positive synergy)**.** *If there exists a cross-type emergent compression pattern for b at level τ, then $\Sigma(\mathcal{T}_1, \mathcal{T}_2; \tau) > 0$.*

Remark 825. *The proposition says that the emergent compression condition is not merely poetic: it entails a strict inequality at the level of the optimal contrivance frontiers. Thus, emergence (as defined) is a sufficient condition for positive synergy gain. In other words, an explicit witness E whose cost beats every separable decomposition forces the joint optimum to beat the sum of separate optima by at least some nonzero margin (potentially small, but strictly positive in the sense of the inequality).*

Remark 826. *This connects tightly to the definition of Σ: the synergy gain is exactly the amount by which the joint optimum beats the sum of the separate optima. Emergent compression provides a witness E that beats* every *separable decomposition, hence it beats the optimal separable costs in particular. Concretely, if one denotes by C_{sep} the infimum of* $\mathrm{Con}(E_1)+\mathrm{Con}(E_2)$ *over all admissible (E_1, E_2) with* Fit $\geq \tau$*, then emergent compression asserts* $\mathrm{Con}(E) < C_{\text{sep}}$*, while Proposition 24 ensures the joint optimum is at most C_{sep}; together these force a strict improvement and hence $\Sigma > 0$.*

Proof. Let E witness emergent compression. By definition, $\mathrm{Con}(E) < \mathrm{Con}(E_1) + \mathrm{Con}(E_2)$ for any admissible decomposition. Taking infima over admissible E_1 and E_2 implies $\mathrm{Con}(E) < \mathrm{Con}^*(\mathcal{T}_1; \tau) + \mathrm{Con}^*(\mathcal{T}_2; \tau)$. Since $\mathrm{Con}^*(\mathcal{T}_1 \cup \mathcal{T}_2; \tau) \leq \mathrm{Con}(E)$, we obtain strict subadditivity and hence a positive synergy gain.

To unpack the two inequality steps: the emergent witness E is itself a jointly-constructed explanation drawn from the hypothesis class available when $\mathcal{T}_1$ and $\mathcal{T}_2$ are allowed to interact, so it is a feasible candidate in the joint optimization defining $\mathrm{Con}^*(\mathcal{T}_1 \cup \mathcal{T}_2; \tau)$. Meanwhile, each admissible decomposition corresponds to a pair of feasible candidates for the separate optimizations defining $\mathrm{Con}^*(\mathcal{T}_1; \tau)$ and $\mathrm{Con}^*(\mathcal{T}_2; \tau)$, so their infima provide a lower envelope over all separable ways of reaching fit threshold τ. The strictness is crucial: because $\mathrm{Con}(E)$ is strictly below *every* decomposed cost, it is strictly below the best decomposed cost as well. ☐

Remark 827. *The proof is a direct "witness to strictness" argument. The emergent compression hypothesis is already quantified over all decompositions; taking infima simply extracts the best possible decomposed costs and preserves strict inequality. The final step uses that the joint optimum is no worse than any particular joint explanation.*

Equivalently, one can view the argument as comparing two feasible regions: (i) the joint feasible set in which hypotheses may couple degrees of freedom across $\mathcal{T}_1$ and $\mathcal{T}_2$, and (ii) the restricted feasible set in which hypotheses must factor into components sourced separately. Emergent compression asserts that the restricted feasible set cannot realize the low-contrivance point achieved by E. The infimum operation then formalizes "best possible under the restriction" without changing the direction (or strictness) of the comparison.

Proof sketch. Use the emergent E to show it beats every decomposable pair (E_1, E_2). Therefore it beats the best decomposable pair, i.e. the sum of the separate optima. Since the joint optimum is at most the cost of E, the joint optimum is strictly less than the sum, giving $\Sigma > 0$.

In other words, E is a certificate that "interaction helps": once you exhibit a single joint construction whose contrivance lies below the entire separable baseline, you immediately obtain a nonzero gap between the joint optimum and the best separable performance. ☐

Remark 828. *Visually, if one plots the best-achievable contrivance as a function of enforced modularization constraints, emergent compression says the unconstrained curve dips below the sum of the constrained minima. This is a precise sense in which interaction creates a new "path of least contrivance" through hypothesis space.*

The same picture can be read as a "regularization relief" effect: the constraint that hypotheses must split across representational types can force each side to pay separate description length for structure that, in a coupled representation, is shared or reused. The dip corresponds to a regime where shared latent structure is expressible only when cross-type coupling is allowed.

15.5.6 A criterion for "synergy increases effective intelligence"

This paper later defines intelligence in terms of tasks (Section 21). For present purposes we state a local criterion that connects synergy to solvable task sets under resource limits.

Definition 211 (Budgeted solvability criterion)**.** *Fix a fit threshold τ and a contrivance budget B. A task/dataset b is* solvable by knowledge set $\mathcal{T}$ at budget B *if* $\mathrm{Con}^*(\mathcal{T};\tau) \leq B$.

Note that this definition is intentionally one-sided: it declares solvability whenever there exists some *explanation meeting the fit threshold with contrivance at most B, i.e. it uses the minimal contrivance* Con^* *as a summary of the most efficient available strategy within $\mathcal{T}$.*

Remark 829. *This is the simplest possible "resource-bounded competence" definition: competence is meeting fit τ, and resource use is contrivance cost. The budget B should be understood as an abstract proxy for the system's available representational and computational resources, mirroring the genenergy budgeting earlier in the section (Hyperseed-Concept* **??***).*

In particular, B can be interpreted as fixing a "feasible complexity band" of hypotheses: if the system's architecture or training regime can only realize hypotheses up to contrivance B, then any task whose best achievable contrivance exceeds B is effectively out of reach, even if it is learnable with unbounded resources.

Remark 830. *A concrete reading is: if B is small, only very weak (highly general, low-description-length) explanations are permitted. If the task requires a very contrived explanation, then it is not solvable at that budget even if solvable in principle. This provides a clean interface between architectural synergy and "effective intelligence" under scarcity [9].*

This criterion also makes the "capabilities under scaling" story explicit: increasing B expands the solvable set monotonically, but architectural synergy can shift the required budget for a given task downward by reducing Con^**. In that sense, synergy acts like an efficiency gain in how the system allocates limited representational capacity to meet the same fit level.*

Proposition 26 (Synergy expands the solvable set relative to non-synergistic partitions)**.** *Let $\mathcal{T}_1, \mathcal{T}_2$ be disjoint knowledge sets and suppose $\Sigma(\mathcal{T}_1, \mathcal{T}_2; \tau) > 0$ for a given task/dataset b. Define the "partition-limited" contrivance level*

$$\mathrm{Con}^{\mathrm{part}}(\mathcal{T}_1, \mathcal{T}_2; \tau) := \mathrm{Con}^*(\mathcal{T}_1; \tau) + \mathrm{Con}^*(\mathcal{T}_2; \tau),$$

which corresponds to architectures in which the two knowledge sets may each build an explanation, but only in a separable (non-emergent) way. Then there exists a budget B such that b is solvable by $\mathcal{T}_1 \cup \mathcal{T}_2$ at budget B, but is not solvable by any separable partition-limited architecture at budget B.

The disjointness assumption is meant to rule out double-counting the same representational resources: if $\mathcal{T}_1$ and $\mathcal{T}_2$ overlapped heavily, then the sum $\mathrm{Con}^*(\mathcal{T}_1; \tau) + \mathrm{Con}^*(\mathcal{T}_2; \tau)$ could overstate the true cost of a separable design by charging twice for shared structure. Under disjointness, the comparison to a strictly synergistic joint solution is cleanly attributable to cross-type interaction rather than to bookkeeping artifacts.

Remark 831. *The statement translates synergy into an operational advantage: there is a range of budgets for which the synergistic architecture succeeds while any architecture forced to keep the two knowledge sets separable must fail. This is exactly the kind of "capability gap" one expects when intermediate results can be exchanged across representational types rather than only combined at the end.*

Concretely, a separable architecture must "pay" separately for whatever structure is required to reach fit τ from within each knowledge set, whereas a synergistic one may express a single joint hypothesis whose parts co-adapt and share explanatory burden. The proposition isolates this advantage as a strict separation in feasible budgets, not merely as a mild reduction in cost at high budgets.

Remark 832. *The result connects back to the earlier subadditivity propositions: if synergy is strict, then the joint contrivance frontier lies below the separable one. The proposition simply chooses a budget in the strict gap. This is a small but principled instance of a more general tradeoff theme in the Hyperseed line of work: architectural constraints translate into provable capability limits under budgets [9].*

One can also read the result as a robustness statement about evaluation under resource limits: if a benchmark is run at a fixed budget B lying in the gap, then observed success/failure becomes diagnostic of whether the system is exploiting cross-type coupling, rather than merely having a larger raw budget.

Proof. Let $C_{12} := \mathrm{Con}^*(\mathcal{T}_1 \cup \mathcal{T}_2; \tau)$ and $C_{\text{part}} := \mathrm{Con}^{\text{part}}(\mathcal{T}_1, \mathcal{T}_2; \tau)$. Positive synergy means $C_{12} < C_{\text{part}}$. Choose any budget B satisfying $C_{12} \le B < C_{\text{part}}$. Then b is solvable by $\mathcal{T}_1 \cup \mathcal{T}_2$ at budget B by definition. On the other hand, any architecture restricted to separable explanations built independently from $\mathcal{T}_1$ and $\mathcal{T}_2$ requires contrivance at least C_{part}, hence cannot meet the same fit threshold within budget B.

Existence of such a B follows immediately from strict inequality: there is at least one real value between C_{12} and C_{part} (for example, $B = \frac{1}{2}(C_{12} + C_{\text{part}})$ when both quantities are finite). If Con^* is defined via an infimum rather than a minimum, the use of "$\le B$" in the solvability criterion is important: even if the optimal contrivance is not attained, any B above the infimum still permits arbitrarily close feasible solutions, while the strict lower bound $B < C_{\text{part}}$ continues to exclude all separable architectures at that budget. ☐

Remark 833. *The proof is essentially interval arithmetic: strict inequality $C_{12} < C_{\text{part}}$ implies there exists a nonempty open interval of budgets between them. Picking any B in that interval creates a regime where joint explanations are affordable but separable ones are not.*

This also clarifies why the result is framed as an existence *statement: it does not claim that every budget benefits from synergy, only that whenever there is a strict cost gap, one can select a budget that lands inside that gap and thereby forces an observable difference in solvability.*

Proof sketch. Let the synergistic optimum cost be C_{12} and the best separable cost be C_{part}. Since $C_{12} < C_{\text{part}}$, choose B between them. Then the synergistic system meets the budget while every separable system exceeds it.

In the language of decision thresholds, B is chosen so that it accepts the joint model class but rejects the separable model class, turning a quantitative synergy gain into a qualitative difference in whether the task can be solved under the imposed resource constraint. ☐

Remark 834. *Geometrically, one can picture two thresholds on the number line: synergy moves the required budget leftward. One threshold corresponds to the minimum budget at which the task becomes solvable when types are allowed to interact emergently, while the other corresponds to the* *minimum budget when the types are forced to contribute in isolation. In this picture, "leftward" does not mean that the task becomes easier in an absolute sense; it means the architecture makes better use of the same scarce computational currency by enabling multi-type regularities to be captured earlier. The "intelligence increase" is then not mystical; it is the existence of tasks that cross from impossible to possible when the architecture permits cross-type emergent compression patterns (Hyperseed-Concept* **??** *provides a related intuition about gains from moving between representational levels). In particular, the shift can be interpreted as a reduction in contrivance: fewer ad hoc special cases are required because structure discovered in one type can constrain search or learning in another.*

Remark 835. *Proposition 26 isolates a simple operational implication: synergy can make a task solvable under a budget that would be insufficient for any architecture that forces the two knowledge sets to contribute only in a separable (non-emergent) way. This is one clean sense in which synergy can increase effective intelligence. Equivalently, if one thinks of a system designer choosing an architecture under a fixed resource envelope, synergy expands the set of tasks that can be completed without increasing the envelope. The "separable" constraint is important here: it rules out the possibility that partial results in one type reshape the hypothesis space, loss landscape, or action space explored by the other type, and thus rules out precisely the kind of cross-type compression that yields strict subadditivity.*

15.6 Attention as the gating mechanism for synergy

Cognitive synergy requires frequent exchange of intermediate results. In bounded systems, such exchange competes for attention. Thus attention is the architectural "gate" that decides whether potential synergy is realized. One can read this as an opportunity-cost claim: every unit of attention devoted to translation and cross-type integration is a unit not devoted to within-type refinement, and so the system must continuously trade off short-horizon progress against longer-horizon integrative gains. Conversely, if attention never "pays" for communication, then even a richly multimodal or multi-algorithmic architecture behaves like a set of loosely coupled modules with minimal mutual constraint.

Definition 212 (Inter-type communication graph)**.** *Let $\mathcal{T}$ be a set of knowledge types. Define a directed graph Γ on $\mathcal{T}$ where an edge $T \to T'$ indicates that items in K_T can be transformed into inputs for $\mathsf{Alg}(T')$. Assign each edge a time-dependent bandwidth allocation $b_t(T \to T') \geq 0$ with $\sum_{T,T'} b_t(T \to T') \leq B_t$. We interpret b_t as the fraction of the attention budget devoted to cross-type communication. In general b_t may be sparse (concentrated on a few edges) or diffuse (spread over many edges), and its temporal variation encodes when the system chooses to integrate versus when it chooses to specialize. If desired, one can also interpret Γ as including only genuinely cross-type edges (within-type processing handled separately), though allowing $T = T'$ edges can be convenient when one wants a uniform accounting of all attentional expenditures in a single graph formalism.*

Remark 836. *The graph Γ is a wiring diagram for cognitive synergy: it says which translations are available. The scalar $b_t(T \to T')$ then says which translations are being actively exercised at time t, under the same budget logic as earlier attention policies. The constraint $\sum_{T,T'} b_t(T \to T') \leq B_t$ treats cross-type communication as something that consumes the same scarce currency as within-type updates. It also makes explicit that "having a translator" is distinct from "running the translator often enough": the former is a structural capability (an edge exists), while the latter is an attentional commitment (a nontrivial b_t over time). In particular, a system can possess many potential cross-type edges but still behave effectively unimodally if the policy allocates negligible bandwidth to them.*

Remark 837. *A simple example is a pipeline* $T = \mathrm{sens} \to T' = \mathrm{dec}$*, where sensory embeddings are converted into declarative propositions, or* $T = \mathrm{dec} \to T' = \mathrm{proc}$*, where declarative constraints shape action selection. If the corresponding* b_t *values are near zero, the translations exist only as dormant possibilities; if they are substantial, the system is actively weaving together types into joint explanations [19, 7]. In realistic cases, the most synergy-rich subgraphs are often not simple pipelines but feedback loops, e.g.* $\mathrm{sens} \to \mathrm{dec} \to \mathrm{proc} \to \mathrm{sens}$*, where actions select new observations, observations revise beliefs, and revised beliefs reshape policies. The directed nature of* Γ *matters here: translation can be easier in one direction than the reverse (for example, procedural skill may be difficult to verbalize), so high synergy may require asymmetric allocations* $b_t(T \to T')$ *that reflect these representational asymmetries.*

Remark 838. *This makes precise the intuitive claim that synergy is not merely a structural property of an architecture, but a dynamical property of an architecture under attentional governance. A system may have the representational machinery for cross-type emergence, yet fail to realize it because attention is monopolized by short-term demands (Hyperseed-Concept* **??***). A complementary failure mode is oscillation without integration: attention repeatedly switches types but allocates insufficient bandwidth for any translation to become reliable, yielding overhead without commensurate cross-type constraint. On the other hand, sustained attention to translation can bootstrap itself: once intermediate results become easier to exchange (e.g. via learned interfaces, shared latent variables, or cached abstractions), the effective cost of future communication drops, making synergy more likely to persist.*

Remark 839 (Two limiting regimes)**.** *If the cross-type bandwidths are near zero, then even if synergy is latent (in principle), it will not be expressed. If the bandwidths are substantial, the system can form and exploit cross-type emergent compression patterns, supporting the strict inequalities in Section 15.5. Between these extremes lies a practically important intermediate regime: modest bandwidth can be sufficient if the translated artifacts are high-leverage (e.g. a small number of declarative constraints that sharply prune procedural search), while in other domains the same modest bandwidth may be ineffective because useful intermediate products are numerous, noisy, or require iterative back-and-forth refinement. In this sense, the "gate" metaphor should be read quantitatively: the question is not only whether the gate is open, but how wide it is and for how long.*

Hyperseed concepts covered

- Attention; attentional focus; genenergy-based attention measure; self-reflective attention (Hyperseed-Concept 60; Hyperseed-Concept **??**; Hyperseed-Concept **??**).
- Varieties of knowledge: declarative, procedural, sensory, attentional, intentional (Hyperseed-Concept **??**; Hyperseed-Concept 65; Hyperseed-Concept 157).
- Cognitive synergy: usefulness of learning algorithms by knowledge type; synergy as strict subadditivity of contrivance/weakness; attention as the gating mechanism for synergy (Hyperseed-Concept 73; Hyperseed-Concept 202; Hyperseed-Concept **??**).

16 Self, continuity, development, and mind-world correspondence

This section formalizes a cluster of Hyperseed notions that are often treated informally in cognitive science and philosophy of mind: *self/other boundaries*, *diachronic self-continuity*, *development*, and *mind–world correspondence* (world-model quality). Hyperseed's distinctive move is to define these notions in terms of *pattern structure and its persistence*, rather than in terms of a privileged substance or an observer-independent identity relation [1, 5]. In the present reconstruction, "self" is thus not a metaphysical atom but a repeatedly reconstituted cut through a web of relations, and continuity is not an all-or-nothing identity but a degree of structural persistence. This cluster of ideas connects directly to the Hyperseed core-concept set: Self vs. Other (Hyperseed-Concept 165), Self-Continuity (Hyperseed-Concept 166), Development (Hyperseed-Concept 95), and Mind-World Correspondence (Hyperseed-Concept 112).

Throughout, fix an observer/context O and a commutative quantale $(\mathbb{V}, \leq, \otimes, \bigvee, \mathbf{1})$ as in Section 3.

Remark 840 (Notation and conventions used throughout)**.** *Here $\mathbb{V}$ is the domain of "degrees" (truth-like, evidence-like, or strength-like values), $\leq$ is its order (so $u \leq v$ means "u is no stronger than v"), $\otimes$ is the monoidal product (interpretable as conjunction/combination of constraints), and $\bigvee$ is the join (supremum; interpretable as "best possible" or "least upper bound"). We will also use $\bigwedge$ (the infimum/meet) when defining degrees via "for all" constraints. The element $\mathbf{1}$ is the unit for $\otimes$ and typically plays the role of a maximal (or perfectly adequate) degree. Quantales (and their "weakness"-flavored interpretations) are discussed more broadly in [3, 2].*

When we want explicit paraconsistency we take $\mathbb{V}$ to be the p-bit-valued quantale used in the toy model (Section 5). Time is treated as an observer-indexed proto-time ordering (Section 7); we write I, J for time intervals, and we treat a "time slice" as data aggregated over such an interval.

The key representational objects are pattern webs and pattern-flow networks (Sections 9 and 12). In this section we focus on morphisms between such networks: maps that preserve pattern-relational structure up to controlled degradation. This emphasis on morphism and transport is aligned with Hyperseed's broader stance that cognition is best modeled by what can be carried along transformations, rather than by what is statically possessed [7]. Pattern and Pattern Flow Networks are treated as core notions (Hyperseed-Concepts 130 and 131).

To situate the above commitments: fixing an observer/context O is not merely a notational convenience, but a way to make explicit that the relevant pattern decompositions, degrees of fit, and even the effective "time slices" are all relative to an information-gathering and information-organizing standpoint. In particular, what counts as the "same" pattern across two intervals I and J will typically be mediated by representational choices (feature sets, granularity, segmentation) that are part of O; the formalism does not attempt to erase this dependence, but instead makes it explicit and therefore comparable across contexts.

Likewise, the quantale of degrees $(\mathbb{V}, \leq, \otimes, \bigvee, \mathbf{1})$ is meant to carry the minimal algebra needed to talk about *approximate preservation* and *graded failure*. In concrete applications one may instantiate $\mathbb{V}$ as a unit interval $[0, 1]$ with a t-norm, as a Boolean algebra, or as a more information-structured object (e.g. the paraconsistent p-bit choice mentioned above). The point is that the same definitions can be read as (i) graded truth of relational constraints, (ii) graded evidence for relational constraints, or (iii) graded strength of pattern-couplings, provided that $\otimes$ plays the role of "putting constraints together" and that joins/meets provide the appropriate extremal aggregations.

The phrase "controlled degradation" will be made precise by requiring that morphisms between pattern-flow networks preserve relations not necessarily *exactly* but to a specified degree in $\mathbb{V}$. Informally, such morphisms can be read as transports that (a) identify which parts of a network correspond, (b) quantify how much relational structure survives the transport, and (c) localize where structure is lost, distorted, or newly introduced. This is the technical hinge on which the section turns: self/other boundaries, self-continuity, development, and mind–world correspondence will each be cast as particular patterns of existence (or non-existence) of such structure-respecting transports.

With this in mind, the four headline notions can be previewed as follows (with full definitions deferred to the subsequent subsections). A *self/other boundary* will be treated as a context-relative partitioning of a pattern web into subnetworks whose internal transports are comparatively strong and whose cross-boundary transports are comparatively weak (all measured in $\mathbb{V}$). *Diachronic self-continuity* will then be a degree of transportability from the "self"-designated subnetwork at interval I to the corresponding subnetwork at interval J, where the degree tracks which relational constraints remain satisfiable (or approximately so) over time. *Development* will be expressed not as mere accumulation of states but as a structured sequence of network morphisms whose typical effect is to expand or reorganize the space of patterns and flows available to O (for example, by adding new stable motifs or by reweighting existing habit-like transitions). Finally, *mind–world correspondence* will be expressed as the existence and quality of morphisms (or adjoint-like pairs of morphisms) that align an internal pattern-flow network (the "model") with an external or action-embedded pattern-flow network (the "world as encountered"), again with degradation explicitly represented rather than idealized away.

The use of paraconsistent degrees (via p-bit) is especially relevant here because both self-models and world-models are typically inconsistent in the weak sense: they contain partial, conflicting, and context-shifting constraints that remain practically useful. In such cases, mind–world correspondence is not well represented by a single global consistency requirement, but rather by a pattern of locally strong correspondences coexisting with tolerated contradictions—a situation the quantale semantics is designed to encode.

16.1 Self/other boundary as a paraconsistent, observer-relative cut

Hyperseed treats "self" as something *constructed* by a mind: a self is a distinguished subsystem (often hierarchical) carved out of a broader coherence field. A crucial point is that the self/other boundary is not always crisp; it can be fuzzy, context-dependent, and even genuinely inconsistent (one may simultaneously experience something as "me" and "not-me"). This is the formal face of Self vs. Other (Hyperseed-Concept 165) and of Non-Duality motifs (Hyperseed-Concept 121) in an otherwise highly analytic framework; compare the paraconsistent stance motivating such coexistence of opposites [23, 24]. In particular, "observer-relative" here should be read literally: different observers (or the same observer under different modeling stances) can induce different partitions of the same underlying dynamics, because the cut is made in representational space rather than assumed to be a pre-given ontological seam in the world. The time-interval parameter I likewise matters: self/other boundaries are treated as *temporally situated* practices, so that drift, context-switching, and rapid oscillation can be expressed as changes in σ_I across I.

We model this by attaching to each representational item a p-bit degree of self-membership. The use of a two-component degree is intended to capture not only vagueness (weak evidence in either direction) but also conflict (strong evidence in both directions), which is precisely the configuration that classical single-valued membership functions cannot represent without forcing a premature resolution.

Definition 213 (Self-evidence and self-groupings)**.** *Fix a time interval I. Let X_I be the set of representational tokens (entities, situations, pattern-nodes) used by the observer/model O to describe the system under study on I. A* self-evidence function *is a map*

$$\sigma_I : X_I \to [0,1]^2, \qquad \sigma_I(x) = (\sigma_I^+(x), \sigma_I^-(x)),$$

where $\sigma_I^+(x)$ is the degree of evidence that "x is part of the self" and $\sigma_I^-(x)$ is the degree of evidence that "x is not part of the self." No consistency constraint is imposed. Equivalently, σ_I may be read as a graded, paraconsistent labeling of tokens by the observer O: the two coordinates are not complements, and their joint values are informative precisely when they fail to sum to 1.

Given thresholds $\theta^+, \theta^- \in [0,1]$, the corresponding crisp self-grouping *(induced by σ_I) is*

$$\mathrm{Self}_\theta(I) := \{x \in X_I : \sigma_I^+(x) \geq \theta^+ \text{ and } \sigma_I^-(x) \leq \theta^-\},$$

where $\theta = (\theta^+, \theta^-)$. The complementary crisp other-grouping *is $\mathrm{Other}_\theta(I) := X_I \setminus \mathrm{Self}_\theta(I)$. The particular choice of θ is best understood as a downstream modeling decision (e.g. needed to define an agent boundary for credit assignment, control, or responsibility), rather than as an intrinsic parameter of the phenomenon.*

Remark 841 (Threshold monotonicity and decision-sensitivity)**.** *For fixed σ_I, the map $\theta \mapsto \mathrm{Self}_\theta(I)$ behaves monotonically in the expected directions: increasing θ^+ (demanding stronger positive evidence) can only shrink $\mathrm{Self}_\theta(I)$, while decreasing θ^- (demanding weaker negative evidence) can only shrink $\mathrm{Self}_\theta(I)$. Thus, varying θ interpolates between permissive and conservative self-ascriptions without altering the underlying evidence profile encoded by σ_I. This makes explicit a methodological separation between (i) evidence accumulation about self-relevance and (ii) the practical need to make a binary cut for a particular analytic task.*

Remark 842 (Intuition and examples for self-evidence)**.** *Intuitively, $\sigma_I(x)$ is not a statement of fact about an object x but a statement about O's* boundary-making practice *on interval I. The pair $(\sigma_I^+(x), \sigma_I^-(x))$ records that evidence can point both ways at once: this is the mathematical counterpart of the phenomenological observation that some contents are experienced as "mine" and "not mine" in different respects (or even simultaneously). One can also view $(\sigma_I^+(x), \sigma_I^-(x))$ as distinguishing four qualitative regimes in a graded way: predominantly-self (high $+$, low $-$), predominantly-other (low $+$, high $-$), mixed or conflicted (high $+$, high $-$), and unassigned/irrelevant (low $+$, low $-$). The last regime is important in practice because many tokens in X_I may simply not participate in the self-model at all, even though they are present in the observer's overall description of the situation.*

A simple example is bodily sensation: let $x =$ "pain in the arm." One may have high $\sigma_I^+(x)$ because the pain is experienced as happening "to me," while also having nontrivial $\sigma_I^-(x)$ because the pain is experienced as an intrusive, alien event. Another example is a tool in skilled use (e.g. a tennis racket): during fluent action one may assign it substantial positive self-evidence, while still retaining negative evidence because it is not literally part of the body. The usefulness of this definition is that it turns boundary vagueness into a manipulable object: thresholds θ yield crisp sets when needed for downstream constructions, without erasing the underlying ambiguity. A further class of examples arises in social and extended-cognition settings: a group "we" token, a conversational role, or an institutional identity can carry high σ_I^+ during coordination (the group-agent is treated as self-like) while simultaneously carrying high σ_I^- because the same observer recognizes non-identity at the individual level; the model records this tension rather than forcing an all-or-nothing verdict.

Remark 843 (Boundary and non-duality)**.** *The* boundary region *between self and other is naturally modeled as*

$$\partial\mathrm{Self}_\theta(I) := \{x \in X_I : \sigma_I^+(x) \geq \theta^+ \text{ and } \sigma_I^-(x) \geq \theta^-\}.$$

Elements in $\partial\mathrm{Self}_\theta(I)$ carry substantial evidence in both directions. This is a simple formal representation of the Hyperseed motif that experienced categories can be simultaneously distinct and *not-distinct. Note that $\partial\mathrm{Self}_\theta(I)$ is not a topological boundary but a decision-relative "zone of conflict": it depends on θ, and it expresses the coexistence of incompatible self-ascriptions at the level of representation rather than an ambiguity about where matter ends and begins.*

Remark 844 (Further intuition: why model a boundary region?)**.** *The set $\partial\mathrm{Self}_\theta(I)$ is where explanatory work tends to be needed: it marks tokens whose role in agency, responsibility, and prediction is inherently unstable. In Russellian terms, it allows us to speak precisely about cases where the "class"* Self *fails to be sharply defined, without thereby abandoning logical discipline. In Peircean terms, it acknowledges that the sign-process by which the self is constituted may place the same token under multiple interpretants (Hyperseed-Concepts 190 and 157); and in Whiteheadian terms it treats the self-boundary as a process-dependent abstraction rather than a substance boundary [14, 15]. Operationally, boundary-region tokens are also the ones for which small shifts in attention, affect, or narrative framing can lead to large shifts in downstream attributions (e.g. "I did that" versus "it happened to me"), which is precisely the kind of sensitivity that motivates keeping σ_I^+ and σ_I^- separate rather than forcing a single net score.*

Remark 845 (Multiple selves and hierarchical self-models)**.** *In many systems it is natural to consider multiple nested "selves" (e.g. bodily self, actional self, narrative self, social self). Formally, one may use a family of self-evidence functions $\sigma_I^{(k)} : X_I \to [0,1]^2$ indexed by a level k (or by a context label). Nestedness can be encoded either by pointwise inequalities $\sigma_I^{(k+1),+}(x) \le \sigma_I^{(k),+}(x)$ (stricter self at higher k) or by explicit inclusion of crisp groupings $\mathrm{Self}_\theta^{(k+1)}(I) \subseteq \mathrm{Self}_\theta^{(k)}(I)$. Conceptually, this accommodates the possibility that "what counts as me" is not a single flat set but a stratified construction: some tokens are self-like only at certain descriptive levels, and conflicts can occur not only within a level (high $+$ and high $-$) but also between levels (e.g. bodily self-evidence positive while narrative self-evidence negative).*

Remark 846 (Example: nested selves)**.** *As a concrete illustration, let $k = 0$ denote "bodily self" and $k = 1$ denote "narrative self." A heartbeat token may have high $\sigma_I^{(0),+}$ (it is bodily-me) but low $\sigma_I^{(1),+}$ (it is not typically part of the narrative-me), while a biographical memory may show the reverse. The nestedness conditions formalize the idea that higher-level selves are often more selective: they include fewer tokens, but possibly with greater stability across time. This multi-level framing is also compatible with phenomenological taxonomies that sort experience into "locations" or "modes" of selfhood [4, 12]. One can also treat social roles (e.g. "teacher in the classroom") as a higher-level self that activates only on certain intervals I, making $\sigma_I^{(k)}$ an explicitly context-gated construction; in such cases, the same underlying token (say, a verbal utterance) may alternate between being ascribed to the role-self and being experienced as alien or forced, naturally landing in $\partial\mathrm{Self}_\theta(I)$ during periods of role strain.*

Where does σ_I come from? Hyperseed motivates selfhood via *persistence of patterns over time* and via *coherence* (a mind often draws a boundary separating a mutually coherent group from other entities). In this paper we treat σ_I as derived data, typically computed from: (i) persistence statistics across time (Section 16.3); (ii) coherence/interaction weights within the pattern web (Section 9); and (iii) control/agency signals (Sections 14 and 15). The formal point is that none of these drivers need be consistent.

Remark 847 (Why self-evidence is placed "upstream" of identity)**.** *A tempting move in philosophy is to posit an identity relation and then to explain experience by reference to that identity. Hyperseed inverts this: boundary-making and persistence are primary, and "identity" is (at best) an* *emergent, context-sensitive convenience (Hyperseed-Concepts* **??** *and* **??***). This inversion matters in engineering terms as well: in adaptive systems, the representational vocabulary and the modeled objects can both change, so insisting on fixed identity would force one either into brittle bookkeeping or into ignoring precisely the developmental dynamics one wants to describe [19, 5].*

16.2 Approximate morphisms of quantale-weighted networks

Self-continuity and mind–world correspondence are both defined by Hyperseed using "approximate morphisms" between *pattern-flow networks*. We now make this precise in a form that is compatible with enriched-category theory.

Definition 214 (Quantale-weighted directed graphs)**.** *A* $\mathbb{V}$-weighted directed graph *(briefly, a* $\mathbb{V}$-graph*) is a pair* $G = (X, G)$ *where* X *is a set of nodes and*

$$G : X \times X \to \mathbb{V}$$

assigns a weight to each ordered pair of nodes. We write $G(x, y)$ *for the weight on the directed edge* $x \to y$*.*

Remark 848 (Intuition and examples for $\mathbb{V}$-graphs)**.** *A* $\mathbb{V}$*-graph is the simplest object that can carry graded relational structure. If* $\mathbb{V} = [0, 1]$ *with* $\leq$ *the usual order and* $\otimes$ *interpreted as multiplication or* min*, then* $G(x, y)$ *can be read as the strength of an influence or a similarity from* x *to* y*. If* $\mathbb{V} = [0, 1]^2$ *(a* p-bit *domain), then* $G(x, y)$ *can record positive and negative evidence for that influence simultaneously, echoing the earlier paraconsistent attitude [23, 24].*

This definition is useful because both "mind" and "world" can be represented as such graphs: nodes stand for tokens in the representational scheme, and edges for pattern-conditioned flow, predictive linkage, or habitual propagation (Hyperseed-Concepts 132 and 131). The key point is that we do not assume the node sets match across time or across domains; instead we will compare graphs by maps between node sets.

Definition 215 (Residuation)**.** *Because* $\mathbb{V}$ *is a quantale, the map* $u \otimes (-)$ *preserves arbitrary joins and hence has a right adjoint. Define the* residuum *(implication) by*

$$u \to v := \bigvee \{w \in \mathbb{V} : u \otimes w \leq v\}.$$

Equivalently, for all u, v, w *one has*

$$u \otimes w \leq v \quad \textit{iff} \quad w \leq (u \to v).$$

Remark 849 (Notation and intuition for the residuum)**.** *The symbol* $\to$ *here is not material implication from classical logic; it is the* residuated implication *determined by* $\otimes$*. The defining equivalence*

$$u \otimes w \leq v \iff w \leq (u \to v)$$

says that $(u \to v)$ *is the* largest *degree* w *such that combining* u *with* w *does not exceed* v*. One may read it as: "given that* u *holds to some degree, how much slack is available to reach* v*?" In quantitative settings it behaves like a best-possible conditional bound; in paraconsistent settings it functions as a controlled, non-explosive form of implication, which is precisely why residuation is valuable in the Hyperseed stack [3].*

Remark 850 (Example computations). *If $\mathbb{V} = [0,1]$ and $\otimes = \min$, then*

$$u \to v = \begin{cases} 1 & \text{if } u \le v, \\ v & \text{if } u > v, \end{cases}$$

so the implication is "perfect" when u is already no stronger than v, and otherwise degrades to v. If instead $\otimes$ is multiplication, then $u \to v$ behaves like a truncated ratio (v/u capped at 1), again matching the idea of a maximal compensating factor. These examples illustrate why residuation is the right tool for measuring how well a map preserves edges: it compares source edge-strength with target edge-strength in a way consistent with the quantale's native combination operator.

Definition 216 (Degree of a structure-preserving map). *Let $G = (X, G)$ and $H = (Y, H)$ be $\mathbb{V}$-graphs and let $f : X \to Y$ be a function. Define the* preservation degree *of f by*

$$\deg(f; G, H) := \bigwedge_{x,x' \in X} \big(G(x,x') \to H(f(x), f(x'))\big).$$

Equivalently, $q \le \deg(f; G, H)$ if and only if

$$G(x,x') \otimes q \le H(f(x), f(x')) \qquad \text{for all } x, x' \in X.$$

*We say that f is a q-*approximate morphism *$G \to H$ if $q \le \deg(f; G, H)$.*

Remark 851 (Intuition for $\deg(f; G, H)$ and why the meet appears). *The degree $\deg(f; G, H)$ measures the worst-case adequacy of f over all edges in G. The meet $\bigwedge_{x,x'}$ enforces a universal constraint: the map is only as good as its weakest-preserved relational link. The equivalent condition*

$$G(x,x') \otimes q \le H(f(x), f(x'))$$

should be read as: if an edge in G has strength $G(x,x')$, then after discounting by q it must still fit under the corresponding edge in H. Thus q quantifies a uniform level of tolerated degradation.

A simple example: if G and H encode similarity graphs, and f maps internal concepts to external referents, then q bounds how much similarity structure is lost under interpretation. This is useful because it yields a single composable number capturing the fidelity of a whole map, which will allow us to speak rigorously about continuity and correspondence without assuming any hard identity of tokens.

Remark 852 (Relation to enriched functors). *If G and H are actually* $\mathbb{V}$-categories *(reflexive and transitive in the $\mathbb{V}$-enriched sense), then q-approximate morphisms with $q = \mathbf{1}$ are precisely $\mathbb{V}$-enriched functors. The definition above is intentionally more general: it applies to raw weighted graphs and can be combined with a closure operation (e.g. reflexive-transitive closure) when one wants a genuine enriched categorical semantics.*

Remark 853 (Why we avoid requiring categorical axioms here). *Requiring reflexivity/transitivity at the outset would build in a strong coherence assumption that many empirical pattern webs do not satisfy before closure or smoothing. Hyperseed repeatedly emphasizes that cognition begins in rough, partially contradictory data and only later acquires stable structure via closure processes (compare Hyperseed-Concepts 72 and* **??***). The present choice therefore keeps the interface maximally general while remaining compatible with enriched-category intuitions when the additional axioms hold.*

More concretely: reflexivity and transitivity are precisely the axioms that would let a $\mathbb{V}$-graph be regarded (after suitable interpretation) as the hom-object assignment of a $\mathbb{V}$-enriched category, where *identities and composition are already "baked into" the structure. By postponing these axioms, we allow the weights $G(x, x')$ to be read as raw affinities, similarities, causal supports, or co-occurrence strengths, without presuming that self-links are maximally strong or that indirect support must be mediated by $\otimes$ in a globally consistent way. The closure/smoothing steps can then be understood as the point at which the empirical web is forced into (or approximated by) a more coherent, category-like regime, rather than assuming coherence from the beginning.*

Theorem 14 (Composition law for approximate morphisms)**.** *Let $G = (X, G)$, $H = (Y, H)$, and $K = (Z, K)$ be $\mathbb{V}$-graphs. For functions $f : X \to Y$ and $g : Y \to Z$,*

$$\deg(g \circ f; G, K) \;\geq\; \deg(f; G, H) \otimes \deg(g; H, K).$$

In particular, if f is a q_1-approximate morphism and g is a q_2-approximate morphism, then $g \circ f$ is a $(q_1 \otimes q_2)$-approximate morphism.

It is worth stressing what the direction of the inequality encodes: the composite cannot be worse *than the tensor-combination of the two degradations, but it may be* better *in special cases (for instance, if g collapses distinctions that were responsible for f's worst violations, or if the feasibility constraints become looser after passing through H). Thus the theorem provides a guaranteed lower bound on composite fidelity rather than an exact formula.*

Remark 854 (What the composition law says, and why it matters)**.** *In plain terms: if f preserves the structure of G inside H up to degradation q_1, and g preserves the structure of H inside K up to degradation q_2, then the composite $g \circ f$ preserves the structure of G inside K up to the combined degradation $q_1 \otimes q_2$. This is the algebraic statement that "approximate structure preservation composes."*

The result is crucial for everything that follows: self-continuity will be defined by chaining together approximate morphisms across successive time-slices, and mind–world correspondence will be used inside control and prediction loops (Section 14). Without a composition law, these degrees would not behave like a stable currency of fidelity across multiple steps.

Two limiting cases help anchor the interpretation. First, when $\deg(f; G, H)$ is the monoidal unit (of $\mathbb{V}$) so that f is "exact" in the sense of not requiring any weakening, the theorem reduces to the familiar closure of exact structure preservation under composition. Second, in common numerical quantales (e.g. $\mathbb{V} = [0, 1]$ with $\otimes$ as multiplication or a t-norm), the combination $q_1 \otimes q_2$ matches the intuition that independent degradations multiply, so long chains decay in a controlled, algebraically predictable way rather than in an ad hoc manner.

Proof. Let $q_1 := \deg(f; G, H)$ and $q_2 := \deg(g; H, K)$. By definition of deg, for all $x, x' \in X$,

$$G(x, x') \otimes q_1 \leq H(f(x), f(x'))$$

and for all $y, y' \in Y$,

$$H(y, y') \otimes q_2 \leq K(g(y), g(y')).$$

Apply the second inequality with $y = f(x)$ and $y' = f(x')$ and compose:

$$G(x, x') \otimes (q_1 \otimes q_2) = (G(x, x') \otimes q_1) \otimes q_2 \leq H(f(x), f(x')) \otimes q_2 \leq K(g(f(x)), g(f(x'))).$$

Thus $(q_1 \otimes q_2)$ satisfies the defining feasibility condition for $\deg(g \circ f; G, K)$, so $\deg(g \circ f; G, K) \geq q_1 \otimes q_2$.

Note that the proof uses only the basic quantale/enrichment primitives already in play: the monotonicity of $\otimes$ in each argument (so inequalities can be tensored on the right), and associativity (so "weakening twice" is unambiguous). No reflexivity or transitivity assumptions on G, H, K are needed, which is consistent with the preceding remark about avoiding categorical axioms at this stage. □

Remark 855 (Proof sketch and geometric intuition). Proof sketch. *Use the equivalent characterization of* deg*: a lower bound q is feasible exactly when every edge in the source, weakened by q, fits under the corresponding edge in the target. Apply this twice (first for f, then for g) and associate the tensor product to conclude feasibility for $g \circ f$ with weakening $q_1 \otimes q_2$.* □

The key step is substituting $y = f(x)$ and $y' = f(x')$ so that the second inequality speaks about exactly the images of the nodes used in the first inequality. Associativity of $\otimes$ then ensures the degradation factors combine cleanly. Visually: think of each morphism as allowing you to "shrink" all edge weights by a factor and still embed them into the next graph; doing this twice multiplies (or otherwise $\otimes$-combines) the shrinkage.

Order-theoretically, the same picture can be read as follows: the set of feasible degradations for a map is downward closed in $\mathbb{V}$ (if q works, any weaker $q' \leq q$ works), and deg *is the best achievable bound among them. The theorem exhibits an explicit feasible element for the composite—namely $q_1 \otimes q_2$—so the degree of the composite must lie* above *that element in the $\mathbb{V}$-order. This viewpoint clarifies why the statement is a $\geq$ bound on degrees even though it arises from chaining $\leq$ constraints on weakened edges.*

16.3 Self-continuity as approximate self-morphism across time

We now instantiate the preceding definitions on time-indexed pattern-flow networks.

Definition 217 (Pattern-flow network). *Fix a system S (as modeled by observer O) and a time interval I. A* pattern-flow network *for S on I is a $\mathbb{V}$-graph*

$$F_{S,I} : X_{S,I} \times X_{S,I} \to \mathbb{V},$$

where $X_{S,I}$ is a set of nodes representing specific entities or pattern-tokens, and where $F_{S,I}(a, b)$ quantifies the extent to which pattern that "first appears" in a subsequently appears in b over the interval I. The precise estimator used to compute $F_{S,I}(a, b)$ is observer-dependent and may include sub-interval weighting (temporal discounting).

Remark 856 (Intuition and examples for pattern-flow networks). *A pattern-flow network is a time-slice summary of "how patterns propagate" inside the modeled system. If nodes are tokens like* `belief_X`, `memory_Y`, `action_schema_Z`, *then $F_{S,I}(a, b)$ measures how reliably activity or content associated with a predicts or feeds into activity/content associated with b during I. This packages the Hyperseed emphasis on Pattern and Process (Hyperseed-Concepts 130 and 140) in a way that is directly comparable across times and across domains.*

For a simple example, let a = "see_cup" and b = "reach_cup". Then a high value $F_{S,I}(a, b)$ indicates that within the interval I the perceptual token "see cup" tends to be followed by (or to support) the action token "reach cup." If $\mathbb{V}$ is paraconsistent, then $F_{S,I}(a, b)$ may simultaneously record evidence for and against the flow, capturing the fact that behavior can be context-fragmented or internally conflicted.

Remark 857 (Why observer-dependence is not a defect). *The estimator for $F_{S,I}$ is allowed to be observer-dependent because "pattern" is already observer-relative in Hyperseed: it depends on the distinctions the observer can draw and the resources it allocates (Sections 9 and 15). Rather than pretending away this relativity, we keep it explicit and then build invariants (like morphism degrees) that remain meaningful under representational change [5, 19].*

Definition 218 (Pattern-flow-network self-continuity)**.** *Let I and J be successive time intervals. The* pattern-flow-network self-continuity *of S from I to J is*

$$\mathrm{SC}_S(I \to J) := \bigvee_{f: X_{S,I} \to X_{S,J}} \deg\big(f; F_{S,I}, F_{S,J}\big).$$

We say that S has θ-self-continuity *from I to J if* $\mathrm{SC}_S(I \to J) \geq \theta$.

Remark 858 (Intuition: continuity as best possible relabeling)**.** *This definition says: among all possible ways of matching (or "translating") the system's internal tokens at time-slice I into tokens at time-slice J, pick the one that best preserves the flow structure; that best achievable degree is $\mathrm{SC}_S(I \to J)$. So continuity is not "are the tokens identical?" but "can we find a renaming under which the organizational dynamics remain largely the same?" This is exactly the kind of continuity one expects in developing or learning systems, where representational vocabulary shifts while deeper regularities persist (Hyperseed-Concept 166; compare [5]).*

As a toy example, suppose a child first uses a token `dog` *and later refines it into* `dog` *and* `wolf`*. The node sets differ across time, but there may be a map f that sends earlier* `dog` *into later* `dog` *and preserves many flow relations (e.g. "seeing dog" $\to$ "fear"), yielding high self-continuity despite vocabulary refinement.*

Remark 859 (Interpretation)**.** $\mathrm{SC}_S(I \to J)$ *is the best achievable degree of structure preservation between the system's pattern-flow network on I and on the next interval J. The definition allows the system to "rename" internal nodes across time via the map f. This is essential when the representational vocabulary itself evolves.*

Remark 860 (Why use a join over maps?)**.** *The join $\bigvee_f$ plays the role of an existential quantifier in the quantale: it says "there exists a correspondence between times that works this well." This existential flavor is appropriate because the system need not commit to a single privileged identity map; different contexts and downstream tasks may induce different best correspondences. This flexibility will matter again when we discuss mind–world correspondence, where multiple incompatible interpretations of the world may coexist without explosion [23, 24].*

Corollary 2 (Longer-horizon self-continuity along a realized chain)**.** *Suppose we have a chain of successive intervals $I_0 \to I_1 \to \cdots \to I_n$. Then*

$$\mathrm{SC}_S(I_0 \to I_n) \;\geq\; \mathrm{SC}_S(I_0 \to I_1) \otimes \mathrm{SC}_S(I_1 \to I_2) \otimes \cdots \otimes \mathrm{SC}_S(I_{n-1} \to I_n).$$

Remark 861 (What the chain inequality means)**.** *If the system is fairly continuous from one slice to the next, then it is at least that continuous over multiple steps, with the degree decaying (at worst) by repeated combination via $\otimes$. This is the formal statement that "continuity compounds" rather than resets. It connects directly back to Theorem 14: the corollary is essentially the repeated application of compositionality, but lifted through the join-over-maps definition of* SC_S.

Proof. Choose (for each k) a map $f_k : X_{S,I_k} \to X_{S,I_{k+1}}$ whose degree approximates $\mathrm{SC}_S(I_k \to I_{k+1})$. More explicitly, for any tolerance parameter $\delta \succ 0$ (in the order of $\mathbb{V}$, or after scalarization if one prefers a numerical proxy), one may pick f_k so that its degree is within δ of the join defining $\mathrm{SC}_S(I_k \to I_{k+1})$; this is the standard "$\varepsilon$-optimizer" maneuver when the supremum is not attained. Then Theorem 14 shows that the composition $f_{n-1} \circ \cdots \circ f_0$ has degree at least the stated tensor product. Here the tensor product encodes the cumulative degradation under composition: each step contributes a factor in $\mathbb{V}$, and the quantale multiplication (or its chosen monoidal operation) aggregates these factors in the same order as the composites. Taking joins over choices of the f_k

yields the inequality. In other words, since $\mathrm{SC}_S(I_0 \to I_n)$ is defined as the join of degrees over *all* candidate maps $X_{S,I_0} \to X_{S,I_n}$, it must dominate the degree of any particular composite built from near-optimal adjacent witnesses. □

Remark 862 (Proof sketch and intuition)**.** Proof sketch. *Pick near-optimal matching maps between each adjacent pair of slices, compose them into a single map from I_0 to I_n, use the composition law to bound the degree of this composite map, and then observe that $\mathrm{SC}_S(I_0 \to I_n)$ is the join over* all *such maps, so it must be at least as large as the degree of this particular composite.* □

The only subtlety is the use of "approximates": since the join defining SC_S may not be attained by a single maximizer, one chooses maps close enough to the supremum for the intended application. Conceptually, the statement says that if you can translate your internal vocabulary forward slice-by-slice, you can translate it forward over the whole horizon by composing those translations, with predictable loss. A useful way to read the quantale-valued inequality is as a generalized "triangle inequality" (or, depending on $\otimes$, a multiplicative analogue): stepwise continuity lower-bounds long-range continuity, but cannot in general prevent decay as n grows. This also clarifies why the result is framed as a lower *bound: composing specific witnesses constructs one admissible long-range witness, and the join defining $\mathrm{SC}_S(I_0 \to I_n)$ can only be larger when additional direct correspondences exist that are not decomposable into the chosen stepwise maps.*

Relative-information self-continuity. Hyperseed distinguishes pattern-flow-network self-continuity from a more "information geometric" notion: the mind at I and the mind at J should share a large amount of relative information. To express this in a quantale-friendly way, we use a monotone scalarization of $\mathbb{V}$. This shift is deliberate: the morphism-based notion is invariant under relabelings (and thus tracks *structural* persistence), whereas an information-style comparison presupposes a shared coordinate system (a fixed node set) and then measures *numerical* drift within that coordinate system.

Remark 863 (Connection to information theory)**.** *This "relative-information" variant resonates with classical measures of model drift and state distance. When $\mathbb{V}$ is ultimately derived from probabilistic quantities, one may connect the divergence to familiar information-theoretic functionals [16, 17]. Hyperseed's point, however, is not to privilege any single divergence, but to keep the interface open while preserving monotonicity and composability. In particular, the monotonicity requirement ensures that "more disagreement in $\mathbb{V}$" (in the ambient order) cannot be mapped to a smaller scalar penalty, so that downstream bounds and thresholds behave predictably when one refines or coarsens the underlying edge annotations.*

Definition 219 (Scalarization and graph divergence)**.** *A* scalarization *is a monotone map $\|\cdot\| : \mathbb{V} \to [0, \infty]$. Given two $\mathbb{V}$-graphs $G = (X, G)$ and $H = (X, H)$ on the same node set, define the* edgewise divergence

$$D(G, H) := \sum_{(x,x') \in X \times X} \big\|G(x, x') - H(x, x')\big\|,$$

where subtraction is interpreted componentwise when $\mathbb{V}$ is a product domain (e.g. a p-bit *quantale), and otherwise D is taken as a schematic placeholder for any reasonable scalar divergence induced by $\|\cdot\|$. We say that G and H have* ε-relative-information proximity *if $D(G, H) \leq \varepsilon$. When X is infinite (or merely large), the same definition can be read as selecting a summation convention (e.g. absolute convergence, truncation, or a weighted sum), depending on the modeling choice; the present formulation isolates the conceptual ingredient, namely an edgewise comparison mediated by a monotone scalarization.*

Remark 864 (Intuition and examples for scalarization). *A scalarization $\|\cdot\|$ is simply a way of extracting a nonnegative "size" or "cost" from a $\mathbb{V}$-value. For $\mathbb{V} = [0,1]$ one might take $\|u\| = 1-u$ (turning similarity into distance) or $\|u\| = u$ (treating u itself as a magnitude). For $\mathbb{V} = [0,1]^2$ one might take $\|(p,q)\| = p+q$ or $\|(p,q)\| = \max(p,q)$, depending on whether one wants to penalize total evidence mass or only the strongest polarity.*

The divergence $D(G,H)$ then sums edgewise differences. This is useful when the node set is held fixed (e.g. a stable vocabulary) and one wants to quantify how much the network changed in a numerical sense. It complements the morphism-based continuity, which is structurally invariant under relabeling and thus better suited to developmental regimes where the vocabulary itself evolves. One can also view $D(G,H)$ as a "Hamming-like" comparison generalized to weighted, typed edges: rather than counting mismatched symbols, it accumulates per-edge disagreement costs determined by $\|\cdot\|$. If desired, one may normalize by $|X|^2$ (when finite) to obtain an average per-edge drift; the unnormalized form is often preferable when absolute drift magnitude, rather than density, is the salient quantity (e.g. when small localized changes matter less than widespread global rewiring).

Remark 865 (Two complementary views). *Pattern-flow self-continuity (existence of a high-weight approximate morphism) is a* structural *condition. Relative-information proximity is a* numerical *condition. They are related but not identical: self-continuity allows nontrivial relabelings and can hold even when many edge weights drift, provided the drift is coherent under the relabeling. For example, if a system consistently renames an internal symbol (or splits one concept into two with a systematic bookkeeping map), then a high-degree morphism may still exist even though a naive edgewise comparison on a fixed node set would report substantial divergence. Conversely, a small $D(G,H)$ can occur even when no good relabeling exists (e.g. many small but incoherent edge perturbations), so the two notions probe different failure modes.*

Remark 866 (Why keep both notions). *In applications, one often wants both: structural continuity to justify that a system is still "the same agent" in the operational sense, and numerical proximity to detect subtle instability within a fixed representational frame. Hyperseed treats these as complementary lenses rather than competing definitions, reflecting a broader methodological pluralism: different invariants answer different questions about persistence (Hyperseed-Concept 200). In particular, structural continuity is naturally adapted to scenarios where the system's representational basis is itself part of the dynamical state (so comparing raw coordinates is ill-posed), while numerical proximity is adapted to monitoring and validation tasks in a fixed interface (so that deviations can be alarmed on a stable scale).*

Reflective self-continuity. Hyperseed further distinguishes *reflective self-continuity*: the system is explicitly aware (in its own representational language) of its continuity. Formally this requires a notion of internal self-models and declarative content, developed in Section 17. In the present section we only note the minimal scaffold: reflective self-continuity arises when a self-model contains an explicit representation of (approximate) morphisms witnessing $\mathrm{SC}_S(I \to J)$, and this representation is used in attention and control (Sections 15 and 14). One can think of this as internalizing not only the fact that "there exists a correspondence," but also storing (possibly schematically) the correspondence itself as an object that can be queried, composed, revised, and used as a premise in planning.

Remark 867 (Why reflectivity is an extra requirement). *A system may be continuous without having a representational handle on that fact, just as a river may persist as a process without representing its own persistence. Reflective self-continuity adds a meta-level constraint: the continuity witness must appear as content in the system's representational economy and must be* actionable

(able to steer attention or control). This anticipates the closure phenomena discussed later in the consciousness layer (Section 17) and aligns with fixed-point flavored analyses of self-model stability [10]. Operationally, reflectivity is what allows the agent to treat identity-over-time as a manipulable hypothesis: it can allocate resources to maintaining a correspondence, detect when the correspondence degrades, and initiate repair (e.g. by learning a new alignment map) rather than merely exhibiting continuity as an unexamined byproduct of dynamics.

16.4 Development as continuity plus expanding capability

Hyperseed defines *development* as the conjunction of self-continuity with the acquisition of fundamentally new capabilities over time, typically in a way that extends and enriches rather than obsoletes earlier capabilities. To formalize this we separate the "identity" condition (self-continuity) from a capability preorder. This targets Development as a core notion (Hyperseed-Concept 95) and also interfaces naturally with task-based views of intelligence [19]. In particular, the separation makes explicit that (i) continuity is about *who* or *what* persists across change, whereas (ii) capability is about *what can be done* and how well, which may increase, plateau, or even partially regress while still remaining "the same system" in the sense of Section 16. This also anticipates later discussions where apparent "improvement" in one regime can be explained by changes in attention, habit structure, or observation/interface layers rather than by a simple accumulation of skills.

Definition 220 (Capability profile and capability preorder)**.** *Fix a family $\mathcal{G}$ of goals (or tasks) that may be relevant to the system. For each interval I, define a* capability profile *as a function*

$$\mathrm{Cap}_S(I) : \mathcal{G} \to \mathbb{V},$$

where $\mathrm{Cap}_S(I)(g)$ quantifies the system's ability to achieve goal g (as modeled by O) when operating in the regime represented by I. The pointwise order on $\mathbb{V}^{\mathcal{G}}$ defines a preorder:

$$\mathrm{Cap}_S(I) \preceq \mathrm{Cap}_S(J) \quad \textit{iff} \quad \mathrm{Cap}_S(I)(g) \leq \mathrm{Cap}_S(J)(g) \textit{ for all } g \in \mathcal{G}.$$

Remark 868 (Regimes, evaluation protocol, and dependence on O)**.** *The phrase "regime represented by I" is intended to cover not only internal state (weights, memory, habits) but also evaluation conditions: the distribution of inputs encountered, the available tools, and the interface by which success on g is measured. Formally, this dependence is pushed into the observation/evaluation machinery O, so that $\mathrm{Cap}_S(I)(g)$ is not an abstract Platonic competence but an* operational *quantity: it is always relative to the channel through which performance is read out and aggregated over I. This matters in later sections on mind–world correspondence: an apparent gain in capability can sometimes be a gain in alignment between internal representation and the evaluation context, without a commensurate increase in underlying generality.*

Remark 869 (Intuition and examples for capability profiles)**.** *A capability profile is a many-goal, graded generalization of the idea of "competence." For each $g \in \mathcal{G}$ (say, "solve linear equations," "cooperate with peers," or "navigate a room"), the value $\mathrm{Cap}_S(I)(g)$ records how well the system can achieve g during interval I, in the same quantale-valued language used elsewhere.*

For example, if $\mathbb{V} = [0, 1]$, then $\mathrm{Cap}_S(I)(g)$ can be interpreted as success probability or normalized performance. If $\mathbb{V}$ is p-bit*-valued, then $\mathrm{Cap}_S(I)(g)$ can represent simultaneous evidence for and against competence (e.g. the system sometimes succeeds and sometimes fails in incompatible contexts). The preorder $\preceq$ then formalizes the natural notion that "J is at least as capable as I" when it is no worse on any goal in the family.*

Remark 870 (Scope of $\mathcal{G}$ and "fundamentally new" capabilities)**.** *The family $\mathcal{G}$ should be understood as a modeling choice: it may be narrow (a benchmark suite), broad (a library of tasks parameterized by context), or even implicitly defined (e.g. by a goal generator used in training). In practice, "fundamentally new capabilities" correspond to strict improvements on goals that were previously low or undefined in the relevant evaluation scheme, or to the appearance of new goals that become salient as the system interacts with richer environments. The formalism can accommodate either view: one may keep $\mathcal{G}$ fixed and track new abilities as movement from low to high values on previously included goals, or allow $\mathcal{G}$ to expand over time and interpret development as the ability to maintain performance on incumbent goals while raising performance on newly introduced ones.*

Remark 871 (Why a preorder rather than a total order)**.** *Capabilities across diverse tasks are rarely totally comparable: one system may improve at g_1 while regressing at g_2. The preorder keeps the formalism honest about partial comparability and dovetails with later value-paraconsistent and multi-objective reasoning (Section 18). In engineering terms, this is also the right level of abstraction for discussing tradeoffs and dependency constraints across skill acquisition [9, 8].*

Remark 872 (Strict improvement and ties)**.** *Because $\preceq$ is only a preorder, it may identify distinct profiles as mutually comparable in both directions (i.e. ties up to the induced equivalence). Accordingly, $\mathrm{Cap}_S(I) \prec \mathrm{Cap}_S(J)$ in Definition 221 should be read as "$\mathrm{Cap}_S(I) \preceq \mathrm{Cap}_S(J)$ and not $\mathrm{Cap}_S(J) \preceq \mathrm{Cap}_S(I)$," i.e. a strict increase on at least one goal without any decrease on any goal. This notion is intentionally strong; later variants can weaken it by allowing bounded losses on a small set of goals, which is often necessary for resource-bounded agents.*

Definition 221 (Development path)**.** *A sequence of successive intervals $I_0 \to I_1 \to \cdots$ is a* development path *for S if there exists a threshold $\theta \in \mathbb{V}$ such that:*

(a) (continuity) $\mathrm{SC}_S(I_k \to I_{k+1}) \geq \theta$ for all k;

(b) (nontrivial growth) there exist infinitely many k such that $\mathrm{Cap}_S(I_k) \prec \mathrm{Cap}_S(I_{k+1})$;

(c) (enrichment bias) for typical goals g with high previous capability, $\mathrm{Cap}_S(I_k)(g)$ does not sharply decrease when new goals are added.

Condition (c) is qualitative; in concrete models it is replaced by a quantitative constraint (e.g. bounded loss on a weighted set of incumbent goals).

Remark 873 (On the continuity threshold θ)**.** *The single threshold θ serves as a tunable notion of "identity granularity": higher θ demands a stronger form of persistence across steps, while lower θ tolerates more drift. One can equivalently think of θ as picking out a subcategory of transitions regarded as identity-preserving, or as a robustness margin that separates development from replacement. In empirical settings, θ can be chosen to reflect how stable an external observer (or the system itself, via self-modeling) must judge the system to be in order to treat its learning trajectory as belonging to one continuing agent.*

Remark 874 (Quantitative surrogates for enrichment bias)**.** *A common quantitative replacement for (c) is to fix, at each step k, an "incumbent" subset $\mathcal{G}_k^{\mathrm{inc}} \subseteq \mathcal{G}$ of goals deemed already mastered, together with weights $w_k(g)$ emphasizing what must not be forgotten, and then require a bounded drop such as*

$$\inf_{g \in \mathcal{G}_k^{\mathrm{inc}}} \big(\mathrm{Cap}_S(I_{k+1})(g) - \mathrm{Cap}_S(I_k)(g)\big) \geq -\varepsilon \quad \textit{or} \quad \sum_{g \in \mathcal{G}_k^{\mathrm{inc}}} w_k(g)\, \mathrm{Cap}_S(I_{k+1})(g) \geq \sum_{g \in \mathcal{G}_k^{\mathrm{inc}}} w_k(g)\, \mathrm{Cap}_S(I_k)(g) - \varepsilon,$$

interpreting subtraction and summation in whatever enrichment of $\mathbb{V}$ is being used. When $\mathbb{V}$ is not numeric, the same idea can be phrased order-theoretically as a constraint that the restriction of $\mathrm{Cap}_S(I_{k+1})$ *to* $\mathcal{G}_k^{\mathrm{inc}}$ *remains above a designated lower envelope. This connects directly to catastrophic forgetting in continual learning, where development requires not merely acquiring new tasks but retaining competence on earlier ones under distribution shift.*

Remark 875 (Intuition: development is not mere change). *Condition (a) insists that the system remains recognizably continuous: development is not a replacement of one system by another unrelated system. Condition (b) insists that something genuinely new keeps appearing: without it, a perfectly stable adult-like agent would count as "developing" just by persisting. Condition (c) is the "enrich rather than erase" clause: it encodes the idea that development, in the Hyperseed sense, is not simply optimization for a moving target but a bias toward retaining earlier competences while acquiring new ones.*

A simple example is language learning: early competence at phoneme discrimination should not be destroyed by later acquisition of syntax; rather, later skills should build on earlier ones. This is also precisely where resource-bounded systems encounter tradeoffs, and why Hyperseed connects development to attention allocation and dependency management [19, 9].

Remark 876 (Local regressions and realistic trajectories). *The definition allows that between some consecutive intervals,* $\mathrm{Cap}_S(I_{k+1})$ *may fail to dominate* $\mathrm{Cap}_S(I_k)$*: development paths can include plateaus and periods of reorganization. The requirement is only that strict improvements occur infinitely often, capturing the idea of an open-ended trajectory rather than a one-off training phase. In practice, one may also consider softened variants of (b) that measure improvement relative to a curriculum, or that require strict growth on a sequence of increasingly complex goal families, which better captures development under shifting environments and expanding affordances.*

Remark 877 (Self-transcendence as a special case). *Hyperseed treats "self-transcendence" as a form of development. In the present framework, a mathematically simple proxy is: self-transcendence corresponds to development in which the self/other boundary function σ_I changes in a way that reduces conflict on the boundary (smaller $\partial\mathrm{Self}_\theta(I)$) while preserving continuity. This is only a proxy; richer formalizations depend on the resonance machinery (Sections 12 and 17).*

Remark 878 (Why the proxy focuses on the boundary region). *The boundary region $\partial\mathrm{Self}_\theta(I)$ concentrates the system's "ontological tension" about what counts as self. A reduction in this region (at fixed continuity) formalizes, in one clean variable, the intuition that the self becomes less conflicted about its own scope. In experiential terms this can correspond to a shift toward non-dual integration (Hyperseed-Concept 121); in control terms it can reduce internal contention for attentional resources (Section 15); and in resonance terms it can reflect an increase in coherence across subsystems (compare [5, 13] for broader resonance motifs).*

Remark 879 (Boundary shrinkage versus capability expansion). *The proxy for self-transcendence is intentionally orthogonal to the capability preorder: a system may become less conflicted about self/other while gaining, losing, or redistributing task capabilities. Nevertheless, in many practical settings boundary clarification can indirectly support capability growth by reducing internal interference (fewer competing self-models) and by improving the mind–world interface through which goals are perceived and pursued. This provides a conceptual bridge between "development" in the skill-acquisition sense and "development" in the integration/non-duality sense: both can be viewed as trajectories that increase coherence while maintaining sufficient self-continuity to count as the same ongoing agent.*

16.5 Mind–world correspondence via pattern-flow morphisms

Hyperseed's "mind–world correspondence" is a generalized notion of world-model quality. It is defined in terms of approximate morphisms between two pattern-flow networks: one describing relevant entities inside the system (mind/brain organization), and one describing relevant entities in the environment. This corresponds to Mind-World Correspondence as a core notion (Hyperseed-Concept 112) and is aligned with the engineering view that a model is good insofar as it supports successful prediction and control [19, 20]. A key point is that "quality" here is not identified with any particular representational format (e.g. propositional symbols, neural features, latent-state vectors): it is identified with the existence of a structure-preserving translation between whatever internal units the system uses and whatever external regularities are relevant to its task-context.

Definition 222 (Internal and external pattern-flow networks)**.** *Fix a system S and interval I. Let $M_{S,I}$ be a pattern-flow network on a set $X^{\mathrm{in}}_{S,I}$ representing internal entities (states, representations, memory items, action schemas). Let $E_{S,I}$ be a pattern-flow network on a set $X^{\mathrm{out}}_{S,I}$ representing relevant external entities (objects, events, social partners, affordances) in the environment. Both are $\mathbb{V}$-graphs.*

Remark 880 (Further intuition on what $M_{S,I}$ and $E_{S,I}$ are tracking)**.** *The interval parameter I is included to allow both networks to be context- and history-sensitive: the system's internal organization (what distinctions it makes salient, which memory items are active, which policies are available) may change over time, and the relevant external "world" being tracked may likewise shift (lighting changes, new interlocutors appear, different tools become available). Treating $M_{S,I}$ and $E_{S,I}$ as $\mathbb{V}$-graphs emphasizes that "edges" encode graded strengths of pattern-flow rather than binary relations: the same pair of nodes can have weak, moderate, or strong flow depending on the circumstances and on the semantics of $\mathbb{V}$.*

Remark 881 (Intuition: why two networks?)**.** *The internal network $M_{S,I}$ describes how patterns propagate within the system's own representational economy: which internal tokens lead to which others. The external network $E_{S,I}$ describes how patterns propagate in the environment as the system experiences or models it: which external events lead to which others, which affordances follow which contexts, and so on. By keeping these separate, Hyperseed avoids the simplistic assumption that the system's internal vocabulary is already "the same as" the world's vocabulary.*

A simple example is a robot with an internal node `heat_warning` *and an external node* `high_temperature`*. The system may need to learn a correspondence between these nodes even if their internal causal neighborhoods differ in detail. The value of this definition is that it sets up the exact mathematical situation in which a correspondence morphism can be sought.*

Remark 882 (Many-to-one, partiality, and re-encoding)**.** *Nothing in the setup requires f to be injective: distinct internal states can legitimately map to the same external entity when the system uses multiple internal encodings (e.g. a fast heuristic feature and a slower deliberative concept) that nevertheless pick out the same worldly regularity. Conversely, a single internal node may correspond only coarsely to a cluster of external nodes; in practice this is handled either by allowing $X^{\mathrm{out}}_{S,I}$ to contain suitably coarse-grained external entities (equivalence classes, macro-objects) or by viewing f as selecting a task-relevant proxy in the environment graph. If one wants to model representational "gaps" explicitly, one can also interpret the supremum over f as ranging over maps defined on a chosen subset of $X^{\mathrm{in}}_{S,I}$ (with the subset-selection encoded into the domain), but the present definition keeps the interface simple and delegates such choices to goal-conditioning below.*

Definition 223 (Mind–world correspondence score)**.** *The* mind–world correspondence score *of S on interval I is*

$$\mathrm{MWC}_S(I) := \bigvee_{f : X^{\mathrm{in}}_{S,I} \to X^{\mathrm{out}}_{S,I}} \deg(f; M_{S,I}, E_{S,I}).$$

*We say that S has θ-*mind–world correspondence *on I if* $\mathrm{MWC}_S(I) \geq \theta$*.*

Remark 883 (About the supremum $\bigvee$ and what is being optimized)**.** *The operator $\bigvee$ is the join/supremum in the order on $\mathbb{V}$ (or, when $\mathbb{V}$ is numerical, simply the least upper bound). Conceptually, $\mathrm{MWC}_S(I)$ is an "optimal achievable" alignment score: it asks for the best interpretive translation f available, rather than committing a priori to a particular hand-chosen decoding of internal states. When the set of candidate maps is finite (e.g. finite node sets), $\bigvee$ reduces to a maximum; in more general settings, $\bigvee$ expresses that correspondence is defined by an optimization principle even when a maximizer may not be unique (or may only be approached). This choice matches the intended role of $\mathrm{MWC}_S(I)$ as a capability-like quantity: a system should not be penalized for having multiple equally good internal codings of the same external structure.*

Remark 884 (How $\deg(f; M_{S,I}, E_{S,I})$ should be read)**.** *The degree $\deg(f; M_{S,I}, E_{S,I})$ measures how well the translation f preserves pattern-flow constraints from the internal graph to the external graph. Operationally, it can be read as the largest $q \in \mathbb{V}$ such that f is a q-approximate morphism (in the sense used throughout the pattern-flow formalism): higher q means that whenever there is strong internal flow from x to x', there is correspondingly strong external flow from $f(x)$ to $f(x')$. This is why $\mathrm{MWC}_S(I)$ is naturally interpreted as "world-model quality": it evaluates whether internal dynamics can be soundly reinterpreted as statements about the environment, rather than merely being internally coherent.*

Remark 885 (Intuition and examples for $\mathrm{MWC}_S(I)$)**.** *The score $\mathrm{MWC}_S(I)$ is the best achievable degree to which internal pattern-flow can be interpreted as external pattern-flow. It asks: is there a translation f from internal tokens to external tokens such that internal edge-structure (flow regularities) survives under interpretation?*

For example, if internally the system has a rule-like flow `see_red` $\to$ `stop` *and externally there is a flow* `red_light` $\to$ `cars_stop`*, then a map sending* `see_red` $\mapsto$ `red_light` *and* `stop` $\mapsto$ `cars_stop` *will score highly when these flows align. The usefulness is that correspondence becomes a measurable, composable quantity that can feed into capability profiles and control policies, without requiring perfect isomorphism between mind and world. A further advantage is that the criterion is inherently relational: it does not demand that individual nodes be "correctly named" or that internal tokens have any privileged semantics in isolation; it only demands that the transition/implication structure among tokens can be matched to a transition/implication structure among worldly entities.*

Remark 886 (Goal-conditioned correspondence)**.** *Hyperseed notes that mind–world morphisms are often strongest on the subgraphs most relevant to the system's active goals. A convenient formalization is to use a goal-dependent node-filter $U_{g,I} \subseteq X^{\mathrm{in}}_{S,I}$ and $V_{g,I} \subseteq X^{\mathrm{out}}_{S,I}$ representing the internal/external entities relevant to goal g on I. Define*

$$\mathrm{MWC}_S(I; g) := \bigvee_{f : U_{g,I} \to V_{g,I}} \deg\bigl(f; M_{S,I}|_{U_{g,I}}, E_{S,I}|_{V_{g,I}}\bigr).$$

The family $g \mapsto \mathrm{MWC}_S(I; g)$ can be used as one component of the capability profile $\mathrm{Cap}_S(I)$. In many systems, the filters $U_{g,I}$ and $V_{g,I}$ can be understood as formal counterparts of attention and state-abstraction: they specify which internal distinctions the system is actually deploying, and which external distinctions matter for success, for the particular goal and time window under consideration.

Remark 887 (Why goal-conditioning is philosophically natural)**.** *What counts as a "relevant" portion of the world is not fixed; it is indexed by purpose, attention, and action (Hyperseed-Concepts* **??***, 60, 87). Goal-conditioned correspondence makes this indexicality explicit, preventing the notion of world-model quality from silently smuggling in an observer-independent ontology. In Russell's idiom, it avoids treating "the world" as a single completed totality; it treats it as a structured field carved by inquiry and action. Put differently, it treats correspondence as a relation between an agent's operative semantics and a task-salient slice of environmental structure, rather than as a once-and-for-all alignment between two complete descriptions.*

Lemma 4 (Transport of predicted flow under correspondence)**.** *Assume $\mathbb{V}$ is ordered so that larger values mean "stronger flow". Let $f : X^{\text{in}}_{S,I} \to X^{\text{out}}_{S,I}$ be a q-approximate morphism from $M_{S,I}$ to $E_{S,I}$. Then for all internal nodes x, x',*

$$M_{S,I}(x, x') \otimes q \leq E_{S,I}(f(x), f(x')).$$

In particular, if the system uses $M_{S,I}$ as a predictive model of external flow (under the interpretation f), then the correspondence degree q provides an explicit lower bound on the predicted external flow strength.

Remark 888 (What this lemma says and why it is important)**.** *The lemma is the operational heart of mind–world correspondence: it says that an approximate morphism is exactly the kind of object that allows the system to* transport *predictions from internal dynamics to external dynamics. If q is high, then strong internal flow $M_{S,I}(x, x')$ guarantees strong external flow between the interpreted nodes; if q is low, the guarantee weakens accordingly. This makes correspondence actionable: the score is not merely a descriptive similarity measure, but a quantitative certificate about which inferences made in the internal model remain valid (up to degree q) when read as claims about the environment. It also clarifies why $\otimes$ appears: the same conjunction-like operator that combines evidence or flow within the $\mathbb{V}$-semantics is used to discount internal strength by the quality of the interpretation.*

Remark 889 (Practical reading: robustness, calibration, and failure modes)**.** *When $\mathrm{MWC}_S(I)$ is low, the system may still exhibit rich internal dynamics, but those dynamics do not reliably "latch onto" the environment: internal transitions may correspond to spurious correlations, hallucinated causal links, or purely self-referential loops. When $\mathrm{MWC}_S(I)$ is high only for certain goals g, the system may be well-calibrated in domains it actively trains on or attends to, while remaining poorly grounded elsewhere; this matches the empirical observation that competent behavior can be highly domain-local. In design terms, raising correspondence can be pursued either by improving $M_{S,I}$ (learning better internal predictive structure), improving $E_{S,I}$ (using a better external abstraction of the environment), or improving the map f (learning a better grounding/decoder); the definition is agnostic about which of these is the appropriate intervention.*

Remark 890. *This connects back to Section 14: prediction and control require not just a model, but a way to interpret model-variables as world-variables. Here that interpretive act is formalized as f, and its reliability is summarized by q. In particular, f plays the role of an "observational semantics" that turns internal distinctions (nodes and edges in the internal pattern-flow network) into externally meaningful distinctions (nodes and edges in the world pattern-flow network), so that claims like "x tends to lead to x'" can be transported to claims like "$f(x)$ tends to lead to $f(x')$." The scalar (or truth-degree) q is then a single, uniform lower bound on how well this transportation preserves edge-constraints across* all *internal pairs, thereby separating the questions "what is the agent internally representing?" (encoded by $M_{S,I}$) and "how accurate is that representation when interpreted externally?" (encoded by q and f together).*

Proof. Immediate from the definition of q-approximate morphism. More explicitly: the statement of the lemma is exactly the defining inequality (or its equivalent reformulation via the degree $\deg(\cdot;\cdot,\cdot)$), so no additional construction is required beyond instantiating the definition with the particular internal and external edge-structures under discussion. □

Remark 891 (Proof sketch and intuition)**.** Proof sketch. *Unpack the definition: $q \le \deg(f; M_{S,I}, E_{S,I})$ is equivalent to $M_{S,I}(x, x') \otimes q \le E_{S,I}(f(x), f(x'))$ for all x, x'. Here $\otimes$ is the monoidal product of the underlying truth-value/weight structure (e.g. a t-norm in a fuzzy setting, multiplication in a probabilistic-weight setting, or $\wedge$ in an order-theoretic setting), and $\le$ is the corresponding entailment/order on edge-weights; thus the inequality states that "internal support, discounted by q, is never stronger than the external support after interpretation."* □

There is no further trick: the lemma simply names, in predictive language, the inequality that constitutes "being an approximate morphism." Geometrically, q is the uniform amount by which internal edge strengths may be discounted so that the interpreted edges fit inside the world graph. Equivalently, q can be read as a global safety margin*: if $q = 1$ then f is fully structure-preserving at the level of edge-weights (an exact morphism in the chosen enrichment), while smaller q quantifies how much one must "shrink" internal claims to guarantee external validity. This is useful when internal edges encode strong expectations or control-relevant dependencies that are only partially realized in the world: the same f may remain meaningful even as conditions change, by lowering q to reflect reduced reliability rather than abandoning the interpretive mapping entirely.*

Remark 892 (Why this is a useful notion of "world model")**.** *A classical world model in AI typically consists of: (i) a representational vocabulary for external states, and (ii) a transition/prediction structure on that vocabulary. Mind–world correspondence adds two important generalizations: (1) it does not assume the internal vocabulary matches the external one; and (2) it measures fidelity by the existence of an approximate structure-preserving map, not by equality of probability distributions. This is well-suited to observer-relative modeling and to cases where multiple incompatible models coexist (paraconsistency). One consequence is that the internal model may be* coarser *(many-to-one) or* refined *(one-to-many, via auxiliary internal distinctions) relative to the world description, and the framework still assigns a clear quantitative notion of adequacy: the question becomes whether there exists an f that makes the internal transition claims conservatively true about the world, up to the uniform slack q. In contrast, equality (or close match) of full distributions typically presupposes a shared event space and a shared semantics of state variables; here those assumptions are replaced by an explicit correspondence map. Moreover, the approximate-morphism criterion aligns with the practical role of a model in control: for action selection, one often needs* sound *(non-overconfident) predicted constraints more than perfectly calibrated probabilities, and the inequality $M_{S,I}(x, x') \otimes q \le E_{S,I}(f(x), f(x'))$ is exactly such a soundness condition after interpretation. When the agent maintains multiple internal descriptions that disagree, paraconsistency becomes manageable because each description can be paired with its own (f, q) witness of partial correspondence, rather than forcing premature reconciliation into a single globally consistent probabilistic account.*

Remark 893 (Relation to transfer and abstraction)**.** *The use of a morphism f as an interpretation map parallels the role of representation mappings in transfer learning: one succeeds by finding a structure-preserving translation between domains. Hyperseed's stance is that "modeling the world" is itself a transfer problem between internal and external pattern-flow networks [7]. This also clarifies why mind–world correspondence is a natural ingredient in general intelligence: it is the quantitative form of "having the right abstractions" (Hyperseed-Concept 51). Concretely, if an agent has learned an internal pattern-flow network in a latent space (shaped by its sensors, embodiment, or prior tasks), then applying that competence to a new environment requires a map f that aligns latent* *nodes and transitions with externally meaningful ones; the parameter q then measures how much of the learned relational structure survives that alignment. In this sense, abstraction is not merely discarding detail, but creating internal variables whose induced transition structure admits a high-q morphism into a broad class of world-structures. This viewpoint also supports compositionality: when correspondences can be chained (e.g. internal $\to$ intermediate $\to$ external), one can interpret successive abstractions as composing morphisms, where the effective reliability degrades in a controlled way (typically through the monoidal product of the respective q values). Such compositional degradation formalizes an intuitive fact about transfer: each additional representational "gap" may introduce some loss, but good abstractions are exactly those for which the loss remains bounded and predictable across contexts.*

16.6 Space as a structure on which correspondences are defined

Hyperseed uses "space" in a broad sense: not only physical space, but also conceptual/semantic spaces on which similarity, neighborhood, and correspondences can be formulated. A pattern web already induces a notion of distance/similarity between entities. Here we package the minimal structure needed for correspondence-based reasoning. This connects to Space as a core notion (Hyperseed-Concept 173) and to the general idea that similarity is not merely geometric but can be representational and process-relative.

In particular, the relevant "space" may be tied to a task, a sensorimotor loop, or a model class: two entities can count as "near" when they are hard to distinguish by the agent's available measurements, when they afford similar actions, or when they play the same role in a recurrent process (even if they are far apart geometrically). This makes the choice of space part of the agent's theory of what distinctions matter, and it is precisely these distinctions that later support self/world separation and the persistence of identity across time.

Definition 224 (Enriched spaces)**.** *A* $\mathbb{V}$-space *is a* $\mathbb{V}$*-category* $\mathcal{S}$ *(objects with* $\mathbb{V}$*-valued hom/similarity) together with a chosen scalarization* $\|\cdot\| : \mathbb{V} \to [0,\infty]$*. The induced extended pseudo-metric on objects is*

$$d_{\mathcal{S}}(a,b) := \big\|\mathcal{S}(a,b)\big\|.$$

Depending on $\mathbb{V}$ *and* $\|\cdot\|$*, this may behave like a similarity, a cost, or a distance.*

A useful way to read Definition 224 is as a separation between (i) a compositional notion of comparison, encoded by enrichment (how comparisons compose along paths), and (ii) a numerical projection used for heuristics, thresholds, and optimization. The enrichment supplies the analogue of a "triangle inequality" at the $\mathbb{V}$-level (via composition in the $\mathbb{V}$-category), while the scalarization supplies a computable summary. In applications, the scalarization is often chosen to be monotone and to respect the intended direction of comparison (e.g. "larger in $\mathbb{V}$ means more similar" versus "larger means more costly"), but the definition is deliberately permissive: the agent may carry multiple scalarizations for different downstream uses (planning, clustering, anomaly detection), all over the same underlying enriched structure.

Remark 894 (Intuition and examples for $\mathbb{V}$-spaces)**.** *A* $\mathbb{V}$*-space is an enriched generalization of a metric space: instead of real-valued distances, we have* $\mathbb{V}$*-valued comparisons* $\mathcal{S}(a,b)$*. If* $\mathbb{V} = [0,\infty]$ *ordered oppositely and* $\otimes$ *is addition, then one recovers the Lawvere view of generalized metric spaces; if* $\mathbb{V} = [0,1]$ *with* $\otimes = \min$ *one obtains a fuzzy similarity space.*

The scalarization $\|\cdot\|$ *then turns enriched similarities into an ordinary extended pseudo-metric* $d_{\mathcal{S}}$ *that can be used for numerical reasoning (e.g. nearest neighbors), while preserving the option to work directly in* $\mathbb{V}$ *when composability is more important. This is useful because correspondence* *reasoning often needs both: categorical structure for compositional semantics and scalar distances for optimization.*

One practical intuition is that $\mathcal{S}(a, b)$ can encode *typed* or *structured* evidence of relatedness that would be lost by prematurely collapsing to a number. For instance, $\mathbb{V}$ could record not only a magnitude but also the "mode" of similarity (perceptual, functional, linguistic), or it could be a product quantale that combines independent channels of evidence. Scalarization then becomes an explicit design choice: when projecting to $[0, \infty]$, one decides how to trade off these channels, which in turn affects what the agent treats as stable identity versus incidental variation. This makes it easier to state, within the same formalism, both (a) hard correspondences induced by strong and consistent evidence, and (b) soft correspondences that are provisional and revisable.

It is also important that $d_{\mathcal{S}}$ is only required to be an *extended pseudo*-metric: distinct objects may have zero distance (indistinguishability at the agent's resolution), and distances may be infinite (no meaningful comparison available). Both behaviors occur naturally in developmental settings, where early representations may collapse many distinct world states, and later refinement splits them as new sensors, concepts, or actions become available.

Definition 225 (Correspondence space)**.** *Let $M = (X^{\text{in}}, M)$ and $E = (X^{\text{out}}, E)$ be $\mathbb{V}$-graphs. A* correspondence space *for (M, E) is a $\mathbb{V}$-space $\mathcal{S}$ together with maps $i : X^{\text{in}} \to \mathrm{Ob}(\mathcal{S})$ and $e : X^{\text{out}} \to \mathrm{Ob}(\mathcal{S})$. The pair (i, e) induces a $\mathbb{V}$-valued correspondence relation*

$$R_{\mathcal{S}}(x, y) := \mathcal{S}(i(x), e(y)) \qquad (x \in X^{\text{in}},\ y \in X^{\text{out}}).$$

This definition is intentionally weak: i and e need not be injective (multiple tokens can be embedded to the same point of $\mathcal{S}$, representing aliasing or abstraction), and they need not preserve any structure beyond whatever regularities are captured by the induced relation $R_{\mathcal{S}}$. In particular, i and e can be read as *representation functions*: they say how the agent chooses to represent internal items and external items in a common comparison medium. When these representation functions change over time (learning, sensor drift, concept acquisition), the correspondence space view still applies by treating i and e as time-indexed families, so that development becomes movement (or re-embedding) within a stable $\mathcal{S}$, or else co-development of $\mathcal{S}$ itself.

Remark 895 (Intuition: an interlingua for comparison)**.** *The correspondence space $\mathcal{S}$ plays the role of a shared medium in which internal and external entities can be compared. The maps i and e embed internal tokens and external tokens into this medium, and $R_{\mathcal{S}}(x, y)$ then measures how well internal token x matches external token y in the space.*

For example, if $\mathcal{S}$ is ordinary physical space, then i may map internal body-schema tokens to physical locations and e may map external objects to their locations, making correspondence spatial. If $\mathcal{S}$ is a semantic embedding space, then i and e may map tokens to vectors, making correspondence conceptual. The utility of this definition is that it supports a third mode of correspondence reasoning: not only by direct morphisms f, but also by metric/neighbor structure in $\mathcal{S}$ (Hyperseed-Concept 59).

The "interlingua" reading is especially apt when internal and external tokens have different native structures (different feature vocabularies, different temporal granularities, different modalities). Rather than forcing a direct alignment $X^{\text{in}} \leftrightarrow X^{\text{out}}$, one chooses $\mathcal{S}$ so that the agent can ask meaningful comparative questions: Which external candidates lie in the neighborhood of an internal hypothesis? Which internal states cluster around the same external referent? Which correspondences remain stable under small perturbations of sensors or attention? These are neighborhood questions, and they can be answered even when no single crisp morphism is yet justified.

Remark 896 (Interpretation). *A correspondence space provides an "interlingua" in which internal and external entities can be compared. When $\mathcal{S}$ is physical space (or spacetime), i and e may represent embodied localization. When $\mathcal{S}$ is a conceptual space, i and e encode semantic embeddings. In either case, approximate morphisms $M \to E$ can be seen as arising from (or inducing) regularities in $R_{\mathcal{S}}$.*

One can also regard $R_{\mathcal{S}}$ as a *field of constraints* that guides the search for morphisms. A high-quality morphism f typically selects, for each $x \in X^{\text{in}}$, an output $f(x)$ lying in a high-similarity region of the slice $y \mapsto R_{\mathcal{S}}(x, y)$, while also respecting relational constraints coming from the edges/flows of M and E. Conversely, if repeated successful morphisms are found over time, they provide empirical pressure to adjust i, e, or $\mathcal{S}$ so that the corresponding pairs become nearer, i.e. so that the interlingua becomes better adapted to the agent's world.

Remark 897 (Why introduce correspondence spaces if we already have morphisms?). *The morphism view (f with degree q) is crisp and compositional, but it chooses a single matching. A correspondence space supports softer, many-to-many relations: one can represent ambiguity and polysemy as neighborhoods rather than as a hard assignment. This is especially important in paraconsistent settings, where it may be rational for a system to retain multiple incompatible correspondences until further evidence or action resolves them [24, 23].*

In addition, the correspondence-space view makes explicit room for *partial* alignment. When the agent only knows how to compare some internal tokens to some external tokens (because other tokens are newly formed, occluded, or not currently observable), a crisp morphism may be forced to guess, whereas $R_{\mathcal{S}}$ can simply remain diffuse or uninformative on those pairs. This matters for continuity of self-models: the agent can maintain a persistent "core" alignment (e.g. body schema) while leaving peripheral correspondences unresolved, thereby avoiding the need to collapse uncertainty into premature commitments.

Example 14 (A minimal embodied correspondence sketch). *Consider a toy agent with internal nodes $X^{\text{in}} = \{\texttt{body}, \texttt{pain}, \texttt{reach}\}$ and external nodes $X^{\text{out}} = \{\texttt{arm}, \texttt{heat}, \texttt{cup}\}$. Suppose M encodes the internal regularity "pain follows heat-on-body" and "reach tends to precede cup-in-hand," while E encodes the external regularity "heat tends to follow contact between arm and heat source" and "cup-in-hand tends to follow reaching." A correspondence map f sending* `body` $\mapsto$ `arm`*,* `pain` $\mapsto$ `heat`*, and* `reach` $\mapsto$ `reach` *(if a matching external token exists) will have high degree precisely when these flow regularities align. The same data can be represented by a correspondence space $\mathcal{S}$ in which* `body` *and* `arm` *are close,* `pain` *and* `heat` *are close, and so on.*

In such examples, the self/other boundary (Section 16.1) can also be grounded: `body` *tends to be a persistent, highly self-evidenced node, while* `cup` *is typically other-evidenced, and* `pain` *may live on the paraconsistent boundary (both "me" and "not-me").*

To connect this sketch to continuity and development: if the agent experiences repeated episodes in which `reach` is followed by `cup`-contact and then by proprioceptive changes in `arm`, the neighborhood structure in $\mathcal{S}$ can support a stable triangulation between intended action, observed outcome, and body state. On this reading, "self" corresponds not to a single node but to a region (or subspace) of $\mathcal{S}$ that is repeatedly implicated by high-confidence internal–external correspondences across time, while "other" corresponds to regions that are only indirectly predictable or only sporadically coupled. This also clarifies how paraconsistency can be localized: incompatible evidence can be retained as multiple nearby candidates in $\mathcal{S}$ (a multi-modal neighborhood) until interaction reduces the ambiguity.

Remark 898 (Reading the example as a miniature theory of embodiment)**.** *The example shows how embodiment can be described without reducing "mind–world matching" to direct identity of variables. The correspondence f is justified not because* `pain` *and* `heat` *are the same thing, but because their* relational roles *in their respective networks align. In particular, what matters is that the incoming and outgoing constraints of the nodes (how they co-vary with other nodes, what they modulate, and what they are modulated by) are preserved up to the tolerance encoded by the enrichment: the match is a claim about structural position in a web of dependencies, not about shared intrinsic labels. This is precisely the structuralist spirit behind the morphism definitions. At the same time, the mention of the boundary illustrates how "self" is not merely the set of internal nodes: it is the subset that the system treats as self-evidenced, potentially with a nontrivial boundary region, echoing Self vs. Other (Hyperseed-Concept 165). One can read the "boundary region" as the locus where evidence is mixed or contested (e.g. partially self-generated and partially externally driven), so that self/other is not a crisp partition but a graded or even paraconsistent classification that can still support stable control policies. On this reading, embodiment is the practical situation in which the system must maintain a workable correspondence despite such mixed provenance, and the morphism formalism supplies a way to state when the correspondence is coherent enough to guide action.*

Summary of Hyperseed concepts handled in this section. The constructions above provide rigorous handles for:

- **Self/other boundary:** a (possibly paraconsistent) self-evidence function and induced self/other groupings. Here the function operationalizes "what counts as mine" as a rule for tagging states or flows, while allowing inconsistent or context-sensitive tagging without collapse.
- **Self-continuity:** existence (and degree) of high-weight approximate morphisms between successive internal pattern-flow networks. The weight (or enrichment value) makes continuity a matter of degree rather than an all-or-nothing identity, which matches the phenomenology of gradual change, interruption, and recovery.
- **Relative-information self-continuity:** proximity of time-slice networks under a scalar divergence. This provides a complementary summary statistic that can be compared across systems or scales, even when explicit node-to-node matching is underdetermined.
- **Reflective self-continuity:** flagged here, and developed further in Section 17 using self-model recursion. The key additional requirement is that some of the preserved structure is explicitly *about* the system's own continuity claims (i.e. meta-representations that constrain future updates).
- **Development:** continuity plus expanding capability profile. In the present language, capabilities correspond to families of morphisms or controlled transformations that become available, so development can be tracked as an enlarging repertoire together with sufficient diachronic coherence.
- **Pattern flow networks and mind–world correspondence:** approximate morphisms between internal and external flow networks. This treats "aboutness" as a map between relational structures (the dynamics of internal patterns and the dynamics attributed to the world), rather than as a static lookup table of symbols.

- **Space:** an enriched correspondence space on which mind/world embeddings can be compared. Concretely, this is the arena in which different candidate correspondences (or embeddings) can be measured against one another, so that "spatial" comparison is recovered as comparison of mappings by their induced distortions, costs, or constraint-violations.

Remark 899 (How these pieces compose with the rest of the document)**.** *Self/other boundary feeds into attention and control by determining what is treated as "inside" the locus of action (Sections 15 and 14). This matters because downstream optimization and resource allocation typically presuppose a boundary: credit assignment, risk attribution, and intervention selection all depend on which variables are treated as under the agent's remit versus merely observed. Self-continuity and development provide the diachronic scaffold needed for later discussions of reflective will and consciousness (Section 17), where closure and self-reference become explicit. In particular, without a notion of "same system over time" (even only approximately), recursive self-modeling would have no stable target, and reflective endorsement would be ill-posed. Mind–world correspondence is the bridge from internal pattern dynamics to external prediction and intervention, providing a quantale-valued measure of model adequacy that remains meaningful under vocabulary drift and paraconsistent evidence [19, 20]. The quantale-valued aspect is what allows adequacy to be aggregated and compared even when evidence is multi-graded or partially ordered (e.g. different kinds of constraint satisfaction that do not collapse to a single probability), and the paraconsistent tolerance is what prevents isolated contradictions from trivializing the evaluation. In this sense, the same enriched structure that supports "space" as a comparison domain also supports robustness of correspondence across re-parameterizations, relabelings, and incremental revision of the internal vocabulary.*

17 Consciousness, reflective will, and autonomy

17.1 Orientation: what gets formalized here

By this point in the reconstruction we have: (i) paraconsistent p-bit evidence values and a p-bit-quantale substrate (Section 3, especially Sections 3.2–3.4); (ii) pattern webs and habit dynamics (Sections 11–12); (iii) mind/representation/perception and semiotic modes (Section 13); (iv) prediction/control and temporal composition (Section 14); (v) attention and synergy as resource-allocation over competing processes (Section **??**); and (vi) self/continuity as a context-dependent boundary and a constraint on self-model evolution (Section 16).

Hyperseed's consciousness layer is not introduced as a new primitive, but as a *closure phenomenon* involving:

- *global accessibility* of some representational content ("what is present to experience"),
- *integration/coherence* across multiple subsystems (often mediated by resonance),
- *self-reference* in the weak (non-explosive) sense appropriate to paraconsistent settings,
- and *control leverage*: conscious contents can steer attention and action.

The goal of this section is to pin down a small mathematical interface for these ideas that is compatible with: (1) observer-relativity; (2) paraconsistency; and (3) resource sensitivity.

What is meant by "small interface" is that we are not trying to axiomatize everything that could be called conscious life, but to isolate the minimal structural commitments that let the earlier pieces talk to each other in a recognizably "conscious" regime. Concretely, the earlier machinery already provides (a) a semantics of graded, possibly inconsistent evidence; (b) a dynamics in which patterns stabilize into habits; and (c) an attentional scheduler that allocates limited computational and behavioral bandwidth. The present task is to specify when these ingredients collectively implement a *globally available, integrated, self-involving* representation that also has downstream causal consequences for control. In other words, consciousness will be treated as a particular kind of *functional closure* in the agent's ongoing inference–attention–action loop, rather than as an extra ontological ingredient.

It is important that all four bullets above are intended to be read in a way that respects paraconsistency. "Global accessibility" does not mean that all modules agree, or that a single classical "belief state" is broadcast without contradiction; rather, it means that certain representational items become accessible *as shared constraints* across multiple processes even when those processes maintain divergent or locally inconsistent p-bit valuations. Likewise, "integration/coherence" is not synonymous with full logical consistency: it is closer to the notion that, at the level relevant for control and report, the system achieves a stable working alignment between competing evidence streams, typically via resonance or other synergy mechanisms introduced earlier. A system can therefore exhibit conscious access to a content while still containing unresolved tensions (e.g., competing interpretations of the same stimulus), and the formalism must allow such tensions to be represented without collapse into triviality.

The emphasis on "control leverage" also ties this section to the forthcoming themes of reflective will and autonomy. A content is not merely conscious because it is present in some inner arena; it is conscious, in the present reconstruction, to the extent that it participates in the causal economy that selects policies, re-allocates attention, and reshapes habits. This point matters because the step from consciousness to autonomy is not made by adding a new faculty, but by showing how globally accessible and self-referential contents can *modulate* the very mechanisms that generate future attention distributions, action tendencies, and self-model updates. In this sense, reflective will is anticipated here as a special case of control leverage: the system can represent not only world-directed contents, but also the structure of its own decision situation (including conflicts, constraints, and higher-order preferences), and thereby change what it will do next under resource limitations.

Observer-relativity enters at two levels. First, "what is present to experience" is not treated as an absolute, system-independent predicate, but as indexed to a modeling context: different observers (or different internal meta-models) may disagree about which contents are globally accessible, or even about the granularity at which "contents" are individuated. Second, the closure phenomenon itself is evaluated relative to a chosen decomposition into subsystems and channels (perception, memory, valuation, motor control, etc.), so that the same underlying dynamics can be described at multiple scales. This is aligned with the earlier treatment of self/continuity as context-dependent: the boundary of "the experiencing system" and the boundary of "the conscious workspace" need not coincide, and both are subject to pragmatic constraints from modeling and control.

Resource sensitivity is similarly not an afterthought but a defining constraint. Global accessibility cannot be taken to mean unlimited broadcast; it must be implemented as a selective, capacity-limited mechanism that trades off precision, breadth, and speed. Integration is likewise bounded: coherence must be measured relative to limited attention and finite synergy budgets, rather than as an ideal limit of perfect mutual consistency. In paraconsistent terms, this means that the system may carry contradictions forward when the cost of resolving them exceeds the value, and that consciousness can co-exist with such tolerated inconsistency as long as the resulting closure remains stable enough to support coordinated action.

Remark 900. *Philosophically, the stance here is deliberately anti-mysterian: "consciousness" (Hyperseed-Concept 85) is treated neither as an ineffable substance nor as a mere synonym for behavior, but as a particular* organizational closure *in the dynamics of evidence, attention (Hyperseed-Concept 60), and control. The formalism is a kind of austere Russellian bookkeeping: we do not pretend to capture the whole phenomenology, but we insist that whatever consciousness is, it must show up as a stable pattern in the inferential and control economy of a bounded system [1, 19].*

17.2 A minimal interface: evidence states, workspace closure, and access

17.2.1 Languages and evidence states

Fix an observer/context Ob (a mind, or mind-plus-reality slice). Let $\mathcal{L}_{\mathrm{Ob}}$ be a finite (or at least well-founded) set of propositions the observer can represent at the current level of modeling granularity. Elements of $\mathcal{L}_{\mathrm{Ob}}$ may include:

- world propositions, e.g. "there is an apple on the table";
- bodily propositions, e.g. "the left arm is moving";
- internal propositions, e.g. "I feel tension" (self-report tokens in the sense of Section 13);
- relational propositions, e.g. "A tends to lead to B" (predictive implication from Section 14).

Definition 226 (p-bit evidence state)**.** *An* evidence state *for* Ob *is a map*

$$E : \mathcal{L}_{\mathrm{Ob}} \to \mathbb{V} = [0,1]^2, \qquad \varphi \mapsto E(\varphi) = (E^+(\varphi), E^-(\varphi)).$$

We order evidence states pointwise by the componentwise order on $\mathbb{V}$.

Remark 901. *Intuitively, an evidence state is the observer's current "epistemic posture" toward each representable proposition: $E^+(\varphi)$ is how much support there is for φ, while $E^-(\varphi)$ is how much support there is for "not-φ". The crucial choice is that we store* both *numbers explicitly rather than forcing them to sum to* 1 *(as in ordinary probability) or to be mutually exclusive (as in classical truth values). This is the* p-bit *move from earlier sections, aligned with constructive/paraconsistent semantics such as those explored in paraconsistent logics and their computational interpretations [23, 24].*

A simple example is a tiny language $\mathcal{L}_{\mathrm{Ob}} = \{\varphi, \psi\}$ where $E(\varphi) = (0.9, 0.1)$ (strongly supported) while $E(\psi) = (0.7, 0.8)$ (both supported and opposed). The latter represents a situation of genuine tension: the system has substantial evidence on both sides. The pointwise order means that $E \leq E'$ precisely when every proposition has no less *positive evidence and* no less *negative evidence in E' than in E; i.e. E' is, in this formal sense, "more evidenced" than E. This definition is useful because it makes the space of epistemic states into an ordered structure well-suited to monotone "closure" operators and fixed-point reasoning later in the section.*

Remark 902 (Paraconsistency is a feature)**.** *Allowing $(E^+(\varphi), E^-(\varphi))$ with $E^+(\varphi) + E^-(\varphi) > 1$ is essential to modeling: (1) borderline predicates ("soggy predicates" in Hyperseed's terminology; Hyperseed-Concept 172); (2) perceptual conflict (ambiguous or adversarial signals); (3) value conflict (next section; Hyperseed-Concept 198); and (4) self-referential modeling without explosion.*

Remark 903 (Granularity and well-foundedness)**.** *The "finite (or at least well-founded)" condition on $\mathcal{L}_{\mathrm{Ob}}$ is not intended to deny that agents can in principle form arbitrarily complex thoughts, but to delimit a* current *workspace-level interface at a given moment of modeling. In practice, $\mathcal{L}_{\mathrm{Ob}}$*

can be taken as the set of propositions currently expressible in the agent's active representational scheme (including compressed, schematic, or indexical propositions), while the well-foundedness assumption is what makes iterative closure constructions converge rather than chasing an infinite regress of ever-finer re-representations. This also matches the intended use of evidence states as interfaces*: they summarize what is currently at stake for the agent, not an exhaustive ontology of the world.*

17.2.2 Subsystem reports and attention-weighted integration

Let $\mathcal{M}$ be a finite index set of concurrently running subsystems/modules for Ob (perception streams, memory retrieval, imagination, verbal thought, somatic monitoring, etc.). Each module produces its own evidence state.

Definition 227 (Module evidence and attention weights)**.** *For each $m \in \mathcal{M}$, let*

$$E_m : \mathcal{L}_{\mathrm{Ob}} \to \mathbb{V}$$

*be the evidence state generated by module m. Let $a : \mathcal{M} \to [0,1]$ be an attention allocation, with $a(m)$ interpreted as the fraction of available cognitive resource dedicated to m (cf. Section **??**).*

Remark 904. *This definition separates two things that are often conflated in informal discussion: (i) what a module computes (its evidence state E_m), and (ii) how much the system is currently "listening" to that module (the allocation $a(m)$). A classical cognitive-science picture might call this a distinction between local processing and global broadcast; Hyperseed frames it in terms of genenergy bottlenecks and attentional focus (Hyperseed-Concept 60) [19].*

As a small example, one can imagine $\mathcal{M} = \{vision, memory\}$ and a proposition $\varphi =$ "there is a cat". Vision might output $E_{vision}(\varphi) = (0.8, 0.2)$ while memory, primed by a recent cat discussion, outputs $E_{memory}(\varphi) = (0.6, 0.4)$. If attention is mostly on vision, say $a(vision) = 0.9$, then vision dominates the integrated story; if attention shifts to memory, the integrated state changes without any change in the modules' intrinsic computations. This is useful because it gives a precise handle on the idea that "conscious content depends on attention" without reducing either to the other.

To combine module reports we use the p-bit-quantale operations. We need a way to treat a real attention weight as a quantale element.

Definition 228 (Scalar embedding into p-bit values)**.** *For $\alpha \in [0,1]$ define its* diagonal embedding *into $\mathbb{V}$ by*

$$\overline{\alpha} := (\alpha, \alpha) \in [0,1]^2.$$

Remark 905. *The diagonal embedding is the simplest way to regard a scalar "strength" α as affecting both positive and negative evidence magnitudes uniformly. It is not the only possibility, but it is the most conservative: α is treated as a resource-like multiplier rather than as a truth-value bias. For instance, $\overline{0.5} \otimes E_m(\varphi)$ will (given the* p-bit*-quantale tensor from Section 3.4) act like scaling down the module's contribution in a symmetric way.*

Remark 906 (Why uniform scaling is the right default)**.** *Uniform scaling is appropriate when attention is interpreted as* bandwidth or gain *rather than as* valence*. In that reading, allocating less attention to a module reduces the magnitude of whatever it would have contributed, regardless of whether that contribution is for or against a given φ. This matches the intended role of attention in a minimal interface: it gates access to the workspace rather than directly changing the module's internal epistemic stance. More expressive embeddings (e.g. scaling E^+ and E^- differently, or mixing them) can be treated as additional modeling assumptions about bias, framing, or motivated cognition, but are not required for the basic global-workspace story developed here.*

Definition 229 (Attention-weighted integration (pre-closure)). *Given module evidence states $\{E_m\}_{m\in\mathcal{M}}$ and attention weights a, define the* integrated pre-closure evidence state E_{pre} *by*

$$E_{\mathrm{pre}}(\varphi) \;:=\; \bigoplus_{m\in\mathcal{M}} \overline{a(m)} \otimes E_m(\varphi), \qquad \varphi \in \mathcal{L}_{\mathrm{Ob}},$$

where $\oplus$ and $\otimes$ are the p-bit*-quantale join and tensor (Section 3.4), applied pointwise over $\mathcal{L}_{\mathrm{Ob}}$.*

Remark 907. *The choice of $\oplus$ in the integration step implements a minimal "accumulation of support" picture: the workspace-facing state records whatever evidence is currently contributed by any attended module, without forcing premature reconciliation of conflicts. Because $\oplus$ is monotone and associative, increasing attention to a module or strengthening a module's own evidence state can only move E_{pre} upward in the pointwise order (i.e. toward "more evidenced"). This monotonicity is one of the reasons for setting the interface up in an order-theoretic way: it ensures that later closure steps (which will also be monotone) can be studied using fixed-point and convergence arguments rather than ad hoc case analyses.*

Note also that no normalization condition such as $\sum_{m\in\mathcal{M}} a(m) = 1$ is required for the definition to make sense: $a(m)$ is interpreted as a resource fraction relative to a maximal per-module gain, and the quantale operations already enforce the codomain constraint to $[0,1]^2$. If one does impose a normalization constraint, it can be viewed as an additional model of limited global resource, but it is not logically necessary for defining E_{pre}.

Remark 908 (Integration does not resolve contradiction). *Even after integration, it is possible (and often expected) that $E_{\mathrm{pre}}(\varphi)$ has both large positive and large negative components. This is not a bug: on the present view, "what is globally available" is not identical to "what is already consistent". The workspace can contain tensions (e.g. perceptual ambiguity, competing predictions, or value conflict) and the next modeling step—workspace closure—is where inferential propagation and constraint satisfaction are represented. Keeping contradiction visible at the interface level is precisely what prevents the system from spuriously collapsing into a single forced narrative when the underlying evidence is genuinely mixed.*

Remark 909. *This is useful because attention is meant to be a* capacity allocation *(genenergy budget) more than a semantic commitment: turning down attention should reduce how strongly a module's results enter the global workspace, regardless of whether those results are pro-φ or anti-φ. In later sections, one can generalize this to non-diagonal embeddings to model systematic biases (e.g. anxiety amplifying negative evidence), but the diagonal case provides a clean baseline. In particular, the diagonal case isolates the purely "gain control" role of attention: it scales a module's contribution without reinterpreting its internal polarity structure. This matters when one wants the algebra to distinguish* what *is represented (the evidence values themselves) from* how strongly *it competes for global access (the weight), so that attenuation can be understood as lowering broadcast priority rather than as a change of mind about φ.*

Definition 230 (Attention-weighted aggregation operator). *Define the integrated evidence state $\Gamma_a(\{E_m\}_{m\in\mathcal{M}})$ by*

$$(\Gamma_a E_\bullet)(\varphi) := \bigoplus_{m\in\mathcal{M}} \overline{a(m)} \otimes E_m(\varphi),$$

where $\oplus, \otimes$ are the join and tensor of the p-bit *quantale (Section 3.4), applied pointwise in φ.*

Remark 910. *Notation check: $E_\bullet$ is a convenient "bundle" notation for the family $\{E_m\}_{m\in\mathcal{M}}$, and $(\Gamma_a E_\bullet)(\varphi)$ denotes the $\mathbb{V}$-value assigned to proposition φ after aggregating all module contributions* *with weights $a(m)$. The symbol $\bigoplus$ is the quantale join over the finite index set $\mathcal{M}$, and the tensor $\otimes$ is the quantale's multiplicative operation; both act in $\mathbb{V} = [0,1]^2$ and here are applied separately for each proposition φ ("pointwise in φ").*

It is helpful to keep in view the ambient order: evidence states are compared pointwise *in φ, and values in $\mathbb{V} = [0,1]^2$ are compared componentwise (so "more evidence" means no less positive support and no less negative support, as determined by the order specified in Section 3.4). With this convention, both $\oplus$ and $\otimes$ are monotone in each argument, which ensures that increasing a module's evidence or increasing its attention weight cannot decrease the integrated result. This monotonicity is one of the reasons for using quantale operations rather than an ad hoc averaging rule.*

The overline in $\overline{a(m)}$ is doing conceptual work: it is the embedding that turns an attention scalar (a resource or gain parameter) into an element of the evidence-value algebra so that it can interact with $E_m(\varphi)$ via $\otimes$. In the diagonal baseline, this embedding treats positive and negative channels symmetrically, so that "listening less" to a module downweights its entire *evidential profile rather than selectively distorting one channel.*

Intuitively, Γ_a is a formal version of "what you get when you listen to multiple voices according to how much attention you grant them." A minimal example with two modules $m = 1, 2$ gives

$$(\Gamma_a E_\bullet)(\varphi) = \overline{a(1)} \otimes E_1(\varphi) \ \oplus \ \overline{a(2)} \otimes E_2(\varphi).$$

In this two-module case one can already see the separation between within-module *structure (whatever constraints relate $E_m(\varphi)$ across different φ) and* between-module *arbitration (implemented by $\oplus$ after attention-weighting). The join $\oplus$ should be read as an "integration" or "pooling" operation internal to the chosen semantics: it may behave like a max-like merge, a bounded sum, or another quantale join, but in all cases it provides a principled way of expressing that multiple sources can contribute to the global evidential standing of the same proposition.*

The utility of this definition is compositionality: once module outputs and attention weights live in the same algebraic setting, later "workspace closure" can be written as a map on evidence states without having to mention the modules again. Equally importantly, Γ_a makes explicit what parts of the story are architectural *(the choice of $\mathcal{M}$, the attention allocation a, and the integration rule) and what parts are* semantic *(the evidence values that the modules compute). This distinction will matter when comparing different hypotheses about deficits of access: e.g. whether a failure is due to low attention (small $a(m)$), weak local evidence (small $E_m(\varphi)$), or the downstream effects of workspace dynamics (the behavior of W below).*

Remark 911 (Interpretation)**.** *This makes explicit a Hyperseed-compatible picture:* conscious-accessible content is a product of representation plus attention*. Low-attention modules may still compute rich content, but it will not appear strongly in the integrated state unless it is "amplified" by attention. One can also read this as a minimal formal analogue of the common distinction between* availability *(a module has computed something) and* access *(that content is poised to influence report, planning, or control): Γ_a converts a distributed availability profile $\{E_m\}$ into a single access-oriented evidential profile by explicitly modulating each module with its current attentional gain. On this view, attention does not create representational content; it changes which already-computed contents become decision-relevant in the global aggregate.*

17.2.3 Global accessibility and workspace closure

Hyperseed's "conscious/unconscious" contrast can be modeled as a distinction between:

- content that is globally accessible for downstream reasoning/control/report; and

- content that exists in local modules but is not globally broadcast.

We model this using a *workspace closure* operator. The intended separation is thus not between two different ontological kinds of content, but between two regimes of *functional connectivity*: some information remains encapsulated (local), whereas some is placed into a format that can be consumed by many downstream processes (global).

Definition 231 (Workspace operator)**.** *A* workspace operator *is a monotone map*

$$W : \mathbb{V}^{\mathcal{L}_{\mathrm{Ob}}} \to \mathbb{V}^{\mathcal{L}_{\mathrm{Ob}}}$$

intended to represent the effect of "global broadcasting" and "cross-module stabilization": given an integrated evidence state E, the workspace produces a refined state $W(E)$ in which globally accessible propositions may be mutually reinforced, disambiguated, or inhibited.

Remark 912. *Notation check: $\mathbb{V}^{\mathcal{L}_{\mathrm{Ob}}}$ denotes the set of all functions $E : \mathcal{L}_{\mathrm{Ob}} \to \mathbb{V}$, i.e. all evidence states over the language. Thus W is an* operator on evidence states*. Monotonicity means: if $E \leq E'$ pointwise (every proposition has no less evidence in E'), then $W(E) \leq W(E')$.*

Intuitively, W stands in for whatever mechanisms make some contents "globally present": recurrent stabilization, cross-checking, binding, report preparation, etc. A very simple example is a workspace rule that enforces a single implication "φ implies ψ": it could map a state E to a new state $W(E)$ that increases $E^{+}(\psi)$ whenever $E^{+}(\varphi)$ is high. More generally, one can think of W as encoding a family of (possibly soft) constraints among propositions in $\mathcal{L}_{\mathrm{Ob}}$ that only become effective once information is broadcast into a shared arena: consistency pressures, binding constraints (e.g. linking a feature to an object), winner-take-most competitions, or normalization steps that reduce ambiguity by distributing support across mutually exclusive hypotheses.

The definition is useful because it packages all such cross-module interactions into one map, so that consciousness can be analyzed as a property of the map's fixed points rather than as a mysterious extra ingredient. In particular, the map-based view allows one to ask structural questions about the workspace independently of any specific module architecture: e.g. whether W tends to sharpen evidence into stable patterns, whether it admits multiple distinct stable states (supporting a notion of multistability), and how sensitive stable states are to small changes in the integrated input.

It is also useful to note that this is deliberately stated at the level of a single-step *operator. In applications, one may imagine iterating W (or iterating W interleaved with renewed integration) until changes become negligible, and then treating the resulting stabilized state as the workspace-resolved outcome. The fixed-point formulation below captures the equilibrium notion without committing to any particular implementation of the iterative dynamics.*

Remark 913 (What monotonicity means here)**.** *Monotonicity is the minimal sanity constraint: if all modules provide at least as much positive/negative evidence for every proposition, then the workspace should not reduce evidence. More sophisticated models may introduce inhibitory competition via additional state variables, but the present reconstruction stays deliberately lightweight. In this lightweight setting, inhibition is modeled (when needed) not by literally decreasing evidence when inputs increase, but by how the workspace may preferentially* increase *some propositions more than others in response to the same increment of input, thereby changing comparative salience while preserving the basic "more in, no less out" ordering. This keeps the formalism compatible with the idea that the workspace is a stabilizing broadcast mechanism rather than an adversarial filter that destroys information.*

Definition 232 (Conscious content as a fixed point). *An evidence state E is* workspace-stable *if $W(E) = E$. We define a* conscious evidence state *to be a workspace-stable state that is reachable from module integration, i.e. of the form*

$$E = W\big(\Gamma_a(E_\bullet)\big) \quad \textit{for some module collection } E_\bullet \textit{ and attention } a.$$

Remark 914. *The fixed-point condition $W(E) = E$ is the formal avatar of "closure": once the content is broadcast and mutually adjusted, it does not immediately change under the same broadcasting dynamics. In other words, a conscious evidence state is not merely a momentary aggregate, but a* self-consistent global posture *of the system's representational economy. This aligns with the Hyperseed emphasis that consciousness is stabilized accessibility, not a raw data dump. The additional reachability condition (being of the form $W(\Gamma_a(E_\bullet))$ for some inputs) prevents the definition from treating* every *abstract fixed point of W as conscious: it ties workspace-stable states to those that can actually be produced from the system's modules under some attention allocation. Conceptually, this separates "mathematical equilibria" from "attainable equilibria," mirroring the architectural idea that conscious contents arise from the interaction between what modules deliver and what the workspace can stabilize and broadcast.*

Finally, note that the definition leaves open whether conscious states are unique: different attentional settings a, or different module bundles $E_\bullet$ (e.g. reflecting different sensory inputs or internal memory retrievals), may lead to different workspace-stable outcomes. This provides a clean place to later discuss phenomena like context dependence, priming, and multistable perception as differences in which reachable fixed point (or approximate fixed point) is selected.

Remark 915. *As an example, suppose W enforces that "if pain is present then I am aware of pain" by boosting a proposition I(pain) whenever pain is supported (we implement this more explicitly below with introspection). One can think of this as a minimal "linking rule" from first-order content to a matching higher-order access claim: W does not create pain evidence ex nihilo, but it ensures that, once pain has become salient enough to enter the workspace dynamics, the corresponding access marker is also made available for downstream use (e.g., for verbal report, control, or memory routing). Then a workspace-stable state cannot have strong pain evidence but zero evidence for awareness of pain; closure forces a consistency relation at the level of access. In this sense, workspace closure behaves like an access-level coherence condition: it suppresses configurations in which the system would be poised to act as if pain is present while simultaneously lacking any globally available representation that it is aware of pain. This is intentionally weaker than an identity claim between pain and awareness-of-pain; it is merely a constraint on which evidence profiles can be stable once W has done its organizing work. The definition is useful because it lets us separate two questions: (i) what modules compute and attention selects (Γ_a), and (ii) what becomes globally organized and reportable (W). Equivalently, Γ_a concerns the formation and prioritization of candidate contents, whereas W concerns the system-level integration that turns some of those contents into accessible, mutually supporting commitments that can guide centralized decision and communication.*

Remark 916 (Conscious vs unconscious). *Given a workspace-stable state E, one can define (for a chosen threshold $\theta \in (0,1)$) the* conscious proposition set

$$\mathrm{Con}_\theta(E) := \{\varphi \in \mathcal{L}_{\mathrm{Ob}} : E^+(\varphi) \geq \theta\}$$

and treat the complement as "unconscious" at that moment. Formally, $\mathrm{Con}_\theta(E)$ is monotone in the expected direction: if $\theta' > \theta$ then $\mathrm{Con}_{\theta'}(E) \subseteq \mathrm{Con}_\theta(E)$, so raising the bar yields a stricter notion of what counts as conscious. This allows one to model "degrees" of access without changing the *underlying evidence state: the same E can support a thin conscious set (high θ) or a thick one (low θ), depending on how demanding we want the operational criterion to be. This is not meant as a metaphysical claim; it is a modeling move that operationalizes the conscious/unconscious boundary in observer-relative terms. In particular, the threshold is a tool for linking the graded internal quantities $E^+(\varphi)$ to binary behavioral predicates (e.g., "reportable now" or "available for deliberate choice") that often appear in experiments and in ordinary descriptions.*

Remark 917. *The thresholding move is deliberately pragmatic: it turns graded evidence into a crisp set that can be used to define reports, action conditions, or "what is currently in mind". It also makes explicit that the model is not committed to a sharp boundary in the mechanism itself: the sharpness is introduced by the analyst as a way to interface a continuous internal description with discrete explanatory targets such as yes/no report, categorical memory encoding, or rule-based action selection. Different observers or modeling contexts may choose different θ, reflecting different granularities of introspective access and different criteria for "present to experience." For example, a coarse-grained behavioral readout may justify a higher θ (only very strong evidence counts as conscious), while a fine-grained phenomenological or neural readout may justify a lower θ (allowing weak but systematic availability to count). This observer-relativity is not a bug: it is consistent with the broader Hyperseed stance that many ontological boundaries are context-indexed constructions rather than absolute partitions. In that spirit, the model can also accommodate intermediate categories (e.g., "fringe" or "preconscious" contents) by considering multiple thresholds or by tracking how close $E^+(\varphi)$ is to θ, without changing the underlying definition of workspace stability.*

17.3 Reflective consciousness as higher-order representational closure

Hyperseed distinguishes ordinary consciousness from *reflective consciousness*. The simplest way to capture the difference is:

- ordinary consciousness: workspace-stable integration of world/body/internal content;
- reflective consciousness: workspace-stable integration that includes *meta-content* about the agent's own representations and attention.

Remark 918. *This contrast parallels a familiar philosophical distinction between merely having experiences and also* taking oneself *to be having them. But the present reconstruction refuses to treat this as an unanalysable "light" added on top of cognition. Instead, reflective consciousness is characterized by adding a further layer of representational tokens and requiring that the global workspace stabilize* including *those tokens. In Hyperseed terms, reflective consciousness is a particular kind of stable self-reference enabled by paraconsistency rather than forbidden by it (compare Hyperseed-Concept 84 and 166).*

17.3.1 Adding a reflective layer

Introduce a syntactic operator $\mathsf{I}(\cdot)$ producing "introspective" propositions. For each $\varphi \in \mathcal{L}_{\mathrm{Ob}}$, $\mathsf{I}(\varphi)$ is read as "Ob is aware of φ" (or "φ is present to experience").

Definition 233 (Reflective language extension)**.** *Define the* reflective extension *of the language by*

$$\mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}} := \mathcal{L}_{\mathrm{Ob}} \ \cup \ \{\mathsf{I}(\varphi) : \varphi \in \mathcal{L}_{\mathrm{Ob}}\}.$$

An evidence state on $\mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}}$ is a map $E : \mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}} \to \mathbb{V}$.

Remark 919. *Intuitively, $\mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}}$ doubles the vocabulary: for every base proposition φ we include a corresponding meta-proposition saying "φ is in awareness". This is not claimed to be psychologically exhaustive; it is a minimal representational hook that lets the model distinguish between (i) a proposition being supported somewhere in the system and (ii) that proposition being* accessible as experienced content*. In Russellian terms, we introduce a new set of propositions that talk about the* status *of propositions, thus allowing the theory to make "aboutness of aboutness" explicit.*

A simple example: if φ is "there is an apple" then $\mathsf{I}(\varphi)$ is "I am aware that there is an apple" or "the apple is present to experience." The definition is useful because it makes reflective consciousness an ordinary fixed-point/stability question in an enlarged evidence space, rather than a sui generis phenomenon.

Definition 234 (Introspection operator)**.** *An* introspection operator *is a monotone map*

$$\mathsf{Int} : \mathbb{V}^{\mathcal{L}_{\mathrm{Ob}}} \to \mathbb{V}^{\mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}}}$$

that assigns evidence to introspective propositions based on base evidence. A minimal choice is:

$$\big(\mathsf{Int}(E)\big)\big(\mathsf{I}(\varphi)\big) := \big(E^{+}(\varphi),\ 1 - E^{+}(\varphi)\big),$$

*but more realistic choices incorporate attention (Section **??**) and coherence (resonance, Section 3.9).*

Remark 920. *The minimal choice says: "awareness of φ tracks positive support for φ." It is intentionally crude, but it has two virtues: it is monotone, and it makes introspective support computable from the same evidence quantities already present. More elaborate* Int *can (and in realistic modeling should) depend on attention and workspace organization: one may have high $E^{+}(\varphi)$ in a local module but low evidence for $\mathsf{I}(\varphi)$ if attention is elsewhere.*

For example, let φ be "background music is playing." A perception module may support φ strongly, yet if the system is deeply focused on a math problem, attention to that stream is low and introspective awareness of the music may be absent. The usefulness of Int *is that it gives a formal bridge from first-order content to meta-content, enabling a precise statement of reflective closure and self-reference in a paraconsistent setting [23, 24].*

Remark 921. *It is also important that $\mathsf{I}(\cdot)$ is treated here as a* representational *operator rather than a factive epistemic one: $\mathsf{I}(\varphi)$ is not read as "φ is true and known to be true," but as "φ is tokened in a way that is globally available as experience." This matches the intended use in global-workspace-style models, where what matters for consciousness is accessibility and stabilization, not guaranteed veridicality. Accordingly, $\mathsf{I}(\varphi)$ can be present even when φ is false, and (conversely) φ can be well-supported in a peripheral subsystem without $\mathsf{I}(\varphi)$ being supported.*

Remark 922 (Paraconsistent self-reference)**.** *Nothing prevents the model from supporting evidence for both $\mathsf{I}(\varphi)$ and $\mathsf{I}(\neg\varphi)$ simultaneously. This is a direct formal analog of "I am aware of conflicting impressions" without collapse into triviality.*

17.3.2 Reflective workspace closure and a fixed-point existence theorem

Let W^{ref} be a workspace operator on the reflective language:

$$W^{\mathrm{ref}} : \mathbb{V}^{\mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}}} \to \mathbb{V}^{\mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}}}.$$

Combine module integration, introspection, and workspace closure into a single update map.

Definition 235 (Reflective update map)**.** *Fix attention a and module evidence $E_\bullet$ on $\mathcal{L}_{\mathrm{Ob}}$. Define the* reflective update *map*

$$F := W^{\mathrm{ref}} \circ \mathsf{Int} \circ \Gamma_a,$$

with codomain $\mathbb{V}^{\mathcal{L}^{\mathrm{ref}}_{\mathrm{Ob}}}$.

Remark 923. *The intended reading of the composition is operational: Γ_a performs attention-weighted integration of first-order contents into a candidate workspace state;* Int *then generates (or updates) the corresponding introspective tokens $\mathsf{I}(\varphi)$; finally, W^{ref} imposes the global-workspace constraint* on the extended state *in which first-order and meta-level tokens co-determine stability. On this picture, reflective consciousness is not a separate process added after ordinary integration, but a closure condition for a larger state space in which awareness-claims are among the stabilized representations.*

Definition 236 (Reflective closure / reflective consciousness state)**.** *An evidence state $E^* \in \mathbb{V}^{\mathcal{L}^{\mathrm{ref}}_{\mathrm{Ob}}}$ is* reflectively closed *(with respect to F) if it is a fixed point:*

$$F(E^*) \;=\; E^*.$$

When such a fixed point is reached (or approximately reached under iterative dynamics), the model treats the agent as being reflectively conscious in the sense that the workspace has stabilized over both object-level content and the corresponding introspective/meta-content.

Remark 924. *This definition makes the higher-order aspect precise: what is stabilized is not only φ-tokens about the world/body/internal state, but also $\mathsf{I}(\varphi)$-tokens about what is* present. *In particular, the model distinguishes (a) stable first-order representations without stable $\mathsf{I}(\cdot)$ support (a formal analog of "processing without reportable experience") from (b) stable joint support for φ and $\mathsf{I}(\varphi)$ (a formal analog of reportable, globally accessible experience). Because the workspace operates over $\mathcal{L}^{\mathrm{ref}}_{\mathrm{Ob}}$, the availability of meta-content can feed back into which first-order propositions remain stable, capturing the intuitive idea that "noticing" something can itself reorganize what is experienced.*

Theorem 15 (Fixed-point existence under monotonicity)**.** *Assume Γ_a,* Int*, and W^{ref} are monotone with respect to the pointwise order on evidence states (inherited from the order on $\mathbb{V}$). Then the reflective update map*

$$F = W^{\mathrm{ref}} \circ \mathsf{Int} \circ \Gamma_a$$

is monotone, hence (on the complete lattice $\mathbb{V}^{\mathcal{L}^{\mathrm{ref}}_{\mathrm{Ob}}}$) admits at least one fixed point. Moreover, F has a least fixed point and a greatest fixed point.

Remark 925. *The theorem expresses the "closure" idea in a mathematically standard way: if the dynamics are order-preserving, then reflective stabilization is guaranteed in the sense of fixed-point existence (even when the contents stabilized may be paraconsistent). Interpretively, the least fixed point can be read as the minimal reflectively closed workspace compatible with the update rules, while larger fixed points represent richer stabilized profiles of both object-level and introspective tokens. In applications, one typically studies the iteration $E_{t+1} := F(E_t)$ and asks when (and in what sense) it converges, using the fixed points as attractors or equilibrium candidates for reflectively conscious episodes.*

Remark 926. *This is the formal "assembly line" of reflective consciousness in one equation. Starting from distributed module reports, Γ_a builds an integrated base evidence state; then* Int *adds meta-evidence about what is present to awareness; then W^{ref} applies the global stabilization/broadcasting* *dynamics in the enlarged language. The composition order matters: it reflects a modeling judgment that introspective tokens are built from base content (and its attention-mediated integration) and then are themselves subject to workspace-level reinforcement, inhibition, and coherence constraints.*

A minimal example is: a sensory module yields evidence for φ; attention is high; introspection adds $\mathsf{I}(\varphi)$; the reflective workspace then may propagate this to further tokens like "I am attending to φ" (if included in the language) or may suppress contradictions. The usefulness of the definition is that it makes reflective consciousness amenable to standard order-theoretic tools: we can ask when F (or a variant) has fixed points and how they are selected. Moreover, reading the pipeline left-to-right helps separate three distinct roles that are often run together in informal discussions: (i) integration *of first-order contents (modeled by Γ_a), (ii)* re-representation *of those contents as available-to-awareness (modeled by* Int*), and (iii)* global constraint satisfaction and propagation *over the resulting mixed vocabulary (modeled by W^{ref}). In particular, the model does not assume that introspection is infallible or "transparent": since we work in an evidence lattice,* Int *can add graded support and/or graded counterevidence for reflective propositions, allowing misintrospection, uncertainty about one's own states, or even simultaneous partial evidence for and against $\mathsf{I}(\varphi)$ without trivialization.*

To speak about fixed points we consider the complete lattice $\mathbb{V}^{\mathcal{L}^{\mathrm{ref}}_{\mathrm{Ob}}}$ with pointwise order. Concretely, an element of $\mathbb{V}^{\mathcal{L}^{\mathrm{ref}}_{\mathrm{Ob}}}$ assigns to each sentence $\psi \in \mathcal{L}^{\mathrm{ref}}_{\mathrm{Ob}}$ a pair of values in $\mathbb{V} = [0,1]^2$ (e.g. degrees of support and counter-support), and the pointwise order compares such assignments proposition-by-proposition. This is the natural setting for treating reflective updates as global operators on entire evidence *profiles*, rather than as isolated updates to single tokens.

Theorem 16 (Existence of reflective conscious fixed points)**.** *Assume W^{ref} and* Int *are monotone and $\mathcal{L}^{\mathrm{ref}}_{\mathrm{Ob}}$ is finite (or more generally that $\mathbb{V}^{\mathcal{L}^{\mathrm{ref}}_{\mathrm{Ob}}}$ is a complete lattice). Then the operator*

$$\widehat{W} := W^{\mathrm{ref}} \circ \widehat{\mathsf{Int}} \quad \textit{on} \quad \mathbb{V}^{\mathcal{L}^{\mathrm{ref}}_{\mathrm{Ob}}}$$

admits at least one fixed point, where $\widehat{\mathsf{Int}}$ is any monotone extension of introspection that can read reflective propositions as input (e.g. by ignoring them or by treating them as additional signals). In particular, $\widehat{W}$ has a least fixed point and a greatest fixed point.

Remark 927. *In plain language, the theorem says: if your reflective workspace update rule is monotone, then "reflectively stable" global states are guaranteed to exist. This is important because self-reference is often thought to invite paradox; in classical logic, naive self-reference can indeed be explosive. Here, by working in an ordered paraconsistent evidence lattice and using monotone closure, we obtain an existence guarantee rather than a contradiction. This theorem thus connects directly to the Hyperseed theme that "weak" (non-explosive) forms of self-reference are not only possible but structurally natural in bounded cognitive systems [2, 3]. A useful way to read the monotonicity requirement is as a "no retraction of evidence by fiat" constraint: when the input state is informationally larger (more support and/or more counterevidence, in the lattice order), the output is not allowed to become informationally smaller. This captures, at an abstract level, the idea that the workspace dynamics are a kind of closure or propagation process rather than a capricious rewrite rule; it is precisely this closure-like behavior that makes fixed-point existence the default expectation rather than a delicate special case.*

The result also connects forward: later, when we talk about reflective will and autonomy as fixed points of meta-control maps, we again rely on the idea that monotone self-modification dynamics can have stable regimes; compare the use of fixed-point theorems to analyze stability of self-modifying goal systems [10]. In that later application, the presence of multiple fixed points should be interpreted *as a formal analogue of multiple admissible "self-stabilizing" agent regimes (e.g. different coherent reflective stances), with least/greatest fixed points providing extremal anchors among them.*

Proof. The set $\mathbb{V}^{\mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}}}$ is a complete lattice under pointwise order because $\mathbb{V} = [0,1]^2$ is a complete lattice under componentwise order and products of complete lattices are complete. By monotonicity, Tarski's fixed point theorem applies, yielding existence of least and greatest fixed points of $\widehat{W}$. One may also note that the "finite language" hypothesis is a convenient sufficient condition: if $\mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}}$ is finite, then the product lattice is automatically complete, so no additional set-theoretic assumptions are needed to ensure existence of arbitrary joins and meets. □

Remark 928. Proof sketch. *The strategy is purely order-theoretic: build a big ordered space of possible reflective evidence states, check that it has enough completeness (all joins/meets exist), and then invoke the general fixed-point principle that monotone maps on complete lattices must have fixed points. No special properties of the particular* p-bit *operations are needed beyond completeness and monotonicity. This robustness is part of the point: the existence claim is intended to survive a wide range of choices for how evidence is aggregated, so long as those choices respect the underlying order.*

The key step is recognizing $\mathbb{V}^{\mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}}}$ as a product lattice: each proposition contributes a copy of $[0,1]^2$, and the product of complete lattices is complete. Once this is in place, Tarski's theorem does the heavy lifting. If one wants a visual intuition, imagine iterating $\widehat{W}$ from the "least evidence" state and watching evidence accumulate monotonically until it can no longer increase; this limiting state is the least fixed point. Dually, iterating downward from the top element yields the greatest fixed point. In many cognitive readings, the least fixed point can be interpreted as the minimally committed reflective stabilization compatible with the dynamics (only what is forced by closure), whereas the greatest fixed point represents a maximally saturated stabilization (everything that can be maintained without violating the order constraints). Nothing in the theorem requires that the fixed point be unique; rather, the lattice-theoretic framework anticipates the possibility of multiple stable reflective equilibria, which can be selected among by additional constraints (e.g. cost, simplicity, or policy-level preferences) not encoded in monotonicity alone.

Remark 929 (Interpretation)**.** *Theorem 16 is a small but useful "sanity anchor": it ensures that if one models reflective consciousness as a closure process on a paraconsistent evidence lattice, then reflective conscious states exist as fixed points. This matches the Hyperseed intuition that reflective awareness is a* stabilized *regime of self-referential modeling rather than a one-shot predicate. It also clarifies what kind of mathematical object a "reflective conscious state" is in this setup: not a single privileged sentence, but a whole valuation over an enriched language that includes both world-directed claims and (possibly fallible) claims about what is present to awareness. Finally, the extremal fixed points provided by Tarski offer canonical reference states even when empirically plausible dynamics admit many equilibria; they supply baseline targets for subsequent questions about selection, robustness under perturbation, and the effect of adding further reflective operators to $\mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}}$.*

17.4 Resonance and coherence as stability selectors

In Hyperseed, resonance functions both as: (i) a dynamical amplifier (habit reinforcement, morphic resonance; Section 12); and (ii) an experiential signature of coherence vs conflict (motivational resonance; see also the core construction in Section 3.9).

Here we use resonance as a *selector* among the fixed points guaranteed by Theorem 16. Concretely, the existence of multiple fixed points can be read as the formal analogue of multiple internally stable "interpretations" or "self-consistent closures" of the same evidential situation; resonance is then the additional principle that ranks (or biases trajectories toward) some closures rather than others. In other words, the closure theorem supplies *possibility* (stable self-maps exist), while resonance supplies *preference* (some stable self-maps are lived as coherent, others as fragmented or tense).

Remark 930. *The existence theorem above is generous: a monotone closure map may have many fixed points. Phenomenologically, however, consciousness is not an arbitrary fixed point; it has a felt signature of coherence, dissonance, tension, and release (Hyperseed-Concept 159 and 97). The role of resonance here is to provide a principled mechanism for preferring some stable closures over others, echoing the broader Hyperseed account of pattern emergence and reinforcement (Hyperseed-Concept* **??**, *130, and 115) [5, 13]. A useful way to think about this is as a two-stage constraint: (a) a workspace dynamics imposes logical and evidential closure, producing a set of fixed points compatible with monotonic updating; (b) a resonance criterion then acts like a Lyapunov-style or energy-style selector that makes some fixed points attractors (or makes them more robust against perturbation), while others remain merely mathematically admissible. This distinction mirrors the everyday fact that many "interpretations" of oneself and the world are compatible with the available evidence, yet only some are experienced as settling, integrated, or action-guiding.*

17.4.1 Coherence scores from paraconsistent evidence

Assume we have a logic-to-complex mapping σ_C as in Section 3.9. For an evidence state E and a chosen feature map Φ from propositions to vectors (e.g. by stacking $\sigma_C(E(\varphi))$ for a designated list of propositions), define a coherence score. The key modeling move is that σ_C allows one to treat paraconsistent structure as a signal in a continuous space, so that "coherence" can be computed, compared, optimized, and coupled to dynamics, rather than remaining a purely qualitative label.

Definition 237 (Coherence functional)**.** *Let $\mathcal{K} \subseteq \mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}}$ be a finite set of propositions regarded as the "currently relevant workspace contents" (this may depend on attention and task). Define*

$$z_E \in \mathbb{C}^{|\mathcal{K}|}, \qquad (z_E)_\varphi := \sigma_C\big(E(\varphi)\big),$$

and define the coherence functional

$$\mathrm{Coh}(E) := \frac{1}{|\mathcal{K}|} \sum_{\varphi \in \mathcal{K}} |(z_E)_\varphi|^2.$$

Remark 931. *Notation check: $\mathcal{K}$ is a finite index set of propositions; $|\mathcal{K}|$ is its cardinality. The vector z_E has one complex coordinate for each $\varphi \in \mathcal{K}$, obtained by applying σ_C to the* p-bit *value $E(\varphi)$. The modulus $|(z_E)_\varphi|$ is the usual complex absolute value, and $\mathrm{Coh}(E)$ is the mean squared magnitude over the chosen proposition set.*

Intuitively, this turns a structured paraconsistent evidence configuration into a single scalar that can play the role of a "stability" or "coherence" signal. A simple example: if σ_C maps high net support to large real magnitude, then a workspace state with many strongly supported propositions yields high $\mathrm{Coh}(E)$. If instead σ_C maps tension to imaginary magnitude, then a state full of conflicts also yields high $\mathrm{Coh}(E)$ (but in a different complex direction), allowing the modeler to decide whether to favor or penalize tension, as in paraconsistent resonance constructions [24]. This is useful because it provides an explicit numerical criterion to prefer one fixed point over another, rather than appealing to an informal "coherence" notion.

One can also unpack the contribution of each proposition: if $(z_E)_\varphi = a_\varphi + ib_\varphi$, then $|(z_E)_\varphi|^2 = a_\varphi^2 + b_\varphi^2$. Thus the chosen σ_C implicitly defines which aspects of evidential state count as "large": pure support-dominant regimes correspond to a_φ dominating, while conflict/energy-dominant regimes correspond to b_φ dominating. The squared magnitude is convenient because it is additive across coordinates and insensitive to global phase conventions, but it is not the only possible choice; it is simply a minimal functional that is (i) nonnegative, (ii) decomposable across propositions, and (iii) compatible with treating σ_C as a feature embedding.

Remark 932 (Reading). *Large $|(z_E)_\varphi|$ corresponds (by design of σ_C) to either strong net support (real part) or strong paraconsistent tension/energy (imaginary part). Depending on modeling goals, one can prefer net support, prefer "energized tension", or penalize tension. The point is not the specific formula but the existence of a principled bridge from* p-bit *evidence patterns to a continuous stability/interaction signal. A further modeling degree of freedom lies in the choice of $\mathcal{K}$: taking $\mathcal{K}$ to be attention-weighted makes coherence explicitly state-dependent, while taking $\mathcal{K}$ to include self-referential and meta-level propositions makes coherence sensitive to reflective consistency rather than only object-level consistency. In this sense,* $\mathrm{Coh}(E)$ *can be read as a task- and attention-conditioned "felt integrity" measure: it is not a global property of an agent's total belief state, but of the currently active workspace slice that is available for report, control, and reflective endorsement.*

17.4.2 Reflective consciousness as coherence-weighted closure

A simple way to model "states of consciousness" is to treat the workspace operator W^{ref} as depending on parameters controlling:

- external coupling (how strongly sensory evidence anchors the workspace),
- internal coupling (how strongly association/imagination fills in content),
- reflective gain (how strongly introspection amplifies meta-content),
- and coherence preference (how strongly the workspace selects coherent states).

The last parameter is the locus at which resonance enters as a stability selector: it does not create new logical consequences, but changes which closures become salient, persistent, or self-reinforcing under iteration.

Definition 238 (Parametric reflective workspace family). *A* parametric reflective workspace family *is a family*

$$W_\lambda^{\mathrm{ref}} : \mathbb{V}^{\mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}}} \to \mathbb{V}^{\mathcal{L}_{\mathrm{Ob}}^{\mathrm{ref}}}$$

indexed by parameters $\lambda = (\lambda_{\mathrm{ext}}, \lambda_{\mathrm{int}}, \lambda_{\mathrm{ref}}, \lambda_{\mathrm{coh}})$, where each W_λ^{ref} is monotone and can be interpreted as: external evidence anchoring (λ_{ext}), internal completion (λ_{int}), introspection amplification (λ_{ref}), and coherence selection (λ_{coh}).

Remark 933. *Intuitively, λ is a "control panel" for the style of conscious closure. If λ_{ext} is high, the workspace behaves like a sober accountant tethered to registration (Hyperseed-Concept 153); if λ_{int} is high, it behaves more like a novelist weaving completions and associations; if λ_{ref} is high, it tends to generate and amplify meta-content; if λ_{coh} is high, it prefers states that score well according to the chosen coherence criterion. This way of speaking is intentionally suggestive rather than neuroscientific: it says that many qualitative shifts in "state" can be treated as parameter changes, not as changes of metaphysical kind (Hyperseed-Concept 178). Moreover, the parameters* *can be read as implementing different* selection pressures *on the set of fixed points: varying* λ_{ext} *and* λ_{int} *changes which propositions are likely to enter and persist in the workspace, varying* λ_{ref} *changes how strongly the system closes over meta-level descriptions of its own state, and varying* λ_{coh} *changes whether the dynamics tolerates patchwork tension or instead drives toward integrative resolutions. In this sense, "reflective will" can be modeled as the agent's capacity to modulate* λ *(in particular* λ_{coh} *and* λ_{ref}*) so that the eventual fixed point is not only reachable but also endorseable: the closure is selected not merely because it is stable, but because it resonates with the agent's preferred mode of integration.*

Remark 934 (Selector interpretation of fixed points)**.** *Given* λ*, Theorem 16 yields at least one fixed point* $E^* \in \mathrm{Fix}(W_\lambda^{\text{ref}})$*. When there are many, one can impose a resonance-based preference by ranking fixed points via* $\mathrm{Coh}(E^*)$ *(or via a variant that explicitly rewards support and penalizes tension). Formally, one can treat the "selected" conscious closure as an element of*

$$\arg\max \left\{ \mathrm{Coh}(E^*) \ : \ E^* \in \mathrm{Fix}(W_\lambda^{\text{ref}}) \right\},$$

when this set is nonempty and the modeling context licenses a maximization principle. Alternatively (and more dynamically), one can view λ_{coh} *as shaping the iteration trajectory so that high-coherence fixed points have larger basins of attraction, thereby capturing the phenomenological idea that resonant configurations are easier to maintain and return to after perturbation, while dissonant configurations are fragile or effortful to sustain.*

Remark 935 (On the choice of normalization and workspace size)**.** *The factor* $\frac{1}{|\mathcal{K}|}$ *makes* $\mathrm{Coh}(E)$ *comparable across different workspace sizes, which is useful if* $\mathcal{K}$ *is attention-dependent and can expand or contract. If one instead wants larger workspaces to have systematically larger coherence signals (e.g. to model the felt "intensity" of a richly populated conscious scene), one can drop the normalization or replace it with a softer scaling. Likewise, one can introduce proposition weights* w_φ *to model salience:*

$$\mathrm{Coh}_w(E) := \frac{1}{\sum_{\varphi \in \mathcal{K}} w_\varphi} \sum_{\varphi \in \mathcal{K}} w_\varphi |(z_E)_\varphi|^2,$$

without changing the basic role of coherence as a selector; such weights provide a direct handle on how attention and motivational relevance modulate resonance.

Remark 936. *As a concrete example, one could define* W_λ^{ref} *to take a convex combination (in the quantale sense) of "sensory anchoring" constraints and "associative completion" rules, with weights controlled by* λ_{ext} *and* λ_{int}*. In particular, one may read* λ_{ext} *as strengthening the degree to which external error-correction, cross-modal consistency, and stimulus-locked constraints dominate the closure, and* λ_{int} *as strengthening the degree to which internally generated completions, priors, and memory-driven predictions dominate it. The quantale-convex phrasing is meant to emphasize that the combination need not be linear in a vector-space sense: the "mixture" can be expressed through the underlying order and monoidal structure that governs how constraints compose and how entailments accumulate. The definition is useful because it formalizes the claim that waking, dreaming, hallucination, etc., can be understood as regimes of the same computational architecture, tuned differently. On this view, what varies across regimes is not the presence or absence of a workspace/closure mechanism, but which families of constraints are allowed to dominate the selection of stable fixed points of the induced operator.*

This provides a clean formal slot for the Hyperseed claim that many distinct "states of consciousness" are *parameter regimes* rather than separate ontological kinds. It also makes room for intermediate and mixed cases (e.g. lucid dreaming, absorption, meditation, or drug-induced states) as regions in a continuous parameter landscape rather than as discrete labels, since small changes in λ_{ext} and λ_{int} can shift which patterns become coherent enough to persist.

17.5 Reflective will as meta-control on self-model dynamics

Hyperseed uses "(reflective) will" to denote more than mere action selection: it is the capacity to intentionally reshape the mind's own internal dynamics (especially attention and self-model updates). In particular, the relevant "internal dynamics" include not only which contents enter a global workspace, but also which self-descriptions (e.g. "I am safe," "I am failing," "I am curious") are repeatedly re-instantiated by the closure process, thereby becoming behaviorally and phenomenologically dominant.

Remark 937. *In ordinary engineering terms, "will" here is closer to* meta-control *than to control: it is the selection of how control itself is carried out, including how attention is allocated and how self-representations are stabilized. One can think of it as operating on the parameters and operators that determine which internal signals are amplified, which are suppressed, and which are treated as "authoritative" inputs to decision-making. This aligns with Hyperseed's broader interest in self-modifying agents and stability of internal goal/attention structures [10]. It also connects to the concept of Weakness (Hyperseed-Concept 202) in the sense that the system must manage self-reference and self-modification without collapsing into inconsistency or paralysis [2, 3]. In more concrete terms, meta-control must include safeguards (implicit or explicit) that prevent runaway self-editing (e.g. compulsive policy rewriting) while still allowing sufficient plasticity for learning and recovery.*

17.5.1 Will as choice of an intervention on the update operator

Let $\mathcal{S}_{\text{Ob}}$ be a state space of the observer (internal memory, body state, etc.). For example, $\mathcal{S}_{\text{Ob}}$ may include latent variables corresponding to working memory contents, affective tone, estimated uncertainty, and the current self-model, insofar as these are available to the system as inputs to further updating. Let U be a set of interventions that can affect: (i) attention allocation a (Section **??**), (ii) the workspace parameters λ (Section 17.4), and/or (iii) the control policy used to act in the world (Section 14). It is important that U ranges over *internal* as well as external-facing interventions: the notion of "intervening" here is not restricted to motor outputs, but includes changes to the internal routing and gain-control by which information becomes influential.

Definition 239 (Will operator)**.** *A* will operator *is a map*

$$\mathsf{Will} : \mathcal{S}_{\text{Ob}} \to U$$

that selects an intervention $u \in U$ based on the current internal state. Applying u induces an update of the reflective closure operator, i.e. changes $F = W^{\text{ref}} \circ \mathsf{Int} \circ \Gamma_a$ to a new operator F_u. One may view u as selecting (or modulating) one or more components of the composite map—for instance, by altering Γ_a through attention shifts, by altering Int through changes in how sensory evidence is incorporated, or by altering W^{ref} through changes in reflective stabilization strength.

Remark 938. *Intuitively,* Will *is the system's "choice of how to proceed," not only in the world but also in its own cognitive configuration. An example of $u \in U$ might be: "shift attention from rumination to sensory grounding," which changes a and potentially increases λ_{ext}. Another example is: "engage deliberative mode," which might increase the weight of explicit reasoning processes and* *adjust workspace inhibition rules. A further example (in the same spirit) is: "reduce precision on intrusive imagery," which would down-weight certain internally generated candidates before they are stabilized by closure, thereby reducing the chance that they become fixed-point contents.*

This definition is useful because it makes "will" something that has a clear causal footprint in the formalism: it changes the operator whose fixed points are the conscious states. That is, will is not a ghostly add-on; it is a map that selects an intervention that changes the dynamics of closure, thereby changing what is stably present to experience and action. Equivalently, it lets us speak precisely about cases where two agents (or two moments of the same agent) have similar sensory inputs but systematically different stable experiences because the meta-selected operator F_u differs.

Remark 939 (Why this is "will" rather than "control")**.** *Ordinary control (Section 14) chooses actions in the world. Here the intervention may also choose:* what the agent attends to*,* how reflective closure is computed*, and* how self-representations are stabilized*. This corresponds closely to Hyperseed's use of "will" as control over inner dynamics. In particular, it distinguishes between (a) selecting an action under a fixed cognitive pipeline and (b) selecting the pipeline (or its parameters) under which subsequent actions and perceptions will be generated.*

17.5.2 Reflective will as meta-selection

Reflective will occurs when the system can represent and modify the will operator itself. We capture this by allowing interventions that change the policy class. This is the point at which the agent is no longer only choosing within a given meta-control scheme, but is able to restructure the scheme that generates such choices, thereby altering its own future degrees of freedom.

Definition 240 (Reflective will)**.** *Let Π be a space of possible will operators $\pi : \mathcal{S}_{\mathrm{Ob}} \to U$. A* reflective will state *is a pair (π, s) with $\pi \in \Pi$ and $s \in \mathcal{S}_{\mathrm{Ob}}$. A* reflective will update *is a map*

$$\mathsf{RWill} : \Pi \times \mathcal{S}_{\mathrm{Ob}} \to \Pi \times \mathcal{S}_{\mathrm{Ob}},$$

which may change both the internal state and the will operator. In effect, RWill *can be read as a learning (or self-programming) dynamic on Π coupled to an ordinary state-update dynamic on $\mathcal{S}_{\mathrm{Ob}}$.*

Remark 940. *In plain language: a non-reflective will chooses what to do; a reflective will can also choose* how it will choose *in the future. For example, an agent might adopt a new attentional policy "when anxious, ground attention in breath"; this is a modification to the will operator itself, not merely a single action. The pair (π, s) represents "the current chooser" together with the current state it is choosing from. One can also interpret π as encoding commitments or self-binding constraints (e.g. "do not deliberate about X after midnight," or "when uncertain, consult external evidence"), which then shape subsequent trajectories of F_u by restricting or biasing which interventions are selected.*

This definition is necessary if we want to model long-term autonomy and development: an agent that cannot revise its own will policy is confined to a fixed meta-level, whereas reflective agents can enter regimes of self-training, self-regulation, and ethical self-binding. Order-theoretic and dynamical tools then become applicable to questions of stability and drift, linking naturally to fixed-point approaches to self-modifying systems [10]. It also makes it possible to distinguish benign adaptation (slow improvement of π with respect to some internal viability criterion) from destabilizing meta-dynamics (rapid churn in π that prevents coherent stabilization of goals, attention, or self-model contents).

Remark 941 (Fixed point picture)**.** *A stable reflective will regime corresponds to a fixed point (or slowly drifting orbit) of* RWill*. This is one of the cleanest mathematical ways to interpret the*

Hyperseed idea that "reflective will" is a stabilized meta-level capability rather than a single act. In such a regime, the agent's meta-policy π is itself resilient under the pressures of short-term perturbations in s (fatigue, affect, noise), and this resilience can be studied with the same stability intuitions used elsewhere in the framework (e.g. as a selector for coherent, self-sustaining patterns).

17.6 Autonomy and the reflective self as fixed points and higher morphisms

Hyperseed's "natural autonomy" is not maximal independence from world and society; it is the capacity to maintain coherent self-directed dynamics while remaining coupled to larger systems. The earlier sections already provide most of the needed machinery: self as boundary in a pattern web (Section 16), control as attraction-sensitive intervention (Section 14), and habits/self-weaving dynamics (Section 12).

Here we package these ideas into a minimal autonomy criterion.

Remark 942. *This notion of autonomy (Hyperseed-Concept 119) is intentionally non-romantic: it is not "freedom from causation" but the ability to keep one's dynamics within a viable region by selecting interventions, including internal interventions. It is also explicitly relational: the viable region depends on coupling to environment and society, and the self/other boundary (Hyperseed-Concept 165) is itself observer-relative and potentially paraconsistent (Section 16).*

17.6.1 Autonomy as viability under self-directed closure

We treat autonomy as *viability* of self-maintaining closure.

Definition 241 (Viable set and autonomy)**.** *Let $D_u : \mathcal{S}_{\mathrm{Ob}} \to \mathcal{S}_{\mathrm{Ob}}$ denote the state update induced by applying intervention $u \in U$ (this includes both world actions and internal interventions). Let $\mathcal{V} \subseteq \mathcal{S}_{\mathrm{Ob}}$ be a set of "viable" states (states where the mind remains functional, coherent enough, and continuous enough; this is observer- and model-dependent). We say* Ob *has* natural autonomy relative to $\mathcal{V}$ *if for every $s \in \mathcal{V}$ there exists an intervention $u \in U$ such that $D_u(s) \in \mathcal{V}$.*

Remark 943. *Intuitively, $\mathcal{V}$ is the set of states in which the agent "still counts as itself and still works". The condition says: whenever the agent is in a viable state, it has at least one available move that keeps it viable. This is a minimal viability-style autonomy notion, echoing how "life" and "agency" are often made precise via invariance or controlled invariance of a viability region (compare Section 19.2).*

A simple example: if $\mathcal{S}_{\mathrm{Ob}}$ includes a resource variable (energy, attention capacity, etc.) and $\mathcal{V}$ is defined by "resource above threshold," then autonomy means the agent can always choose some intervention that does not immediately exhaust the resource. The definition is useful because it separates autonomy from omnipotence: autonomy is not "I can do anything," but "I can keep going in a coherent way," which is closer to the lived phenomenon and to Hyperseed's emphasis on self-maintaining pattern-web dynamics.

Remark 944 (Connection to self-weaving)**.** *If $\mathcal{V}$ is defined in terms of persistence of a self-weaving subweb (Section 12) plus a continuity constraint (Section 16), then "autonomy" is precisely the ability to choose actions (internal and external) that keep the self-weaving process alive without losing identity.*

17.6.2 Reflective self as a stabilized self-representation

Hyperseed's "reflective self" is not merely a self-model; it is a self-model that becomes a stable reference point for reflective consciousness and reflective will.

Definition 242 (Self-model object and reflective self condition)**.** *Assume $\mathcal{L}^{\mathrm{ref}}_{\mathrm{Ob}}$ includes special propositions of the form $\mathsf{Self}(\psi)$ meaning "ψ is a property of me" (e.g. a pattern/property token as in Section 9 applied to the self-boundary of Section 16). A workspace-stable evidence state E is said to exhibit a* reflective self *if:*

(a) (Self-presence) for a designated set $\mathcal{P}_{\mathrm{self}}$ of self-properties, $E^{+}(\mathsf{Self}(p))$ is above threshold for many $p \in \mathcal{P}_{\mathrm{self}}$;

(b) (Reflective access) for these p, the introspective propositions $\mathsf{I}(\mathsf{Self}(p))$ are also supported above threshold;

(c) (Stability) these supports persist under small perturbations of module evidence and attention.

Remark 945. *This definition makes "having a self" (as a representational fact) different from "having a reflective self" (as a stable, accessible, meta-accessible representational fact). Condition (a) says that many self-attributions are present; condition (b) says they are not merely implicit but are themselves available to awareness; condition (c) says the whole configuration is robust under small changes. In informal terms: it is not enough that the system encodes a self-model somewhere; it must be able to* stand by it *in the workspace and to know (in the formal introspective sense) that it is standing by it.*

A simple example is a bodily self-property p = "this arm is mine." In a reflective self regime, one expects both $\mathsf{Self}(p)$ and $\mathsf{I}(\mathsf{Self}(p))$ to be supported, and not to vanish under minor sensory noise. This definition is useful because it ties together three threads from earlier sections: self/other boundary (Hyperseed-Concept 165), self-continuity (Hyperseed-Concept 166), and attention-mediated global accessibility (Hyperseed-Concept 60). It also provides a place to connect with individual and collective "consciousness location" ideas in the broader Hyperseed program [4, 12].

Remark 946 (Higher morphism reading)**.** *In the enriched-categorical viewpoint, a stable reflective self can be treated as a higher morphism (or a higher cell) relating:*

$$\text{(self-boundary as subobject of a pattern web)} \quad \to \quad \text{(self-representation in the reflective workspace)} \quad \to \quad \text{(meta}$$

We avoid heavy $(\infty, 1)$-categorical machinery here, but the conceptual alignment is direct.

17.7 States of consciousness as parameter regimes

Hyperseed lists a number of "states of consciousness" (ordinary waking consciousness, dreaming, hallucinating, being, oceanic consciousness, creative inspiration, enlightenment, Vedantic strata). In the present reconstruction, these can be modeled as regimes of the parameter vector $\lambda = (\lambda_{\mathrm{ext}}, \lambda_{\mathrm{int}}, \lambda_{\mathrm{ref}}, \lambda_{\mathrm{coh}})$ together with the habit/resonance coupling strengths (Sections 12 and 3.9).

Remark 947. *The modeling posture here is pluralist but disciplined: we do not deny the qualitative diversity of states of consciousness (Hyperseed-Concept 178); rather, we claim that much of this diversity can be represented as changes in coupling strengths and closure preferences inside a single architecture. This is reminiscent of how, in physics, different phases of matter are not different substances but different regimes of the same underlying constituents; here the "constituents" are attention, evidence, workspace closure, and resonance.*

Definition 243 (State-of-consciousness parameters)**.** *A* state-of-consciousness parameter tuple *is*

$$\Lambda := (\lambda_{\mathrm{ext}}, \lambda_{\mathrm{int}}, \lambda_{\mathrm{ref}}, \lambda_{\mathrm{coh}}, \rho_{\mathrm{hab}}, \rho_{\mathrm{res}}),$$

where:

- λ_{ext} *controls anchoring to current sensory registration (Section 13);*
- λ_{int} *controls internal completion/association (pattern web propagation; Section 11);*
- λ_{ref} *controls introspection gain (Section 17.3);*
- λ_{coh} *controls coherence preference (Section 17.4);*
- ρ_{hab} *controls habit reinforcement strength (Section 12);*
- ρ_{res} *controls resonance coupling strength (Sections 3.9 and 12).*

Remark 948. *Intuitively, Λ extends the earlier workspace parameters λ with two further knobs: habit reinforcement and resonance coupling. If ρ_{hab} is high, recently active patterns are rapidly entrenched (Hyperseed-Concept 155); if ρ_{res} is high, distant parts of the pattern web can synchronize and amplify one another (Hyperseed-Concept 159). Thus Λ acts as a compact descriptor of how "tight" or "loose" the system is in binding together contents and in reinforcing repeated flows.*

As an example, a dreaming-like regime might be described by low λ_{ext}, high λ_{int}, and moderate-to-high ρ_{res} (strong internal coupling) with weaker external anchoring. The usefulness of introducing Λ is that it allows the narrative taxonomy of states to be replaced by a parameterized family of operators, which is mathematically tractable and composable with the rest of the framework.

17.7.1 Canonical regimes

The following table is not intended as neuroscience; it is a compact map from Hyperseed vocabulary to a minimal mathematical control panel.

- **Ordinary waking consciousness.** High λ_{ext}; moderate λ_{int}; moderate λ_{ref}; λ_{coh} tuned to prefer sensory-consistent closure. Habits and resonance are active but constrained by sensory feedback.
- **Dreaming.** Low λ_{ext}; high λ_{int}; variable λ_{ref}. Coherence preference may be lower, allowing more internally generated blends and narrative jumps. Habit dynamics may replay or reweight pattern-flow motifs (Section 12) without external error correction.
- **Hallucinating.** Low λ_{ext} but strong internal propagation and high self-consistency pressure: high λ_{int} and high λ_{coh}, with closure dominated by internally generated evidence. Paraconsistency becomes prominent: the system may carry simultaneous support for incompatible world propositions without collapse, while still experiencing strong presence.
- **Being (non-conceptual presence).** Moderate-to-low λ_{int} (less elaborative completion), moderate λ_{ext} (or also low, depending on context), and high λ_{coh} with coherence defined more by low tension than by high net propositional content. In this regime the workspace fixed point contains fewer explicit propositions but higher stability.
- **Oceanic consciousness.** This is naturally modeled by a *reduction of self/other boundary sharpness* (Section 16) together with high global coherence. Formally, this corresponds to: (i) fewer strongly supported self-boundary propositions; (ii) higher coupling between self-typed and world-typed pattern nodes; and (iii) a coherence preference that does not penalize loss of boundary distinctions. This connects back to Hyperseed's non-duality motif (Section 6; Hyperseed-Concept 121).

- **Creative inspiration.** A transient regime with increased resonance coupling ρ_{res} between normally distant subwebs, enabling new blends (Section 9). Here ρ_{res} can be read as a control parameter governing the effective "conductance" of associative links across otherwise weakly communicating regions of the cognitive network, so that activation can percolate between contexts that are usually conditionally independent. One can model this as a temporary increase in cross-context coupling in the habit/resonance kernel, leading to rapid emergence of high-intensity composite patterns [5]. Concretely, if the kernel K weights transitions between subweb states, then "inspiration" is a short-lived deformation $K \mapsto K + \Delta K$ with ΔK concentrated on off-diagonal (cross-context) blocks, so that previously subthreshold combinations become reachable within a few update steps. Phenomenologically, this corresponds to the felt "suddenness" of a novel synthesis: the composite pattern is not built by slow local refinement alone, but by a burst of long-range binding that stabilizes once coherence constraints are satisfied.

- **Enlightenment.** Modeled here as a stable, low-effort, high-coherence regime in which: (i) reflective closure remains stable under perturbation; (ii) will/intervention choices tend to preserve viability with minimal contrivance (foreshadowing Wu Wei; Section 26; Hyperseed-Concept 206 and 207) [21]; and (iii) self/other boundary is flexible without inducing disorganized conflict. Item (i) can be understood as a robustness property: small changes in incoming evidence, affect, or bodily state do not cause reflective propositions to oscillate or fragment, i.e. the closure operator returns to (or remains near) the same fixed point after bounded disturbance. Item (ii) emphasizes that "control" is not absent but becomes economical: interventions align with system dynamics so that fewer corrective moves are required to maintain constraints (e.g. viability, social coordination, or goal satisfaction), resembling a descent along a shallow energy landscape rather than repeated forcing against steep gradients. Item (iii) indicates that increased permeability of self/other modeling does not collapse into indiscriminate identification; instead, boundary flexibility is paired with sufficient coherence to avoid runaway contagion of competing action policies. In quantale terms: low "tension" components across the reflective proposition set while retaining functional coupling for control. More explicitly, if reflective propositions are combined via a monoidal product that aggregates commitments, then "tension" informally tracks the degree to which jointly held propositions require active suppression of incompatibilities; the enlightened regime corresponds to configurations where incompatibilities are either resolved (by re-framing) or rendered non-disruptive (by appropriate contextualization), while the coupling needed for action selection remains intact.

- **Vedantic strata.** A simple formal analogue is a hierarchy of reflective closures: $\mathcal{L}_{\text{Ob}} \subset \mathcal{L}_{\text{Ob}}^{\text{ref}} \subset \mathcal{L}_{\text{Ob}}^{\text{ref},2} \subset \cdots$, where $\mathcal{L}_{\text{Ob}}^{\text{ref},k}$ adds propositions about awareness-of-awareness iterated k times. This mirrors the idea that certain reports distinguish (a) first-order contents, (b) awareness of those contents, and (c) awareness that one is aware, etc., with each level introducing new constraints on what counts as a stable self-description. Different strata correspond to stable fixed points at different k (or different gains λ_{ref}), with the paraconsistent setting allowing such iteration without trivial paradox. Operationally, λ_{ref} can be interpreted as a weighting (or gain) on reflective update terms relative to first-order dynamics: higher λ_{ref} makes meta-level propositions more influential in the closure computation, which can stabilize higher-order self-modeling when the network can sustain it. The reference to paraconsistency matters because awareness-of-awareness claims often generate self-referential structures; allowing controlled inconsistency prevents the entire reflective lattice from collapsing into triviality while still permitting meaningful fixed points that correspond to distinct phenomenological "strata".

Remark 949. *The point of these regime descriptions is not to legislate phenomenology but to show* *that the formalism has enough expressive degrees of freedom to represent qualitative shifts without adding new primitives. In this sense the regimes are parameterized views of one and the same machinery: varying coupling, gain, noise, and boundary-regularization terms can move the system between recognizable macrostates without changing the underlying ontology of operators, propositions, or update rules. In particular, the transition from waking to dreaming becomes intelligible as a movement along the axis from externally anchored closure to internally generated completion; the more "mystical" regimes become movements along the axes of self/other boundary softness and coherence preference, echoing Hyperseed's process-oriented stance in which identity and boundary are dynamically constructed (compare [15, 14] for metaphysical inspirations). One can also view these axes as coordinates on a stability landscape: "waking" corresponds to closures strongly constrained by sensory-anchored evidence and prediction-error correction, whereas "dreaming" corresponds to closures where generative priors and internal completion dominate, with external correction weakened. Likewise, changes in boundary softness can be modeled as shifts in how strongly the system penalizes cross-agent (or cross-model) identification errors, and changes in coherence preference can be modeled as shifts in how aggressively the system resolves or tolerates local inconsistency in the reflective set.*

17.8 Intuition and reason as dual inference channels

Hyperseed explicitly distinguishes intuition and reason, and treats both as essential. A minimal way to integrate this into the present framework is to posit two update channels:

- *Intuitive update*: fast, low-cost propagation in pattern webs, strongly driven by resonance.
- *Reasoned update*: slower, higher-cost composition of explicit predictive/causal relations.

Remark 950. *This distinction corresponds to two complementary modes of cognition: intuition (Hyperseed-Concept* **??***) as quick pattern completion and resonance-driven association, and reason (Hyperseed-Concept 150) as explicit manipulation of articulated relations (implications, causal arrows, plans). The framework does not declare one mode superior; rather, it provides a mathematical place for their interaction, consistent with the Hyperseed emphasis on cognitive synergy (Hyperseed-Concept 73) [19].*

Definition 244 (Two-channel update sketch)**.** *Let E be the current reflective evidence state. Define:*

$$E_{\text{int}} := U_{\text{int}}(E), \qquad E_{\text{rea}} := U_{\text{rea}}(E),$$

where U_{int} is a monotone operator that spreads support along pattern-web morphisms (Section 11) and resonance couplings (Section 17.4), and U_{rea} is a monotone operator that propagates support along explicitly represented implications and attractions (Section 14), with explicit composition. The combined update may be taken as

$$U(E) := W^{\text{ref}}\big(E \oplus \overline{\beta} \otimes E_{\text{int}} \oplus \overline{\gamma} \otimes E_{\text{rea}}\big),$$

with channel weights $\beta, \gamma \in [0, 1]$.

Remark 951. *Notation check: U_{int} and U_{rea} are endomaps on the space of reflective evidence states (they take an evidence state and output another). The scalars β, γ are embedded into $\mathbb{V}$ via $\overline{\beta}, \overline{\gamma}$, and then used to weight the contributions of the two channels using the quantale tensor $\otimes$. The join $\oplus$ combines the baseline state with the two channel-updated states, and finally W^{ref} re-applies reflective workspace stabilization.*

Intuitively, this says: take the current state, add in a resonance-driven intuitive propagation and a relation-driven reasoned propagation, each with its own strength, then stabilize globally. A concrete toy example is: intuition quickly spreads support from "dark clouds" to "it will rain" via a learned association, while reason slowly constructs support for "bring an umbrella" by chaining explicit implications. The definition is useful because it gives a formal grammar for how two inference modes can cooperate without requiring them to be reducible to one another.

Remark 952. *The two-channel form also makes room for an important asymmetry often observed in practice: the intuitive channel is typically* broad *(high fan-out in the pattern web) but* shallow *(limited explicit depth of justification), whereas the reasoned channel is typically* narrower *but* deeper *(longer chains of explicit composition). In the present notation, this difference is not encoded by changing the carrier space of E, but by the structure of U_{int} versus U_{rea}: the former is dominated by resonance couplings and morphism-local propagation steps, while the latter is dominated by explicit relational composition (e.g. repeated application of implications, causal links, or plan operators). This helps clarify why "slower" does not merely mean "smaller γ": it can also mean that U_{rea} itself is implemented as a multi-step computation whose intermediate results may enter the workspace only after partial stabilization by W^{ref}.*

Remark 953. *Although the definition presents a single combined update $U(E)$, the same ingredients can be used to model alternating or interleaved schedules, which better match many cognitive architectures. For example, one may consider a two-phase cycle*

$$E^{(t+\frac{1}{2})} := W^{\text{ref}}\big(E^{(t)} \oplus \overline{\beta} \otimes U_{\text{int}}(E^{(t)})\big), \qquad E^{(t+1)} := W^{\text{ref}}\big(E^{(t+\frac{1}{2})} \oplus \overline{\gamma} \otimes U_{\text{rea}}(E^{(t+\frac{1}{2})})\big),$$

so that intuition rapidly proposes candidate completions that are then subjected to explicit reasoning on the next phase. This interleaving is still monotone at each step (assuming monotonicity of the constituents), and it highlights that "interaction" can mean not only additive combination via $\oplus$ but also sequential coupling through the shared workspace.

Remark 954. *From the perspective of reflective will and autonomy, the weights β, γ can be understood as coarse global controls over where computational effort is spent. A high-β regime privileges fast associative completion (useful for time pressure and exploration), while a high-γ regime privileges explicit justification and longer-horizon planning (useful for high-stakes deliberation). Nothing in the formalism requires β and γ to be fixed constants; they may be taken as functions of the current state (or of a separate control state) to represent attentional gating. For instance, one may write $\beta(E), \gamma(E)$ to indicate that the system shifts toward reason when the workspace contains unresolved conflicts, or shifts toward intuition when the workspace is sparse and requires rapid hypothesis generation.*

Remark 955. *A further use of the two-channel grammar is to separate* proposal *from* justification *without forcing either to be infallible. Intuition may propose a high-support candidate that is later weakened by reason when explicit causal structure does not sustain it; conversely, reason may construct a formally valid chain that remains low-impact in practice if it fails to resonate with the currently active pattern web. In the combined update, these cases correspond to situations where $\overline{\beta} \otimes E_{\text{int}}$ dominates the join but is then attenuated by stabilization, or where $\overline{\gamma} \otimes E_{\text{rea}}$ introduces structured support that nonetheless competes with other attractors already present in E. This is one place where cognitive synergy becomes operational: the channels are allowed to disagree, and the workspace provides the arena in which their contributions are reconciled into an actionable state.*

Remark 956 (Why paraconsistency matters for intuition/reason)**.** *Intuition often produces "both-leaning" states: simultaneous attraction toward incompatible interpretations. In a classical logic* *semantics this would be immediately problematic; in the* p-bit *setting it is a first-class representational state that can later be refined by reason, by attention shifts, or by additional evidence.*

Remark 957. *The preceding point can be sharpened by noting that the intuitive channel may increase support for multiple mutually incompatible hypotheses* at once *because resonance can be triggered by shared features (e.g. similar surface cues) even when deeper causal models differ. Paraconsistent representation allows such "multi-attractor" activation to remain expressible in E long enough for U_{rea} to apply discriminating structure (explicit constraints, explanations, counterfactual checks, or plan feasibility tests). In this sense, paraconsistency is not merely a tolerance of inconsistency but a functional resource: it provides a stable intermediate regime in which the system can entertain competing candidates without collapsing into triviality or prematurely committing to a single narrative.*

17.9 Closing remarks and link to values/ethics

This section has treated consciousness and reflective will as closure and meta-control phenomena. In that framing, "closure" is the emergence of a globally available, self-consistent-enough (in the paraconsistent sense) workspace configuration, while "meta-control" is the system's capacity to act on its own internal dynamics (e.g., to sustain, redirect, inhibit, or reconfigure processes that would otherwise run automatically). Two crucial ingredients have been intentionally bracketed:

- *valuation*: what the system cares about (joy/woe, goals, values);
- *ethical structure*: how value conflicts and social constraints are represented and resolved.

Here, "valuation" is meant broadly: it includes affective salience (what feels good or bad), instrumental priorities (what advances goals), and more reflective endorsements (what the agent takes itself to have reason to pursue), all of which can bias which content is amplified into the workspace and which is ignored or suppressed. Likewise, "ethical structure" is not restricted to explicit moral rules; it includes any internal representation of constraints that have a normative character for the system (e.g., prohibitions, commitments, fairness-like considerations, role obligations, or coordination requirements in multi-agent settings), as well as the mechanisms by which such constraints interact with other goals under conflict. In Hyperseed, these are not add-ons: they shape attention, shape which fixed points are selected, and shape whether reflective will stabilizes into autonomy or degenerates into fragmentation. More concretely, the same capacity for reflective iteration that enables autonomy can also enable rumination, oscillation among incompatible commitments, or opportunistic switching, unless there are stable evaluative gradients and constraint-handling policies that give reflective control a direction and a stopping condition. Accordingly, Section 18 extends the same paraconsistent and resonance-enabled machinery to evaluation, motivation, and rational/ethical decision. This extension matters because evaluation is not merely a label attached after the fact; it enters into the dynamical loop that determines which representations couple resonantly, which attractors are reachable, and which equilibria are robust under perturbation, learning, and social feedback.

Remark 958. *One way to read the logical arc is: this section supplies the* stage *(workspace closure and its reflective iteration), while the next supplies the* drama *(what is attractive, what is aversive, which conflicts matter, and which resolutions count as rational or ethical). The metaphor is intentional: closure and reflective will specify a capacity for integration and self-modification, but they do not by themselves specify* why *the system should integrate in one direction rather than another, nor* which *internal tensions are to be treated as errors versus acceptable trade-offs. Without values, a* *consciousness modeled as "just" a fixed point is underdetermined: many fixed points may exist, and the system needs selection pressures to inhabit some rather than others. This underdetermination appears both at the level of content (which interpretations, plans, or self-models can close) and at the level of policy (which meta-control actions are deemed improvements), so valuation and norm-like constraints function as discriminators over a landscape of possible closures. Hyperseed's claim is that affect and value are among the deepest such selectors, co-evolving with attention, habit, and resonance [5, 24]. On this view, autonomy is not merely the persistence of a reflective fixed point, but the stability of a reflective process under evaluative and normative pressures: it is the ability to maintain coherent commitments over time while still revising them in response to evidence, conflict, and social constraint.*

18 Emotion, values, goals, and rationality

18.1 Orientation: why "emotion" belongs in the formal stack

Hyperseed treats *effort* and *distinction* as primitive and observer-relative. Once effort is taken seriously as a first-class quantity (Sections 8–9), it becomes natural to treat many affective phenomena as *evaluative signals about (i) expected effort/resistance, (ii) expected coherence/resonance, and (iii) expected alignment with values/goals.* In this section we give a minimal, mathematically explicit vocabulary for:

- **joy/woe and pleasure/pain** as scalar projections of paraconsistent evaluative evidence;
- **emotion** as structured (vector-valued, context-dependent) evaluation fields rather than a single utility number;
- **values, feelings, and goals** as stable patterns and constraints in these evaluation fields;
- **implicit vs explicit goals** as a representational distinction;
- **value paraconsistency** as an intended feature (conflict without explosion);
- **rationality** as coherence between belief, value, and action under resource constraints;
- **ethics** (categorical imperative, cultural morality, evil) as constraints on goal selection and action selection that can be stated in the same formal language.

A key motivation for placing "emotion" inside the formal stack is that, in real agents, evaluation is not an optional afterthought appended to belief: it is part of the control loop that determines which distinctions are worth making, which inferences are worth paying for, and which actions are worth attempting under limited time/energy. If the framework already assigns a formal status to *effort* (as an accounting of cost, resistance, and compression difficulty), then it is consistent to treat affective variables as the agent's internal, dynamically updated estimates of that effort landscape, coupled to its goal constraints. On this view, emotion is not primarily a noise source to be "filtered out" from rationality, but a low-latency summary of how current perception and prediction interact with constraints on action selection.

The phrase "observer-relative" is doing additional work here: what counts as "effortful" or "coherent" depends on the representational resources and habits of the observer (or subsystem) doing the evaluation. Thus, the same external situation can induce different affective profiles in different agents, or even in the same agent across time, without requiring that emotion be arbitrary;

it is lawful relative to the agent's current distinctions, priors, and available control policies. This also clarifies why a single scalar utility is often too coarse: distinct appraisal channels can simultaneously register "high resistance," "high resonance," and "high value alignment," yielding mixed feelings that are not well-captured by total ordering.

The three parenthesized components—expected effort/resistance, expected coherence/resonance, and expected alignment with values/goals—should be read as separable but interacting coordinates of evaluation. Expected effort/resistance tracks anticipated cost-to-execute (physical, computational, social) and cost-to-maintain (attention, working memory, ongoing commitment). Expected coherence/resonance tracks how well a candidate interpretation/action integrates with existing patterns (including narrative self-models, predictive models, and social models), and therefore how stable it is under perturbation. Expected alignment tracks the degree to which a candidate is compatible with constraints that the system treats as non-negotiable or priority-weighted (explicit commitments, learned norms, or implicit drives). Later formalisms will allow these coordinates to be aggregated, contrasted, or kept separate depending on the control regime.

The formalisms here are intentionally lightweight: we aim for a scaffold that composes cleanly with the formal core (Section 3), with the control/prediction machinery (Section 14), and with the resonance construction (Section 3.9). In particular, we want definitions that remain meaningful when the agent's beliefs are incomplete, when its goals are partially articulated, and when its evaluative evidence is internally conflicted. This motivates the use of paraconsistent structures: an agent can have simultaneously supported and opposed evaluations of the same option (e.g., "approach" and "avoid") without collapsing into triviality, and without requiring that the conflict be immediately resolved before action is possible.

Concretely, the intended picture is that an agent maintains a collection of context-indexed evaluation fields over its state/action space (or over structured descriptions of situations), and emotions are identifiable patterns in these fields as they change over time. Scalar quantities such as pleasure/pain are then treated as projections or summaries extracted from a richer object, typically for fast control decisions. This retains the practical role of simple affective labels while keeping the underlying representation expressive enough to capture ambivalence, tradeoffs, and norm conflict.

Remark 959. *At the level of philosophical posture, this section takes seriously the idea that "value" is not a decorative gloss atop cognition, but a structural constraint on what a system can coherently do. In Peircean terms, values function as a species of* Thirdness*—habits, norms, and generalities shaping inference and action—while emotions are the time-local manifestations of how that Thirdness collides with the recalcitrance of the world (Secondness) and the immediacy of felt quality (Firstness) [14]. In a Whiteheadian accent, emotions are not opaque atoms but events in a process: they are patterns in the ongoing concrescence of appraisal and action [15]. Put differently, the "formal stack" is not meant to exclude phenomenology, but to provide a disciplined way to talk about the constraints and transformations that make phenomenology actionable for an agent. A value, in this posture, behaves like a general rule that can be instantiated across contexts; an emotion behaves like the local error-signal (or opportunity-signal) generated when that general rule meets a particular world-situation under resource bounds.*

Remark 960. *This section should be read alongside the Hyperseed core-concepts: Effort (Hyperseed-Concept 100), Distinction (Hyperseed-Concept 98), Emotion (Hyperseed-Concept* **??***), Values (Ethical) (Hyperseed-Concept 197), Goals: Explicit/Implicit (Hyperseed-Concepts* **??***,* **??***), Value Paraconsistency (Hyperseed-Concept 198), Rationality (Hyperseed-Concept 148), and Compassion/Evil (Hyperseed-Concepts 81,* **??***). One way to keep the reading coherent is to treat "emotion" (as used here) as the interface layer between (i) descriptive models of the world (belief/prediction), (ii) prescriptive constraints (values/goals), and (iii) the cost model (effort). In that sense, the section is not* *proposing a separate psychology module, but a unifying vocabulary that lets the same mathematics speak about appraisal, commitment, conflict, and action choice.*

18.2 Paraconsistent evaluative evidence and affective projections

18.2.1 Evaluation fields

Let S denote a set of (observer-relative) *situations* or *states* and A a set of *actions*. We also fix a finite set $\mathcal{D}$ of *value dimensions*. Typical elements of $\mathcal{D}$ include:

comfort, safety, truth, beauty, competence, belonging, compassion, individuation, self_transcendence.

Nothing in the math forces these labels; the point is that Hyperseed does not assume values are reducible to one scalar.

Remark 961 (Notation and conventions)**.** *Here $s \in S$ is a modeled situation (which may already bundle a time-slice, an internal state-estimate, and relevant context), and $a \in A$ is a candidate intervention. The finite index set $\mathcal{D}$ is not assumed to be "the true list of human values"; it is the observer's current basis of evaluative distinctions. The choice to make $\mathcal{D}$ finite is pragmatic: it lets us treat value as a vector of coordinates while still allowing the coordinates themselves to evolve later (Section 18.6).*

Remark 962 (Why $S \times A$ rather than S alone)**.** *The dependence of evaluation on (s, a) (rather than on s alone) is essential: many values are primarily* interventional *rather than merely descriptive. For example, a situation s may be high in* safety *as a snapshot, while a contemplated action a may nonetheless be evaluated as strongly anti-*safety *because it increases risk; conversely, s may be low in* comfort *but a may have high pro-*comfort *evidence due to expected relief. The field E_O is thus best read as attaching evaluation to* counterfactuals *("what would happen if I do a in s") rather than to world-states in isolation.*

Definition 245 (Paraconsistent evaluative field)**.** *Fix an observer/context O. A* paraconsistent evaluative field *is a map*

$$E_O : S \times A \times \mathcal{D} \to [0, 1]^2,$$

where

$$E_O(s, a; d) = \left(E_O^+(s, a; d),\, E_O^-(s, a; d)\right)$$

encodes degree of evidence that action a in situation s promotes (resp. opposes) the value dimension d. No consistency constraint is imposed; it is allowed that $E_O^+(s, a; d) + E_O^-(s, a; d) > 1$.

Remark 963 (Interpretation of the two channels)**.** *The pair $\left(E_O^+, E_O^-\right)$ should be read as two separately supported appraisals, not as a single net valence split into positive/negative parts. Concretely, E_O^+ may be driven by cues of opportunity, growth, alignment, or anticipated benefit, while E_O^- may be driven by cues of threat, violation, loss, or anticipated harm. Allowing both to be simultaneously high captures the common case where an option is "meaningful but dangerous," "honest but socially risky," or "safe but stifling." In this sense, the paraconsistent format is not merely tolerant of conflict; it makes conflict representable without forcing an immediate resolution step.*

Remark 964. *Intuitively, E_O is a kind of "moral/affective sensorium" that maps each contemplated option to a two-sided appraisal. The two coordinates are not probabilities; they are independent evidence channels, so one may have strong reasons both for and against. This is the evaluative analogue of the paraconsistent evidence states used earlier for beliefs, and it aligns with the general Hyperseed stance that conflict is often data rather than error (Hyperseed-Concept 198).*

Remark 965 (Sources and observer-relativity)**.** *The subscript O emphasizes that evaluative evidence is indexed to an observer/context, which can include embodiment, developmental history, culture, role, and current commitments. In particular, E_O can legitimately encode information that is not "in the world" as a neutral fact (e.g., attachment dynamics, trauma-conditioned threat detection, social-norm priors), because these factors causally shape both experienced affect and action guidance. This is not a concession to arbitrariness: it is an explicit modeling choice that makes room for calibration, learning, negotiation among observers, and reflective updates of O itself.*

Remark 966. *A simple example is the choice "tell a difficult truth" in a social situation. Relative to $d =$ truth one may have high positive evidence and low negative evidence; relative to $d =$ belonging one may have both substantial positive evidence (authenticity builds trust) and substantial negative evidence (risk of social rupture). The formalism records this without prematurely collapsing it into a scalar utility. This is useful because later decision rules can treat some dimensions as constraints, others as objectives, and can invoke resonance to measure coordination among them rather than forcing a false unanimity.*

Remark 967 (Value paraconsistency is the default, not an exception)**.** *Hyperseed explicitly expects that real agents have value conflicts, self/other boundary ambiguities, and mixed evidence about what is good or bad. The p-bit representation is a direct formalization of this stance: one can carry "pro-d" and "anti-d" evidence simultaneously without collapsing the system into triviality.*

Remark 968 (Incompleteness and neutrality)**.** *Paraconsistency should be distinguished from mere uncertainty: it is possible (and common) that both channels are low, e.g. $E_O(s, a; d) \approx (0, 0)$, representing a kind of evaluative silence or irrelevance with respect to d. This matters because "no strong evidence either way" is not equivalent to "moderate net endorsement": downstream rules can treat low-information dimensions differently (e.g. defer, seek more data, or discount) rather than mistaking neutrality for agreement.*

Remark 969. *This stance resonates with the broader paraconsistent program used in Constructible Duality Logic and related approaches: inconsistency is handled by design rather than by denial [23]. In the Hyperseed context, this also connects to paraconsistent resonance constructions, where structured interference is treated as informative rather than merely pathological [24].*

18.2.2 Joy/woe and pleasure/pain

To connect to the phenomenological words, we need scalar projections of the p-bit.

Definition 246 (Joy/woe intensities as projections)**.** *Given a p-bit $v = (v^+, v^-) \in [0, 1]^2$, define:*

$$J(v) := v^+ \qquad \textit{(joy intensity)}, \qquad W(v) := v^- \qquad \textit{(woe intensity)}.$$

Given an evaluative field E_O, define:

$$J_O(s, a; d) := J\big(E_O(s, a; d)\big), \qquad W_O(s, a; d) := W\big(E_O(s, a; d)\big).$$

Remark 970 (Why take projections rather than a single valence)**.** *The choice to define $J(v)$ and $W(v)$ as direct coordinate projections (rather than, say, $v^+ - v^-$ or $v^+/(v^+ + v^-)$) is deliberate: it preserves the possibility that joy and woe co-occur without being forced into a one-dimensional tradeoff. A net-valence reduction would erase the distinction between $(0.9, 0.9)$ and $(0.9, 0.1)$ even though they plausibly correspond to very different phenomenology and very different action-guidance (the former signaling "high stakes" and the latter signaling "clear endorsement").*

Remark 971. *The intuition is almost austere: joy and woe are taken here as* readouts *of the positive and negative channels of evidence. This does not claim that joy is merely "belief in goodness"; rather, it asserts that whatever else joy and woe are, they can be operationally summarized (for decision purposes) by two monotone coordinates that can coexist. This corresponds to the Hyperseed core-concepts Joy and Woe (Hyperseed-Concepts* **??***, 204).*

Remark 972 (Joy/woe as action-guiding signals)**.** *Under this projection, $J_O(s, a; d)$ can be read as the strength of "pull" toward a along dimension d, while $W_O(s, a; d)$ is the strength of "push-back" or inhibition along the same dimension. Importantly, neither signal by itself dictates choice: a high J_O can be overridden by high W_O (e.g. morally tempting but dangerous actions), and a high W_O can coexist with a high J_O when the agent faces a costly duty or a meaningful sacrifice. This sets up later mechanisms in which regulation, prioritization, or resonance can decide how such tensions are handled rather than assuming they must be eliminated at representation time.*

Remark 973. *As a concrete example, take $v = (0.8, 0.7)$. Then $J(v) = 0.8$ and $W(v) = 0.7$: the system has strong pull and strong repulsion simultaneously. Phenomenologically this resembles ambivalence, dread-excitement, or "I want it and I fear it." The usefulness is that such a state need not be treated as an error to be eliminated; it becomes a stable input to downstream coherence and choice mechanisms.*

Remark 974 (Pleasure/pain)**.** *We treat* pleasure *as joy-dominant affect and* pain *as woe-dominant affect, but we do not identify them with mere sensation. Instead, pleasure/pain are taken to be* evaluative *and can attach to internal or external processes (physical, mental, social, spiritual). Formally, pleasure and pain are scalar summaries of (J_O, W_O) after aggregating across value dimensions and time horizons.*

Remark 975 (Aggregation across dimensions and horizons)**.** *The last sentence is intentionally underspecified: different tasks call for different aggregators. One natural family is a weighted combination across dimensions,*

$$\mathsf{Joy}(s, a) = \sum_{d \in \mathcal{D}} w_d \, J_O(s, a; d), \qquad \mathsf{Woe}(s, a) = \sum_{d \in \mathcal{D}} w_d \, W_O(s, a; d),$$

with context-dependent weights $w_d \geq 0$ (possibly normalized, possibly not), together with a temporal pooling rule that can emphasize short-term impact, long-term impact, or risk-sensitive tails. The key point is that whatever aggregation is used, it is applied after *representing the two-channel evidence per dimension, so that mixed or conflicting evidence remains visible until the stage where explicit policy choices (e.g. prioritizing* safety *as a constraint) are permitted to matter.*

Remark 976 (Why "pleasure/pain" are not identical to any single $d \in \mathcal{D}$)**.** *Although* comfort *is an obvious contributor, pleasure and pain as used here are not confined to the comfort axis: a person can experience pleasure in truth-telling, competence, belonging, or self-transcendence, and can experience pain in betrayal, shame, incoherence, or moral injury even in the absence of physical discomfort. Treating pleasure/pain as aggregated evaluative summaries is therefore a way to model how multiple value dimensions can jointly produce global affective tone, while still allowing finer-grained analysis at the level of $(s, a; d)$ when needed.*

Remark 977. *This remark aligns Pleasure and Pain (Hyperseed-Concepts 137, 129) with the idea that affect is not just peripheral sensation but a control-relevant appraisal. One simple toy aggregation is: average $J_O(s, a; d)$ and $W_O(s, a; d)$ over a chosen subset of d and over a short temporal window, and then compare the two. Yet the formalism deliberately leaves the aggregation operator* *open, because in real agents pleasure/pain is plastic, trained, and context-dependent. In particular, the same underlying stream of two-sided evaluative evidence can be re-weighted by attention, habituation, framing, or learned predictors of downstream outcomes, so that an "affective summary" is best treated as an agent-relative readout rather than a fixed physical observable. Formally, one can regard an aggregation operator as any map from a collection of per-dimension, time-indexed p-bits to a single p-bit (or small tuple of p-bits) that is subsequently used for control; leaving this open allows the theory to represent both hard-coded reflex-like aggregation and slowly learned, meta-cognitively editable aggregation.*

18.2.3 Aggregating across value dimensions without collapsing conflicts

Hyperseed wants aggregation, but not at the cost of erasing conflict. The simplest approach is: keep the vector structure for decision constraints, and use a scalar only as a *tie-breaker*. Concretely, the vector is used to define feasibility or dominance (so that certain tradeoffs are forbidden or at least not silently normalized away), while any scalarization is invoked only after the space of options has already been filtered to those that are acceptable under the explicit multi-dimensional constraints. This separation mirrors common practical decision procedures: first rule out options that violate non-negotiables, then optimize within what remains.

Definition 247 (Value-vector for an option)**.** *For fixed (s,a) define the* value-vector*:*

$$\mathbf{E}_O(s,a) := \big(E_O(s,a;d)\big)_{d\in\mathcal{D}} \in ([0,1]^2)^{\mathcal{D}}.$$

Remark 978. *This is the precise mathematical expression of "values are plural." Each coordinate is itself paraconsistent, so $\mathbf{E}_O(s,a)$ is a structured object: a vector of two-sided appraisals. A simple example is $\mathcal{D} = \{\mathsf{truth}, \mathsf{comfort}\}$, in which case $\mathbf{E}_O(s,a)$ is just a pair of p-bits. The usefulness is that we can express constraints like "must not strongly violate comfort" while still optimizing truth among feasible options. More generally, the formalism supports heterogeneous dimensions whose evidential sources differ: e.g.* truth *may be driven by predictive accuracy and calibration signals, whereas* comfort *may be driven by affective forecasting and physiological proxies; keeping separate coordinates prevents premature averaging from hiding which subsystem is "objecting." This also makes room for asymmetric policy rules, such as treating some dimensions as veto constraints (e.g. "never exceed woe threshold on safety") and others as objectives (e.g. "maximize joy on curiosity"), without forcing all of them into a single commensurate scale.*

Definition 248 (Preference order on p-bits)**.** *For evaluative purposes, define a partial order $\preceq_{\text{pref}}$ on $[0,1]^2$ by*

$$(v^+,v^-) \preceq_{\text{pref}} (u^+,u^-) \quad\iff\quad v^+ \le u^+ \text{ and } v^- \ge u^-.$$

Thus "better" means more positive evidence and less negative evidence.

Remark 979. *The order $\preceq_{\text{pref}}$ is the simplest monotone notion of "at least as good" compatible with two-sided evidence: you can improve by increasing the positive channel and/or decreasing the negative channel. It is partial rather than total because many pairs are incomparable (one has more joy but also more woe). This incomparability is not a technical nuisance; it is the formal reflection of conflicted evaluation (Hyperseed-Concept 198). Note that $\preceq_{\text{pref}}$ makes explicit that "net" affect is not the primitive object: a p-bit with high (v^+,v^-) may represent a tempting but risky option, whereas a p-bit with lower (u^+,u^-) may represent a dull but safe option; neither dominates the other without an additional principle. In this sense, a later tie-breaker scalar (if used at all) is properly interpreted as an* extra *policy commitment about how to resolve incomparabilities, not as part of the evidence itself.*

Example 15. *Let* $v = (0.7, 0.2)$ *and* $u = (0.8, 0.2)$*. Then* $v \preceq_{\text{pref}} u$ *because* u *has at least as much positive evidence and no more negative evidence. But* $v' = (0.9, 0.7)$ *and* $u' = (0.8, 0.2)$ *are incomparable: one is higher joy and higher woe, the other lower joy and lower woe. This is a minimal formal model of ambivalence versus calm satisfaction. One can also view* $(0.9, 0.7)$ *as "high activation conflict" (strong pull and strong push), whereas* $(0.8, 0.2)$ *is "cleanly positive"; treating them as incomparable preserves the psychologically natural distinction between intensity and valence-mixing, which would be lost under a single net score.*

Definition 249 (Pareto dominance for value-vectors)**.** *For two options* (s, a) *and* (s, a') *define:*

$$\mathbf{E}_O(s, a) \preceq_{\text{Pareto}} \mathbf{E}_O(s, a') \iff E_O(s, a; d) \preceq_{\text{pref}} E_O(s, a'; d) \quad \forall d \in \mathcal{D}.$$

An option is Pareto-undominated *if there is no other option that strictly improves at least one dimension and is no worse in all others (under* $\preceq_{\text{pref}}$*).*

Remark 980. *Pareto dominance is the canonical way to aggregate multiple objectives without assigning tradeoff weights: it marks an option as "unambiguously worse" only when it is worse (or equal) in every dimension and strictly worse in at least one. In a value setting, this has a moral flavor: if one option is no worse on every value and strictly better on at least one, then choosing the dominated option looks like pure irrationality or error. This connects directly to the rationality conditions later (Hyperseed-Concept 148). Importantly, using Pareto-undominated options as a first-stage filter does not require the agent to decide how to trade* truth *against* comfort*; it only requires the weaker commitment to avoid options that are jointly worse by the agent's own lights in every tracked dimension. When the undominated set is large (as is typical in high-dimensional, conflict-laden settings), a tie-breaker can be applied* afterwards*—for example, by a context-conditioned scalar functional* $T(\mathbf{E}_O(s, a))$ *that is allowed to depend on situational features, learned norms, or risk sensitivity—but such a functional is then explicitly a second-stage policy choice rather than a covert averaging that would hide the underlying conflict structure.*

This keeps value paraconsistency explicit: conflicts remain visible as non-comparabilities. It also makes room for principled "refusal" or "deferral" behaviors: if all available actions are Pareto-undominated yet each carries substantial woe on some dimension, the formalism can represent the state as one of genuine normative tension rather than forcing a spurious numeric optimum. Conversely, when a clear dominance relation exists, the model predicts stable agreement across a wide class of tie-breakers, since any reasonable scalarization that is monotone in the sense of $\preceq_{\text{pref}}$ will also avoid selecting Pareto-dominated actions.

18.3 Emotion as structured evaluation and resistance signals

Hyperseed's notion of emotion is not merely an add-on to cognition; it is a *control-relevant summary* of value and effort structure.

Remark 981. *The guiding idea is that emotion compresses a large evaluative landscape into a small set of control knobs: what to approach, what to avoid, what to endure, what to postpone. Formally, we will keep the compression mild: rather than forcing a scalar utility, we package (i) predicted value-evidence, (ii) predicted resistance/effort, and (iii) a coherence indicator. This should be read as a mathematical scaffold for the Hyperseed concept Emotion (Hyperseed-Concept* **??***) rather than as an attempt to exhaust phenomenology.*

Definition 250 (Effort/resistance estimator)**.** *Let* $c_O(s, a) \in V$ *denote an observer-relative effort cost (weakness/effort quantale value; cf. Section 3.7 and Section 8). Let* $\rho : V \to [0, \infty)$ *be any* *monotone "readout" mapping from quantale cost to a nonnegative scalar (e.g. ρ could be a chosen norm or a projection). Define the* scalar resistance estimate*:*

$$R_O(s,a) := \rho\big(c_O(s,a)\big).$$

Remark 982. *Here V is the underlying quantale (or cost domain) used earlier to encode weakness/effort; $c_O(s,a)$ is the cost object in that domain; and ρ is a chosen way to read it out as a single nonnegative number so we can compare options by "how hard." The monotonicity requirement on ρ is the only structural assumption: more cost in the quantale sense should not turn into less scalar resistance. This ties the present section back to the weakness/effort program [3, 2] and to the core notion Quantale Weakness (Hyperseed-Concept 143).*

Remark 983. *A simple example is when $V = [0,\infty]$ with the usual order, and $c_O(s,a)$ is already a scalar time/energy estimate; then ρ can be the identity. A more Hyperseed-flavored example is when V encodes multi-resource cost (compute, attention, social risk) and ρ is a chosen projection that fits the observer's current strategic posture.*

Definition 251 (Emotion as an evaluation-resistance pattern)**.** *Fix a time horizon H and let $\widehat{E}_O(s,a;d)$ denote the predicted (future) value-evidence for d over horizon H if action a is taken at s. An* emotion token *for O at (s,a) is a tuple*

$$\mathrm{Em}_O(s,a) := \Big(\ \widehat{\mathbf{E}}_O(s,a),\ R_O(s,a),\ \kappa_O(s,a)\ \Big),$$

where $\kappa_O(s,a)$ is an optional coherence/resonance signal (defined below) indicating how aligned the value evidence is across dimensions and timescales.

Remark 984. *Intuitively, $\mathrm{Em}_O(s,a)$ is what an agent "feels about" doing a from s, in a way that is already poised to influence control: it includes (i) the forecasted evaluative consequences, (ii) the forecasted effort/resistance, and (iii) whether the forecasted consequences harmonize or fight each other. A simple example is "approach a difficult conversation": high predicted truth and belonging benefits, but also high resistance; and depending on the internal model, high or low coherence between dimensions.*

Remark 985. *The usefulness is compositional. The prediction/control layer can be used to compute $\widehat{E}_O$; the weakness/effort layer yields R_O; and the resonance layer yields κ_O. Emotion then becomes a derived interface object that is compatible with the rest of the stack, rather than a new primitive.*

Remark 986 (Why this matches the Hyperseed intent)**.** • *Joy/woe components live in $\widehat{\mathbf{E}}_O$.*

- *"Tension" and "relief" can be modeled as changes in R_O and/or changes in the coherence signal κ_O.*
- *Complex emotions correspond to characteristic patterns in the vector-valued evidence, rather than to single scalar utilities.*

18.3.1 Compassion

Compassion is treated as a value dimension whose evaluation depends on modeled others.

Definition 252 (Compassion as other-referenced evaluation)**.** *Let $\mathcal{A}$ be a set of agents, with distinguished self agent* self $\in \mathcal{A}$*. For each $j \in \mathcal{A}$ assume O carries an estimate of that agent's joy/woe* *for outcomes, encoded as p-bits* $E_{O\to j}(s,a;\textsf{joy})$ *and* $E_{O\to j}(s,a;\textsf{woe})$*. Define a compassion score (as a p-bit) by*

$$E_O(s,a;\textsf{compassion}) := \bigoplus_{j\in\mathcal{A}\setminus\{\mathrm{self}\}} \Big(E_{O\to j}(s,a;\textsf{joy}) \ \otimes\ \neg E_{O\to j}(s,a;\textsf{woe})\Big),$$

where $\neg$ *is p-bit negation (swap evidence components) and* $\oplus,\otimes$ *are the aggregators fixed in the core.*

Remark 987. *This definition treats compassion (Hyperseed-Concept 81) as intrinsically* model-based*: it depends on how* O *represents other agents' prospective joy and woe. In that sense it links value theory to social cognition and to the self/other boundary formalism earlier (Hyperseed-Concept 165). The algebraic structure—combine a model of others' joy with the negation of others' woe, then aggregate over others—makes explicit what is otherwise left as moral rhetoric.*

Remark 988. *A simple example: suppose there is one other agent* j*, and* $E_{O\to j}(s,a;\textsf{joy}) = (0.6, 0.2)$ *while* $E_{O\to j}(s,a;\textsf{woe}) = (0.4, 0.7)$*. Then* $\neg E_{O\to j}(s,a;\textsf{woe}) = (0.7, 0.4)$*, and the combined term is* $E_{O\to j}(\textsf{joy}) \otimes \neg E_{O\to j}(\textsf{woe})$*. The exact numeric result depends on the quantale operations, but the intended qualitative reading is: compassion rises when we foresee others' joy and do not foresee their woe.*

Remark 989. *This definition is only a template: it says compassion is evaluated by modeling others' joy/woe and aggregating. Different observers may use different agent sets, weights, and aggregators. The key point is structural: compassion is not a mysterious extra primitive; it is a particular kind of evaluative dependence on other-modeled affect.*

Remark 990. *In multi-agent contexts, formal compassion also connects to arguments that prosocial constraints can increase group-level efficiency and coordination capacity, rather than merely adding moral overhead [6]. In Hyperseed terms, compassion can be seen as an ingredient in building high-resonance cultural patterns that reduce collective resistance.*

18.4 Values, feelings, goals, and reward

Hyperseed distinguishes between transient *feelings* and persistent *values.* Goals are commitments that bind action selection to values.

18.4.1 Values as stable patterns; feelings as local evaluations

Definition 253 (Value as a stable evaluative pattern)**.** *A value dimension* $d \in \mathcal{D}$ *is said to be a* stable value for observer O *over an interval of proto-time* T *if the induced evaluation function*

$$(s,a) \mapsto E_O(s,a;d)$$

is (approximately) invariant under the observer's typical context changes in that interval (up to a tolerance set by O*'s weakness/effort limits).*

Remark 991. *The intuition is that a value is not a single episodic feeling; it is a* pattern of appraisal *that persists across changing circumstances. "Truth matters" means: across many contexts, actions predicted to support truth tend to receive stable positive evidence relative to that dimension. This explicitly ties values to the broader Hyperseed idea that ontology is reconstructed in terms of stable patterns (Hyperseed-Concept 130; cf. [5]).*

Remark 992. *A simple example: if $d = \textsf{compassion}$ is stable for O over T, then even as the specific people and situations vary, the mapping $(s, a) \mapsto E_O(s, a; d)$ continues to privilege actions that reduce others' woe. The usefulness of this definition is that it gives a crisp criterion for when we are justified in treating some evaluative coordinate as a relatively fixed constraint in planning, rather than as noise.*

Definition 254 (Feeling as time-local affective readout)**.** *A* feeling token *for O at time t is any scalar or low-dimensional readout*

$$F_O(t) = \Phi\Big(\mathrm{Em}_O(s_t, a_t)\Big),$$

where Φ is a bounded map (e.g. combining joy/woe across a small subset of dimensions, plus resistance).

Remark 993. *Here Φ formalizes the act of compression: the mind cannot (and need not) represent the entire evaluative tensor at every moment, so it reads out a small summary. In common terms, this includes things like "anxiety level," "relief," or "contentment." The formal definition is deliberately permissive: many different physiological and cognitive architectures may implement different Φ. This corresponds to Feelings (Hyperseed-Concept* **??***) as time-local indicators rather than enduring commitments.*

Remark 994. *A simple example is $\Phi(\widehat{\mathbf{E}}, R, \kappa) = \sum_{d \in D_0} \lambda_d (J - W) - \beta R$ for a small subset $D_0 \subseteq \mathcal{D}$ active in the current attentional focus. The usefulness is that the theory can talk about feelings without reifying them as primitives: they are observer-dependent readouts of deeper evaluative structure.*

This makes the common-sense relationship precise: feelings are local readouts; values are stable patterns in evaluative fields.

18.4.2 Goals: explicit and implicit

Definition 255 (Explicit goal)**.** *An* explicit goal *for O is a representable constraint G on trajectories or outcomes:*

$$G \subseteq \Omega$$

where Ω is a space of outcomes or histories (as formalized in the prediction/control layer). Explicitness means O can name G in its representational language (Section 13).

Remark 995. *The intuition is that an explicit goal is* declarative*: it lives in the agent's representational economy as something like "finish the proof," "do not lie," or "keep the system within a safety envelope." This corresponds to Goals: Explicit (Hyperseed-Concept* **??***). The set-theoretic form $G \subseteq \Omega$ is standard in control theory: it lets us treat goals as constraints on whole trajectories rather than one-step rewards.*

Remark 996. *A simple example is Ω being the set of finite-length action-observation histories up to horizon H, and G being those histories in which a safety predicate never becomes false. The usefulness is that such a goal can be used as a hard feasibility constraint, independent of how one trades off other values within the safe region.*

Definition 256 (Implicit goal)**.** *An* implicit goal *for O is any stable regularity in action selection induced by E_O and c_O that* need not be representable as a named constraint *in O's language. Equivalently: an implicit goal is a goal implemented by policy/habit rather than by declarative representation.*

Remark 997. *Implicit goals (Hyperseed-Concept **??**) live in the dynamics rather than in the discourse: the agent behaves* as if *it were optimizing or constraining something, even if it cannot articulate it. This matches both everyday psychology (habits, avoidance patterns) and machine learning practice (policies trained end-to-end without symbolic specification). In Hyperseed terms, this is also a bridge from the habit dynamics layer to the goal layer.*

Remark 998. *A simple example is "avoid embarrassment" in a person who never explicitly adopts that phrase as a goal, yet repeatedly chooses actions that lower predicted social woe. Another example is a learned controller that repeatedly chooses low-resistance actions even when no explicit "minimize effort" rule is represented. The usefulness is that it lets the formalism describe goal-directedness as a spectrum rather than a binary property.*

Remark 999 (Hyperseed intent)**.** *This matches the everyday distinction: a person may have an implicit goal of avoiding embarrassment without ever having stated it as a goal. Similarly, many learned systems optimize a reward function (implicit goal) without explicit symbolic commitments.*

18.4.3 Reward as a derived (optional) scalar

Hyperseed often speaks in terms of goals/values rather than rewards. Still, rewards are convenient for algorithms, so we define them as *derived*. In particular, the intent is that the underlying evaluative object remains the structured, potentially conflicting evidence (and any associated constraints), while the scalar is an interface layer for decision procedures that require a single number. This also clarifies a methodological point in this section: "reward" is not treated as metaphysically primitive, but as a deliberately lossy projection that can be turned on or off depending on the reasoning context.

Definition 257 (Paraconsistent reward from evaluative evidence)**.** *Fix weights $\lambda_d \geq 0$ for $d \in \mathcal{D}$ and a resistance weight $\beta \geq 0$. Define a scalar reward proxy:*

$$r_O(s,a) := \sum_{d \in \mathcal{D}} \lambda_d \Big(J_O(s,a;d) - W_O(s,a;d) \Big) \; - \; \beta \, R_O(s,a).$$

It is sometimes helpful to read the expression as a sequence of modeling choices: (i) treat each dimension d as producing two-sided evaluative evidence, (ii) convert that two-sided evidence into a signed "net" quantity via $(J - W)$, (iii) trade off dimensions by nonnegative weights, and (iv) subtract an additional term capturing friction, cost, or internal opposition via R_O. Nothing in the definition requires that the units of $(J - W)$ match those of R_O; rather, the choice of β (and the scale of the λ_d) is what makes the overall scalar comparable across actions. In applications, λ_d and β can be treated as hyperparameters to be elicited, learned, or tuned, with the important caveat that tuning changes the induced trade-offs and can therefore change which conflicts get "smoothed over" by the scalarization.

Remark 1000. *The intuition is utilitarian in form but not in metaphysics: r_O is a* computational convenience*, a single number extracted from a richer evaluative structure. The difference $(J - W)$ is a simple way to turn two-sided evidence into a signed quantity, while βR_O penalizes resistance. This relates to Reward and Reward Maximization (Hyperseed-Concepts 160, 161), while preserving the prior commitment that the vector structure is primary.*

A further implication of calling r_O "derived" is that two agents (or two subsystems) may share the same underlying (J, W, R) structure yet adopt different scalarizations for different tasks. For example, a fast planner might use a coarse scalar proxy for search, while a slower reflective process revisits the same candidate actions using the unsummed vector evidence to surface tensions and failure modes that scalarization can conceal. This is one way to reconcile the convenience of scalar interfaces with the broader aim of keeping value conflict legible.

Remark 1001. *A simple example: if $\mathcal{D} = \{\mathsf{truth}, \mathsf{comfort}\}$ with $\lambda_{\mathsf{truth}} = \lambda_{\mathsf{comfort}} = 1$ and $\beta = 0.5$, then $r_O(s, a)$ rewards actions with net positive evidence on each dimension while also preferring lower-resistance options. The usefulness is that this makes contact with standard planning and reinforcement learning interfaces (cf. broader AGI algorithmic discussions in [19]), without forcing the entire theory to be reward-centric.*

In that example, note that the scalar can increase either by raising J (more supporting evidence), lowering W (less opposing evidence), or lowering R (less resistance). These are not interchangeable changes in the underlying representation: increasing J is not the same as decreasing W, even if both increase $(J - W)$, and the distinction remains available to any procedure that inspects the full evidence structure rather than only the scalar. This is precisely the sense in which the scalar is optional: it can be used for action selection while leaving the evidence geometry intact for explanation, auditing, and conflict management.

Remark 1002 (Reward maximization vs goal seeking)**.** *Reward maximization uses the scalar r_O. Goal seeking treats some constraints as hard or lexicographic (e.g. "do not violate compassion below a threshold") and uses r_O only within the feasible set. Hyperseed's conceptual preference is typically the latter: keep conflicts visible, and use scalars carefully.*

A useful way to formalize the remark is to view goal seeking as a two-stage procedure: first restrict to a feasible region defined by constraints on (some functions of) (J, W, R), and only then optimize a scalar proxy on that region. This helps separate "non-negotiables" (hard constraints, thresholds, or lexicographic priorities) from "trade-off" dimensions where scalarization is acceptable. It also clarifies how resistance can be treated: in some contexts R_O is a soft cost (hence the βR_O term), while in other contexts it can itself induce feasibility constraints (e.g. "avoid actions that trigger extreme internal conflict"), again illustrating that r_O is not the sole decision object.

Proposition 27 (Scalarization implies Pareto optimality when used monotonically)**.** *Fix a finite set of actions A at state s and suppose we define a score*

$$\mathrm{Score}(a) := \sum_{d \in \mathcal{D}} \lambda_d \Big(J_O(s, a; d) - W_O(s, a; d) \Big) - \beta\, R_O(s, a),$$

with $\lambda_d > 0$ for all d and $\beta \geq 0$. If an action $a^\star$ maximizes Score*, then $a^\star$ is Pareto-undominated with respect to the componentwise order*

$$\Big(J_O(s, a; d),\ -W_O(s, a; d) \Big)_{d \in \mathcal{D}} \quad \textit{and} \quad - R_O(s, a).$$

Remark 1003 (Intuition and role in the section)**.** *The proposition says: if you insist on collapsing multiple value dimensions (and resistance) into one scalar by a strictly monotone linear combination, then any scalar maximizer cannot be* obviously worse *than another available action across all dimensions at once. In other words, scalarization cannot accidentally pick an option that is dominated on every criterion that the scalar score rewards.*

Remark 1004. *This result matters because Hyperseed repeatedly warns against premature scalar collapse, yet also acknowledges the practical convenience of scalar rewards. The proposition is a small sanity bridge between these stances: it shows that a monotone scalar proxy at least respects the minimal Pareto boundary of the richer evaluative geometry.*

A small but practically relevant nuance is why the proposition assumes a finite action set. With infinite (or continuous) action spaces, one typically needs additional regularity to guarantee that a maximizer exists (e.g. compactness of the feasible action set and continuity of Score, or else replacing "maximizes" with "is optimal" in the sense of a supremum). The Pareto-undominance conclusion is fundamentally about *any* maximizer that does exist: once an argmax is well-defined, the same dominance contradiction goes through. Thus the finiteness assumption is best read as a convenient sufficient condition for existence rather than a conceptual limitation of the monotonicity idea.

Proof. Assume for contradiction that $a^\star$ is dominated by some a such that for every d, $J_O(s,a;d) \geq J_O(s,a^\star;d)$ and $W_O(s,a;d) \leq W_O(s,a^\star;d)$, with strict inequality for at least one dimension or strictly smaller resistance. Then each term $\lambda_d(J-W)$ is at least as large for a as for $a^\star$, and strictly larger for at least one d. Also $-\beta R_O(s,a)$ is at least as large as $-\beta R_O(s,a^\star)$ (and strictly larger if resistance strictly decreases and $\beta > 0$). Hence $\text{Score}(a) > \text{Score}(a^\star)$, contradicting maximality of $a^\star$. $\square$

Proof sketch. The proof is a direct monotonicity argument. Dominance means every coordinate that contributes positively to Score is at least as favorable for a as for $a^\star$, and at least one is strictly more favorable. Because the weights λ_d are strictly positive (and $\beta \geq 0$), the strict improvement survives summation, contradicting the assumption that $a^\star$ maximizes the scalar score. $\square$

Remark 1005. *The key step is that dominance is expressed in the same direction as the scalar score: increasing J and decreasing W weakly increases each weighted term, and decreasing resistance weakly increases the $-\beta R$ term. This is why strict positivity of λ_d is important: it prevents an improved dimension from being "invisible" to the scalar. Geometrically, the argument says that a linear functional with positive coefficients cannot be maximized in the interior of a region that is strictly dominated in every outward direction.*

One can also read the strict positivity requirement as a warning about "dropping" dimensions during scalarization. If some $\lambda_d = 0$, then improvements in that dimension do not affect the scalar score at all, and the scalar maximizer can be dominated with respect to the full vector order that includes that dimension. In that sense, $\lambda_d > 0$ encodes a minimal respect condition: every dimension declared relevant to the Pareto comparison must have at least some influence on the scalar proxy. Similarly, if $\beta = 0$, then resistance is ignored by the scalar; the proposition still holds for the reduced vector order that omits $-R_O$, but it no longer guarantees undominance once resistance is added back as an additional coordinate.

Remark 1006. *The proposition does not claim scalar rewards are sufficient; it only states a sanity property: if you do collapse to a scalar in a strictly monotone way, you do not accidentally pick a dominated option. The paraconsistent structure still matters because the (J, W) values can encode conflict and incomplete evidence.*

A further limitation is that Pareto-undominance is only a minimal rationality property. Many Pareto-undominated actions can still be mutually incomparable, and the scalarization picks one according to a particular trade-off surface determined by (λ, β). Hyperseed's emphasis on keeping conflicts visible is partly a reminder that, when the underlying evidence is paraconsistent or incomplete, the set of Pareto-undominated actions can be large, and the choice among them may require additional deliberative structure (e.g. constraints, lexicographic rules, or context-sensitive priorities) rather than a single fixed scalar.

18.5 Resonance as coordination signal for value conflict

A core Hyperseed motivation is that action can be "coherent" even when values conflict. We formalize coherence using the resonance mapping from Section 3.9. In this subsection, "coherent" is meant in the dynamical/behavioral sense: the agent can stably select and execute a policy whose internal motivational components are sufficiently aligned to sustain follow-through, even if the agent cannot produce a single propositional description that renders all value-claims jointly satisfiable.

Remark 1007. *The philosophical point is subtle: coherence is not the same as consistency. An agent may coherently act under conflict by aligning many partial tendencies into a single trajectory, even if those tendencies cannot be made mutually noncontradictory at the representational level. Resonance (Hyperseed-Concept 159) is a formal proxy for this kind of alignment; dissonance (Hyperseed-Concept 97) is a proxy for cancellation and internal struggle.*

One practical reason to separate coherence from consistency is that real agents often face incommensurable desiderata (e.g., loyalty vs. fairness, exploration vs. safety, short-term relief vs. long-term health). In such settings, insisting on representational consistency can force an artificial collapse of plural values into a single scalar, whereas the resonance framing aims to preserve plurality while still yielding actionable structure.

Definition 258 (Complex value signal for a dimension)**.** *For each dimension d and option (s, a), define the complex signal*

$$z_O(s, a; d) := \sigma_C\big(E_O(s, a; d)\big) \in \mathbb{C},$$

where σ_C is the logic-to-complex map introduced in the core.

Remark 1008. *Here σ_C is the previously defined embedding of p-bit evidence into the complex plane, used to make "interference" and "phase alignment" algebraically explicit (Section 3.9). The intuition is that each value dimension contributes a complex phasor, and the overall alignment of these phasors measures how coordinated the value system is under the contemplated option.*

It is helpful to keep two roles of $z_O(s, a; d)$ conceptually distinct: its *magnitude* corresponds to the strength or confidence of the dimension-specific evaluation under (s, a), while its *argument* (phase) corresponds to the "direction" of the evaluation (broadly, pro vs. con, or endorsement vs. veto, depending on how σ_C was set up). This separation is exactly what makes it possible for strong but opposing evaluations to cancel, rather than being forced into an arbitrary compromise.

Remark 1009. *A toy example: if two dimensions yield complex signals of similar argument (phase), their sum has larger magnitude; if they yield signals with opposite phase, they partially cancel. This gives a clean mathematical image of "my values pull in the same direction" versus "my values fight each other."*

Note that cancellation can occur even when each individual dimension is "certain" (large magnitude): high-confidence opposition yields large destructive interference. Conversely, weak or ambiguous evaluations (small magnitude phasors) contribute little to either alignment or conflict, which matches the intuition that faint preferences should not dominate the global coordination signal.

Definition 259 (Weighted resonance magnitude)**.** *Fix weights $w_d \geq 0$ and define the total complex signal*

$$Z_O(s, a) := \sum_{d \in \mathcal{D}} w_d \, z_O(s, a; d).$$

Define the resonance magnitude

$$\kappa_O(s,a) := |Z_O(s,a)|.$$

Optionally define an interference term (as in Section 3.9) by

$$I_O(s,a) := |Z_O(s,a)|^2 - \sum_{d\in\mathcal{D}} |w_d z_O(s,a;d)|^2.$$

The nonnegativity constraint $w_d \geq 0$ ensures that weights encode relative salience or priority without inverting a dimension's meaning; sign flips are instead represented through the phase of z_O. In applications, w_d can be used to encode long-run commitments (stable importance weights) while allowing the evidence-to-phase map σ_C to reflect context-sensitive endorsement or rejection.

Remark 1010. *The magnitude $\kappa_O(s,a)$ is a scalar summary of alignment; it is large when many weighted dimensions agree in "direction" (as encoded by the complex phases induced by σ_C). The interference term $I_O(s,a)$ measures whether the whole is more or less than the sum of squared parts; negative values correspond to destructive interference, a particularly crisp signature of internal conflict.*

Because I_O is defined using squared magnitudes, it admits a familiar geometric reading: expanding $|Z_O|^2$ yields cross-terms that are proportional to pairwise phase agreement between dimensions. Thus I_O can be interpreted as aggregating pairwise "coordination" contributions, making it useful when one wants to diagnose which sets of dimensions are jointly supportive versus mutually cancelling (though such diagnosis requires looking beyond the scalar and into the underlying phasors).

Remark 1011 (Interpretation)**.** • *Large κ_O indicates that the dimension-signals line up in phase (coherent "yes" or coherent "no" structure).*

- *Negative interference $I_O < 0$ corresponds to cancellation between dimensions: this is one clean formal proxy for internal value conflict.*

  This gives a mathematically explicit handle on Hyperseed's qualitative talk of resonance/dissonance.

Importantly, κ_O alone does not claim that the option is "good" in a single-dimensional sense; rather, it measures the *degree of coordinated support* among the dimensions as encoded. An option can have high resonance because many dimensions coherently reject it (a coordinated "no"), which is still useful information for an agent that needs to avoid self-undermining action: coordination can be coordination toward refusal as well as toward pursuit.

Definition 260 (Resonant feasible choice rule)**.** *Let $A_{\text{Pareto}}(s) \subseteq A$ be the Pareto-undominated set at s (under $\preceq_{\text{pref}}$ across $\mathcal{D}$). Define a* resonant choice *as any maximizer of*

$$a^\star \in \arg\max_{a\in A_{\text{Pareto}}(s)} \Big(\kappa_O(s,a) - \beta R_O(s,a)\Big),$$

with $\beta \geq 0$.

The Pareto filter plays a normative role: it prevents resonance from favoring an option that is strictly worse on all dimensions (which could otherwise happen if the mapping σ_C induces phases that accidentally align even for uniformly dominated actions). In this sense, resonance is used as a *coordination tie-breaker* among options that are already defensible from a pluralistic standpoint.

Remark 1012. *The rule has a clear two-stage meaning. First, eliminate actions that are unambiguously worse in the Pareto sense. Second, among the survivors, prefer options whose value dimensions mutually reinforce (high resonance) and do not demand excessive resistance. The usefulness is that it preserves pluralism of values while still producing a practical decision rule. It also mirrors a theme that recurs in Hyperseed: do not resolve conflict by denial; resolve it by coordination.*

The parameter β controls the tradeoff between "internal alignment" and "effortfulness" (as measured by R_O). At $\beta = 0$, the rule reduces to selecting the most internally coordinated option among the Pareto-undominated set; as β increases, the agent increasingly favors options that are easier to execute or that require less overcoming of aversion, fatigue, or constraint. This makes the rule suitable both for idealized deliberation (small β) and for bounded, resource-aware choice (larger β).

This rule is intentionally conservative: it does not erase value conflicts; it selects among already-undominated options using coherence and effort. In particular, it treats conflict as a first-class signal: destructive interference lowers κ_O (and can render I_O negative), thereby disfavoring options that would likely produce vacillation, paralysis, or regret due to internal cancellation, even when no single dimension can decisively veto the action.

18.6 Individuation, self-transcendence, and open-ended intelligence

Hyperseed treats *individuation* and *self-transcendence* as key drivers of open-ended growth. Here we formalize them as meta-values: dimensions in $\mathcal{D}$ that regulate how the value system itself evolves. Concretely, calling these dimensions "meta-values" means that they do not merely score external world-states, but also score *candidate updates* to the agent's self-model and evaluative vocabulary: a change to $\mathcal{D}$, to its internal organization, or to the policies that consult it can itself be treated as an object of evaluation in $E_{O,t}$.

Definition 261 (Individuation and self-transcendence as meta-values)**.** *Assume* $\mathsf{individuation}, \mathsf{self\_transcendence} \in \mathcal{D}$.

- *High evaluation on* $\mathsf{individuation}$ *favors options that preserve coherence and continuity of the self-model (Section* **??***) and reduce destructive self-fragmentation.*
- *High evaluation on* $\mathsf{self\_transcendence}$ *favors options that expand the representational and motivational space, including revising or enlarging* $\mathcal{D}$ *itself.*

Remark 1013. *A useful operational reading is that* $\mathsf{individuation}$ *implicitly penalizes updates that increase internal inconsistency, unresolvable goal-conflict, or identity discontinuities across prototime, while* $\mathsf{self\_transcendence}$ *implicitly rewards updates that increase model class capacity, perspective-taking, and the ability to represent previously inexpressible goals. In this sense, these two dimensions can be understood as providing a principled "regularizer" and "expander" for value learning: one controls brittleness and fragmentation, the other controls stagnation and premature closure.*

Remark 1014. *These two dimensions capture a constructive tension. Individuation (Hyperseed-Concept* **??***) protects the integrity of the self as a temporally extended pattern (Hyperseed-Concept 166); self-transcendence (Hyperseed-Concept 167) prevents that integrity from ossifying into a closed world. In Russellian terms, individuation provides logical discipline, while self-transcendence supplies the imaginative expansion that keeps the logical system from mistaking its axioms for the cosmos.*

Remark 1015. *One way to see the tension is to treat the self-model as a hypothesis that must remain predictive enough to coordinate action over time, while also remaining revisable enough to accommodate new evidence and new possibilities. Overemphasizing individuation risks "identity lock-in" (a self-model that refuses to update even when it systematically mispredicts), whereas overemphasizing self-transcendence risks "identity diffusion" (a self-model that updates so freely that long-horizon commitments and responsibility become unstable). The intended regime is neither rigidity nor dissolution but a dynamic equilibrium in which continuity is maintained through intelligible, narratively compressible change.*

Remark 1016. *A simple example: in creative work, individuation may favor maintaining a coherent long-term project identity, while self-transcendence may favor learning a radically new tool or exploring a new domain that reshapes the project. The usefulness of making these explicit dimensions is that "growth" can be formalized as a controlled revision of the value basis rather than as an unstructured drift.*

Remark 1017. *The same structure applies outside creative work. In moral development, individuation can favor keeping faith with prior commitments and relationships (so that change does not become betrayal-by-forgetting), while self-transcendence can favor encountering unfamiliar perspectives that force a refinement of what those commitments mean. In epistemic terms, individuation supports calibration and internal consistency; self-transcendence supports the discovery of new latent variables, new abstractions, and new ethical patient-classes that were previously absent from* $\mathcal{D}$.

Definition 262 (Open-ended intelligence as stable-yet-revisable value dynamics)**.** *Let* $\mathcal{D}_t$ *be the set of active value dimensions at proto-time* t *and* $E_{O,t}$ *the corresponding evaluative field. An observer exhibits* open-ended intelligence *on an interval if:*

1. *(*stability*) there exist nontrivial dimensions in* $\mathcal{D}_t$ *that remain stable for substantial sub-intervals (values do not dissolve into noise);*

2. *(*revisability*) there exist times* $t < t'$ *such that* $\mathcal{D}_{t'} \neq \mathcal{D}_t$ *(the value vocabulary can grow or reorganize);*

3. *(*coherence under revision*) revisions do not make action selection trivial; i.e. the agent retains a non-degenerate Pareto set and nontrivial resonance structure.*

Remark 1018. *Condition (1) can be read as requiring that some evaluative commitments persist long enough to support planning, learning, and accountability, while condition (2) requires that the system can escape local optima in* value space *rather than merely optimizing within a fixed objective. Condition (3) then rules out a degenerate "anything goes" regime: if revisions create a situation where almost all options are mutually incomparable (or all options become equally optimal), then the value system no longer provides actionable guidance. The non-degenerate Pareto requirement is thus not an aesthetic preference but a functional criterion ensuring that evaluation continues to constrain behavior in informative ways.*

Remark 1019. *It is also helpful to distinguish revisability at three granularities: (i)* parameter *revision (reweighting dimensions or changing trade-off curves), (ii)* structural *revision (splitting/merging dimensions, introducing new latent factors, changing the geometry of* $\mathcal{D}$*), and (iii)* semantic *revision (changing what a dimension tracks via new world-model concepts). The definition above permits all three, provided that stability and non-degeneracy are maintained somewhere in the system so that the agent remains a coherent decision-maker throughout the revision process.*

Definition 263 (Value-basis revision operator (one formalization))**.** *Let* Rev *be a (possibly stochastic) operator such that*

$$(\mathcal{D}_{t+1}, E_{O,t+1}) \;=\; \mathsf{Rev}(\mathcal{D}_t, E_{O,t}, \mathcal{M}_t, \mathcal{H}_t),$$

where $\mathcal{M}_t$ denotes the agent's current world/self-model state and $\mathcal{H}_t$ denotes relevant history (experience, reflection, social input). We say Rev *is* individuation-respecting *if it places high weight on preserving identity-continuity constraints (e.g. bounded discontinuity of self-representations across steps), and* self-transcendence-capable *if it assigns nonzero probability (or admissibility) to expansions and reorganizations of $\mathcal{D}_t$ when such changes improve expressive adequacy or reduce systematic blind spots.*

Remark 1020. *This operator view makes explicit that "meta-values" can be implemented as preferences over* updates *rather than only over* outcomes*. For example, individuation-respecting revision can be modeled by continuity penalties (e.g. bounding divergences between successive self-model encodings), while self-transcendence-capable revision can be modeled by allowing hypothesis-class expansion steps (e.g. adding a new dimension when prediction error or moral uncertainty remains persistently high). Importantly, these are not merely engineering conveniences: they correspond to the normative intuition that growth should be both intelligible (continuous enough to remain "me") and exploratory (open enough to become more than prior limitations).*

Remark 1021. *This definition makes "open-ended intelligence" (Hyperseed-Concept 127) a property of* value dynamics*, not only of problem-solving performance. The agent must be stable enough to be itself, yet plastic enough to become otherwise; and the plasticity must not collapse decision-making into incoherence. This connects to the broader AGI view that intelligence is partly the ability to manage changing task and value regimes without losing functional unity [19].*

Remark 1022. *The "stable-yet-revisable" requirement is closely related to the exploration–exploitation balance, but lifted to the level of* normative representation*. Exploitation corresponds to acting coherently under a relatively stable $\mathcal{D}_t$; exploration corresponds not only to trying new actions but to considering new* criteria *for action. On this reading, self-transcendence is a driver of normative exploration (search over value bases), while individuation is a driver of normative exploitation (consolidation and integration so that the expanded basis yields a unified self).*

Remark 1023. *A simple example is an agent that begins with $\mathcal{D}_t = \{\mathsf{safety}, \mathsf{comfort}\}$, later adds* truth*, and later refines* belonging *into separate dimensions for "local community" and "global commons." Revisability is not mere addition: it can involve splitting, merging, or reweighting dimensions. The usefulness of the non-degeneracy condition is that it blocks a pathological case where everything becomes incomparable and the Pareto set becomes uninformative.*

Remark 1024. *A complementary pathological case is the opposite extreme: revisions that collapse the evaluative field so that almost everything becomes tied (e.g. by flattening all distinctions or by introducing an overriding dimension that trivializes the rest). Both extremes destroy guidance: pervasive incomparability yields paralysis, while pervasive ties yield arbitrariness. The point of requiring a nontrivial resonance structure is to ensure that the system retains patterned sensitivities—some options systematically "fit" the current integrated value basis better than others, in a way that can be learned, explained, and used for planning.*

Remark 1025 (Open-ended benefit)**.** Open-ended benefit *is the same idea applied normatively: value evolution is not only open-ended, but tends to expand the feasible set of futures in which multiple agents can realize joy and reduce woe. Formally, this is captured by including compassion and non-destructive coordination constraints in the revision rule for $\mathcal{D}_t$.*

Remark 1026. *The phrase "expand the feasible set of futures" can be read in a multi-objective sense: revisions should (in expectation and subject to uncertainty) increase the set of attainable trajectories that score well across a plurality of agents' evaluative fields, while avoiding expansions that are achieved by exploitation, coercion, or irreversible harm. This is stronger than simple "innovation" or "growth" because it adds constraints on the* means *of expansion (non-destructive coordination) and on the distribution of its benefits (compassion).*

Remark 1027. *Open-ended benefit (Hyperseed-Concept 126) adds a social and ethical tilt: it asks that the expansion of possibilities not be purchased by narrowing others' possibilities. In multi-agent settings, this is naturally connected to compassion and to collective coordination effects, echoing broader Hyperseed arguments about prosocial efficiency [6].*

Remark 1028. *In practice, "compassion and non-destructive coordination constraints" can be interpreted as admissibility conditions on* Rev*: certain updates to* $\mathcal{D}_t$ *(or to the weights and semantics of its dimensions) are disallowed if they systematically increase incentives for domination, deception, or zero-sum lock-in. This makes open-ended benefit a criterion not only on chosen actions but on the long-run* shape *of the evolving value system: it favors meta-stable attractors in which agents remain mutually legible and able to negotiate, rather than drifting toward value regimes that externalize costs onto others or render cooperation impossible.*

18.7 Rationality: coherence between belief, value, and action under constraints

Hyperseed uses "rationality" broadly: not merely logical consistency, but action selection that respects evidence, values, and resource limits. In particular, the term is intended to cover both (i) *epistemic discipline* (how strongly different outcomes are supported by the belief model) and (ii) *practical discipline* (how choices are filtered and ranked when multiple value-criteria and costs compete). This usage intentionally departs from the common identification of rationality with either deductive closure or with unconstrained expected-utility maximization, since the present framework makes room for conflict, incompleteness, and bounded computation as first-class structural features.

Remark 1029. *In this setting, rationality (Hyperseed-Concept 148) is not the classical ideal of a perfectly consistent belief set with a total utility function. It is instead a form of* coherence under limitation*: coherence across paraconsistent belief evidence, paraconsistent value evidence, and the resistances imposed by finite resources. This is consonant with the general Hyperseed ethos that weakness is fundamental rather than accidental [3, 2]. A useful way to read "coherence" here is as a family resemblance between internal components: beliefs constrain which futures are treated as live, values constrain which futures are treated as desirable, and resistances constrain which futures are treated as* reachable without collapse*. The relevant notion of "consistency" is therefore not global consistency of all attitudes at once, but local compatibility sufficient to support stable action selection.*

Definition 264 (Rational decision criterion (minimal version))**.** *Fix state* s*. A choice rule* $\pi_O(\cdot \mid s)$ *is* (Hyperseed-minimally) rational *if it satisfies:*

1. ***Non-explosion under value conflict:*** *if two actions have incomparable value-vectors (due to paraconsistency), the rule still returns a nonempty admissible set (or distribution) rather than degenerating into arbitrary choice over all actions.*

2. ***Dominance respect:*** *if* a *Pareto-dominates* a' *(under* $\preceq_{\text{pref}}$ *across all* d *and has no greater resistance), then* π_O *does not prefer* a' *over* a*.*

3. ***Resource sensitivity:*** *ceteris paribus, if two actions have equal value evidence, the rule prefers smaller resistance $R_O(s,\cdot)$.*

4. ***Belief/value/action coherence:*** *if the observer's belief model assigns negligible plausibility to an outcome, the value attached to that outcome does not dominate action selection unless explicitly designated as a faith-commitment (Section 20).*

The four clauses are intentionally framed as *failure-avoidance* constraints: they do not dictate a unique optimizer, but they rule out characteristic ways a decision procedure can become pathological when paraconsistency and bounded resources are treated as normal. They can also be read as "guardrails" for many different concrete implementations (e.g., rule-based filters, scalarizations, satisficing schemes, or distributions over an admissible set), provided those implementations preserve the stated invariants.

Remark 1030. *These criteria separate three kinds of failure. The first is* explosion *(everything becomes permissible) under conflict—the evaluative analogue of logical explosion. The second is* dominated choice *(choosing something plainly worse). The third is* resource blindness *(preferring an equally good but harder path). The fourth is* wishful incoherence *(acting as if an implausible outcome were assured). Together, they provide a minimal floor, not a full theory of rationality. It is worth emphasizing that "plainly worse" in the second item is defined relative to the agent's own current value-ordering and resistance structure, not relative to any external metric. In this way, the minimal criterion stays neutral about substantive ethics while still forbidding internal self-undermining moves such as paying strictly more resistance for strictly less-supported value outcomes.*

Remark 1031. *A simple example of criterion (4): an agent may value "winning the lottery," but if its belief model makes the probability effectively negligible, then "buy lottery tickets and quit my job" should not be selected unless the agent elevates that goal to a special status (faith-commitment). This links the present section to the epistemic layer (Section 20), where belief systems and commitments are treated as structured and resource-sensitive. More generally, this criterion blocks a common failure mode in multi-criteria settings: a high value attached to a near-impossible outcome can otherwise swamp moderate values attached to plausible outcomes, producing policies that are "optimistic" in a purely formal sense but behaviorally brittle. The "faith-commitment" escape hatch is included to represent deliberate, explicitly endorsed departures from evidential proportionality (e.g., vows, sacred values, or identity-defining goals), rather than allowing such departures to enter implicitly through numerical instabilities or unchecked aggregation.*

Remark 1032. *A simple example of criterion (2): suppose a and a' are two actions and, for every value-dimension d, the evidence-weighted preference ranks a at least as good as a' (and strictly better for at least one d), while also satisfying $R_O(s,a) \leq R_O(s,a')$. Then preferring a' amounts to accepting strictly less of what one already endorses while paying no less resistance. The minimal criterion does not require choosing a uniquely (there may be ties or incomparable alternatives), but it disallows elevating a' above a when a' is dominated in this strong sense.*

Remark 1033. *Criterion (1) can be viewed as the decision-theoretic analogue of paraconsistent non-triviality: a system that tolerates conflicting value evidence must still avoid the collapse in which* every *action becomes equally admissible simply because some values disagree. Practically, this often amounts to requiring that incomparability yields a* frontier *(a set of candidates) rather than a uniform indifference over all actions. In implementations that return a distribution, "non-explosion" can be operationalized by ensuring the support of the distribution remains within an admissible subset rather than spreading mass arbitrarily across clearly inferior or irrelevant options.*

Remark 1034. *Criterion (3) is deliberately stated as ceteris paribus because resistance is not an overriding value in the framework; it is a constraint-sensitive bias. When value evidence does not distinguish two actions (or distinguishes them only within a tolerance or uncertainty band), lower resistance functions as a tie-breaker that preserves operability and avoids gratuitous expenditure of time, energy, risk, or attention. This also connects to bounded rationality: limited resources are not merely external constraints but part of the internal structure that makes planning stable over time.*

Theorem 17 (Nonemptiness of resonant feasible choice in the finite case)**.** *Assume A is finite. Then the Pareto-undominated set $A_{\text{Pareto}}(s)$ is nonempty, and the resonant feasible choice rule admits at least one maximizer.*

Remark 1035 (Intuition and connection)**.** *The theorem says that once we refuse to collapse everything into a single scalar, we do not thereby doom ourselves to indecision—at least not in the finite-action case. There is always at least one undominated option, and once we restrict to the undominated set, any real-valued selection criterion (here $\kappa_O - \beta R_O$) attains a maximum. This provides a minimal existence guarantee for the decision scaffolds introduced above. One can also read this as a structural robustness statement: pluralism (many dimensions) and paraconsistency (incomplete or conflicting comparisons) can enlarge the set of admissible actions, but they do not force the admissible set to be empty. The nonemptiness of $A_{\text{Pareto}}(s)$ ensures that "refusing to scalarize" is not the same thing as "refusing to decide."*

Remark 1036. *This result is not surprising to order theorists, but it is conceptually important in the present document because it reassures us that paraconsistency and pluralism do not automatically destroy operability. It complements Proposition 27: scalarization respects Pareto boundaries, and Pareto boundaries exist (in the finite case), so one can move between scalar and vector viewpoints without falling into emptiness. In particular, the pairing of (i) an undominated-set filter and (ii) a subsequent scalar tie-breaker is a common pattern in practice: the first stage protects against dominated choices and some forms of value-conflict explosion, while the second stage yields a concrete selection when the frontier contains multiple elements.*

Proof. In any finite partially ordered set, there exists at least one minimal element. Apply this to the strict dominance relation (or equivalently to the complement of being dominated) to obtain a Pareto-undominated action. Thus $A_{\text{Pareto}}(s) \neq \emptyset$. Because $A_{\text{Pareto}}(s)$ is finite, the function $a \mapsto \kappa_O(s,a) - \beta R_O(s,a)$ achieves a maximum on it, so a maximizer exists. A slightly more explicit phrasing of the first step is: if every action were dominated by some other action, one could iterate the dominance relation indefinitely, constructing an infinite chain in a finite set, which is impossible; hence at least one action is not dominated. □

Proof sketch. The strategy is purely finitary. First, in a finite set you cannot have an infinite descending chain of "strictly dominated by" relations, so at least one action is not strictly dominated by any other (Pareto-undominated). Second, any real-valued function on a finite set attains a maximum, so the resonance-minus-resistance criterion yields at least one maximizer once restricted to the undominated set. The same schematic argument recurs throughout bounded frameworks: finiteness (or compactness, in continuous variants) is what turns "there are candidates" into "there is a best candidate" for a chosen scoring functional. □

Remark 1037. *The key step is recognizing Pareto-undominated actions as minimal elements in an appropriate order (or, dually, as maximal elements under the reverse order). Geometrically, if you plot all actions as points in a multi-criteria space, the Pareto set is the "frontier" that is not strictly* *overshadowed by any other point. Finite sets always have such a frontier. In paraconsistent settings, the geometry should be interpreted with care: incomparability can arise not only from tradeoffs between dimensions but also from genuinely unresolved or conflicting evidence about ordering within a dimension. Nevertheless, the "frontier" metaphor continues to serve as an intuition pump: the decision procedure first avoids points that are clearly worse by the agent's own lights, and then expends additional structure (e.g.,* $\kappa_O - \beta R_O$*) only within the remaining boundary.*

Remark 1038. *This theorem is deliberately simple, but it encodes a practical sanity check: once we refuse to collapse values into a single scalar, we must still guarantee that action selection does not become undefined. In later sections where action spaces may be large, continuous, or generated on the fly, this finitary sanity check can be treated as a baseline to be approximated: one seeks either finite candidate sets (via search and pruning) or conditions such as compactness and upper-semicontinuity that play the same role as finiteness in ensuring the existence of undominated elements and maximizers.*

18.8 Ethics: categorical imperative, cultural morality, and evil

Hyperseed treats ethics as a real phenomenon (not a mere epiphenomenal story) but also as observer-relative and socially embedded. We therefore model ethics as constraints and evaluation dimensions that are (i) representable, (ii) revisable, and (iii) partly shared across agents.

Remark 1039. *This subsection treats ethical notions as part of the same formal fabric as prediction, value, and action. The intent is not to settle meta-ethics, but to show that ethical constraints can be made computationally explicit without pretending that they are infallible. In Hyperseed terms, ethics is a species of socially stabilized evaluative pattern (Hyperseed-Concepts 197, 170, 91).*

18.8.1 Maxims and universalization

Definition 265 (Maxim)**.** *A* maxim *is a rule* m *mapping a representable context description to an action choice:*

$$m : \mathcal{C}_O \to A,$$

where $\mathcal{C}_O$ *is the set of contexts that* O *can represent (Section 13).*

Remark 1040. *A maxim is a compact representation of policy, but at the level of reasons rather than reflex. It says: "in contexts of type* c*, do action* a*." This corresponds to the Hyperseed emphasis that ethics must be expressible in the same representational medium as other knowledge, if it is to be debated, taught, revised, or enforced (Hyperseed-Concept 71).*

Remark 1041. *A simple example is: "When I borrow something, I return it promptly." Here* $\mathcal{C}_O$ *includes the representable condition "I borrowed item* x *from person* y*," and* m *selects the corresponding return action. The usefulness is that maxims can be fed into universalization tests and compared across agents as explicit social artifacts.*

Definition 266 (Universalization operator)**.** *Let* $\mathcal{W}$ *denote the modeled world dynamics (as in Section 14), including other agents. Define* $\mathrm{Univ}(m)$ *as the counterfactual world in which* all relevant agents *adopt maxim* m *whenever* m *applies. This induces a predicted outcome distribution over histories, denoted* $\mathbb{P}_O(\cdot \mid \mathrm{Univ}(m))$.

Remark 1042. *Universalization turns a first-person rule into a third-person dynamical hypothesis: what happens if everyone follows it? Technically,* $\mathrm{Univ}(m)$ *is not a single history but a modified policy regime inside the world model* $\mathcal{W}$*, which then induces a distribution* $\mathbb{P}_O(\cdot \mid \mathrm{Univ}(m))$ *over possible histories (because the world may be stochastic or partially known).*

Remark 1043. *This is useful because it connects ethical reasoning to the prediction machinery of the earlier sections. Ethics becomes a kind of counterfactual forecasting problem: evaluate the world you would get if the maxim were generalized. The paraconsistent machinery allows that the forecast can contain mixed evidence (e.g. universal lying might increase short-term safety but destroy long-term trust), rather than forcing a single verdict.*

Definition 267 (Categorical imperative test (paraconsistent))**.** *Fix a set $\mathcal{D}_{\mathrm{eth}} \subseteq \mathcal{D}$ of ethical dimensions (typically including* compassion *and possibly* truth*,* nonviolence*, etc.). Define the universalized ethical evaluation*

$$E_O^{\mathrm{univ}}(m; d) := \mathbb{E}_{\omega \sim \mathbb{P}_O(\cdot|\mathrm{Univ}(m))}\big[\, E_O(\omega; d)\,\big],$$

where $E_O(\omega; d)$ is the p-bit evidence that the realized history ω promotes/opposes d (obtained by aggregating stepwise evidence across the history using $\oplus, \otimes$). We say m passes a threshold categorical imperative *if*

$$J\big(E_O^{\mathrm{univ}}(m; d)\big) \geq \tau_d \quad \textit{and} \quad W\big(E_O^{\mathrm{univ}}(m; d)\big) \leq \eta_d \qquad \forall d \in \mathcal{D}_{\mathrm{eth}},$$

for fixed thresholds $\tau_d, \eta_d \in [0, 1]$.

Remark 1044. *This test is a direct formalization of the Kantian structure: evaluate a maxim by universalizing it. The novelty here is not the moral slogan but the computational interface: the output is a paraconsistent p-bit expectation for each ethical dimension, and the pass/fail decision is thresholded. This aligns with Categorical Imperative (Hyperseed-Concept 71) and also with the Hyperseed idea that ethical rules are operational constraints in a world-model, not metaphysical axioms.*

Remark 1045. *A simple example: suppose m is "lie when it is convenient." In a sufficiently realistic model $\mathcal{W}$,* Univ(m) *may predict that communication reliability collapses, undermining coordination and producing large expected woe on* belonging *and* truth*. The usefulness of the formalism is that such effects can be represented as predicted histories and aggregated evidence, rather than asserted by fiat.*

Remark 1046. *This is a formal analogue of "act only on maxims you can will as universal law": universalization is explicit, and paraconsistency is allowed (there can be both-for and both-against evidence). The test does not claim metaphysical finality; it is a computationally meaningful constraint an agent can actually evaluate approximately.*

18.8.2 Cultural morality

Definition 268 (Cultural morality as shared value field)**.** *Let G be a group/community. A* cultural morality *for G is a family of value dimension weights and thresholds*

$$\big(\lambda_d^{(G)}, \tau_d^{(G)}, \eta_d^{(G)}\big)_{d \in \mathcal{D}}$$

together with shared maxims $\mathcal{M}^{(G)}$ such that:

- *members of G tend to evaluate actions using these weights/thresholds (perhaps implicitly);*
- *maxims in $\mathcal{M}^{(G)}$ have high social resonance (Section 12 and Section 18.5), meaning they are reinforced by communication and imitation.*

Remark 1047. *This definition makes cultural morality (Hyperseed-Concept 92) into a partially shared* parameterization *of evaluation: the community supplies default weights and thresholds, plus a repertoire of endorsed maxims. The emphasis on resonance connects morality to habit formation and social reinforcement: moral rules are stabilized because they are repeated, communicated, and emotionally rewarded, not merely because they are "known." In particular, the $\lambda_d^{(G)}$ encode which dimensions are treated as salient or overriding ("what matters most"), while thresholds such as $\tau_d^{(G)}$ and $\eta_d^{(G)}$ encode where the community draws lines between acceptable and unacceptable (or between normal and exceptional) trade-offs within those dimensions.*

Remark 1048. *One should not read "shared" as "perfectly uniform." A cultural morality can be realized as a distribution over individuals clustered around community defaults, with disagreement arising from variance around (λ, τ, η) as well as from different interpretations of which real-world situations instantiate a maxim. Formally, this means that even if $(\lambda_d^{(G)}, \tau_d^{(G)}, \eta_d^{(G)})$ are treated as community-level parameters, the modeling stance can still accommodate subgroups, role-based moral specializations (e.g. professional roles), and context-conditional parameter shifts without abandoning the notion of a cultural field.*

Remark 1049. *A simple example is a professional culture (e.g. scientific practice) where* truth *has high weight and where maxims like "report negative results" have high resonance. The usefulness is that one can model moral disagreement as parameter mismatch (different λ, τ, η or different $\mathcal{M}^{(G)}$), and one can study cultural evolution as dynamics on these parameters. In such a setting, changes in institutional incentives or communication channels can be represented as interventions that alter resonance (which maxims are repeated and rewarded) even when explicit endorsement remains stable, thereby yielding divergence between "stated morality" and the effective evaluative field.*

Remark 1050. *Cultural morality is not assumed to be correct; it is modeled as a socially stabilized pattern in evaluative fields. This matches Hyperseed's stance that morality is both real (behaviorally and experientially) and historically contingent. The point of the definition is therefore descriptive and explanatory: it provides state variables with which to represent moral learning, acculturation, conformity pressures, and conflict between communities, rather than presupposing a final criterion of ethical truth.*

18.8.3 Evil

Definition 269 (Evil as a persistent anti-compassion pattern)**.** *Fix an observer O modeling a multi-agent setting. An action policy π is* evil relative to $(O, \mathcal{D}_{\mathrm{eth}})$ *if, over a substantial interval, it exhibits:*

1. *persistent high expected woe imposed on others, i.e. large W in the* compassion *and related ethical dimensions under universalized or repeated application; and*
2. *a tendency to maintain or increase the resistance/constraint load of others (increasing their R in typical contexts), thereby reducing their feasible action sets.*

Remark 1051. *The definition treats evil (Hyperseed-Concept* **??***) as neither a single act nor a metaphysical substance, but as a* stable pattern *across time: repeated production of others' woe, coupled with constriction of others' agency. The second clause is important because it captures a structural feature of domination: not only harm, but the engineering of a world in which alternatives are hard or impossible for the victims. The qualifier "over a substantial interval" is meant to exclude* *transient accidents and short-lived coordination failures, and to emphasize that the pattern is robust under feedback (e.g. the policy persists even after the harms are visible to the agent implementing π or to the institutions sustaining it).*

Remark 1052. *The reference to "universalized or repeated application" connects the criterion to a categorical-imperative-style stress test: if the policy were adopted as a general practice (or is enacted repeatedly as a standing policy), does it systematically generate woe in compassion-relevant dimensions? This does not require that O endorse Kantian ethics; rather, it uses universalization as an operational probe for whether the harm is structurally tied to the policy rather than to an unusual one-off context. In this sense, the formalism isolates a pattern-level property that is detectable even when agents rationalize or localize responsibility.*

Remark 1053. *A simple example is a policy that repeatedly extracts resources from others while imposing surveillance and dependency so that resistance becomes costly. In the formalism, this shows up as persistently high woe-evidence in compassion-like dimensions and rising R for others' typical actions. The usefulness is that it separates "accidental harm" from a self-maintaining harm pattern, which better matches the ordinary (and political) notion of evil as systemically reproducing injury. A further diagnostic implication is that even if the immediate W is episodically lowered (e.g. through superficial welfare concessions), a policy can remain evil if it continues to ratchet constraints and lock victims into narrowing feasible sets, thereby preserving the long-run capacity to impose woe.*

Remark 1054. *This definition intentionally mixes affect (woe), ethics (compassion), and agency (feasible sets / resistance). This mirrors the Hyperseed intuition: "evil" is not merely violating a rule; it is creating a stable pattern of harm and constriction. It also clarifies why purely outcome-based snapshots can be misleading: a momentary reduction in visible harm does not negate the presence of an agency-constricting mechanism that predictably regenerates harm under ordinary dynamics of compliance, enforcement, and retaliation.*

18.9 Humility, grandiosity, ambition, and "humbition"

Hyperseed highlights a family of self-attitudes that matter for rational agency: humility, grandiosity, ambition, and the proposed synthesis "humbition" (ambition with humility).

Remark 1055. *These notions are included because self-calibration is a hidden hinge between evaluation and action. If an agent systematically overestimates its capability, it will select actions with catastrophic resistance; if it underestimates itself, it will forgo feasible value. Hyperseed treats these not merely as personality adjectives, but as parameters shaping rational decision under uncertainty (Hyperseed-Concepts 148, 195).*

Remark 1056. *In particular, "self-attitude" is meant in a decision-theoretic sense: it determines how internal self-model evidence is translated into action selection, planning depth, risk appetite, and information-seeking. Two agents with identical outward goals and identical external observations can nevertheless diverge sharply in behavior if they map capability evidence to commitment differently.*

18.9.1 Capability p-bits and self-calibration

Definition 270 (Capability evidence)**.** *Let* cap *be a proposition meaning "I (or we) can successfully execute plan* Π *in context* c*." Represent evidence for/against this proposition by a p-bit*

$$C_O(\Pi, c) = \big(C_O^+(\Pi, c),\, C_O^-(\Pi, c)\big) \in [0,1]^2.$$

Remark 1057. *This is the capability analogue of the belief evidence states from Section 17.2: it stores both pro- and anti-evidence for success. A simple example is* Π *being "lift a heavy object" and* c *encoding fatigue state; one may have positive evidence from past successes and negative evidence from current weakness signals. The usefulness is that humility/grandiosity can be expressed as how one aggregates these two channels, rather than as a vague disposition.*

Remark 1058. *Nothing here requires* C_O^+ *and* C_O^- *to be complementary or to sum to* 1*; the representation is explicitly compatible with mixed, conflicting, or incomplete evidence. This matters because many real capability judgments are paraconsistent in practice: e.g. an agent may have strong reasons to think a plan is doable (training, past performance) while simultaneously having strong reasons to think it will fail (new constraints, time pressure, degraded resources). The role of calibration is then not to pretend the conflict is absent, but to decide how conflict is action-relevant.*

Remark 1059. *The context variable* c *is intended to include both external situation features (environmental difficulty, adversarial load) and internal state features (attention, fatigue, coordination quality). This makes capability evidence a function of state rather than a static trait, which is important for distinguishing "I can do this in general" from "I can do this now, under these constraints."*

Definition 271 (Humility and grandiosity parameters)**.** *Fix a calibration parameter* $h \in [0, 1]$ *(humility). Define a calibrated confidence scalar*

$$\mathrm{Conf}_h(\Pi, c) := C_O^+(\Pi, c) \cdot (1 - h) \ + \ C_O^+(\Pi, c) \cdot h \cdot \big(1 - C_O^-(\Pi, c)\big).$$

Interpretation:

- *Large* h *means negative evidence meaningfully suppresses confidence (humility).*
- *Small* h *means confidence tracks positive evidence while ignoring negative evidence (grandiosity tendency).*

Remark 1060. *The formula can be read as a convex interpolation between two attitudes toward negative evidence. When* $h = 0$*, confidence is simply* C_O^+*: "if I see reasons to think I can, I proceed." When* $h = 1$*, confidence becomes* $C_O^+(1 - C_O^-)$*: positive evidence is discounted when substantial negative evidence is present. The usefulness is that the moral-psychological idea of humility becomes a tunable parameter in a decision pipeline.*

Remark 1061. *Algebraically, one may note (without changing the intended interpretation) that*

$$\mathrm{Conf}_h(\Pi, c) = C_O^+(\Pi, c)\big(1 - h \cdot C_O^-(\Pi, c)\big),$$

so humility h *functions as a multiplicative "penalty sensitivity" to counterevidence. This makes several monotonicity properties transparent: for fixed* h*,* Conf_h *increases with* C_O^+*; for fixed* C_O^+*, it decreases with* C_O^- *at a rate proportional to* h*; and for fixed* (C_O^+, C_O^-) *with* $C_O^- > 0$*, it decreases as* h *increases. In other words,* h *is precisely the parameter controlling how costly warning signs are to one's felt feasibility.*

Remark 1062. *One motivation for keeping the two-channel form (rather than collapsing to a single probability) is that it allows "high confidence under dispute":* C_O^+ *can remain high even when* C_O^- *is also high, and humility then determines how the dispute is resolved for purposes of commitment. This provides a simple handle on phenomena like brittle overcommitment (low* h *despite substantial* C_O^-*) versus cautious non-commitment (high* h *even when* C_O^+ *is strong).*

Remark 1063. *A simple numerical example: if* $C_O^+ = 0.9$ *and* $C_O^- = 0.6$*, then* $\mathrm{Conf}_0 = 0.9$ *(grandiose) while* $\mathrm{Conf}_1 = 0.9 \cdot 0.4 = 0.36$ *(humble). This is an intentionally blunt model, but it captures the qualitative effect: humility treats warning signs as real constraints.*

Remark 1064. *The same computation also highlights a behavioral distinction: a low-*h *agent will tend to treat negative evidence as "noise to be overcome" and proceed as if near-certain, while a high-*h *agent is pushed toward either (i) selecting a modified plan* Π' *with lower* $C_O^-(\Pi', c)$*, (ii) performing information-gathering actions that can reduce* $C_O^-(\Pi, c)$ *(diagnostics, rehearsal, obtaining resources), or (iii) deferring the attempt until the context* c *changes. In this sense humility is operationally linked to strategy selection, not merely to a private attitude.*

Definition 272 (Ambition and humbition)**.** *Let* $a \in [0, 1]$ *be an ambition parameter controlling how high a target threshold is set for a goal dimension (e.g. competence, impact, or open-ended benefit). We call the pair* (a, h) *a* humbition profile*.*

- Ambition *corresponds to high* a*.*
- Humility *corresponds to high* h*.*
- Humbition *corresponds to high* a *and high* h *simultaneously: aiming high while not denying uncertainty, resistance, or conflict evidence.*

Remark 1065. *Ambition here is modeled not as sheer intensity but as* threshold-setting*: how demanding are the agent's constraints on success. Humbition (Hyperseed-Concept* **??***) is then the conjunction of demanding thresholds with careful calibration of capability evidence. The usefulness is that it predicts a specific behavioral profile: pursue high-value trajectories, but choose them in a way that is sensitive to resistance and negative evidence rather than propelled by denial.*

Remark 1066. *A useful way to read the interaction is:* a *determines what counts as "good enough to bother" among available objectives, while* h *determines what counts as "feasible enough to commit" among available plans. High ambition without humility tends toward selecting goals whose achievement requires fragile assumptions; high humility without ambition tends toward selecting only low-stakes, easily-verified goals; humbition aims to select high-value targets while actively managing feasibility constraints (e.g. by staging, redundancy, and incremental validation).*

Remark 1067. *Although* a *is introduced as a target threshold on a goal dimension, it can be coupled to capability confidence in concrete decision rules. For example, an agent might require that a plan meets both (i) a value/impact threshold (increasing in* a*) and (ii) a feasibility threshold expressed in terms of* $\mathrm{Conf}_h(\Pi, c)$*. This makes explicit how "aiming high" and "being careful" can jointly shape the frontier of actions the agent considers admissible.*

Remark 1068 (Why these are value-relevant)**.** *Humility and grandiosity change how evidence shapes action; ambition changes which goals are pursued. Thus these are not merely "personality traits"; they are parameters of rational decision making under uncertainty and paraconsistency.*

Remark 1069. *The value-relevance also appears in multi-agent and institutional settings: a "we can do it" judgment often aggregates across people, tools, and coordination protocols. In such cases, grandiosity can manifest as ignoring organizational failure modes (high* C_O^- *from known bottlenecks), while humility can manifest as appropriately discounting rosy projections in the presence of correlated risks. The humbition profile* (a, h) *then becomes a compact way to discuss when an agent (or team) should pursue ambitious projects while remaining sensitive to real constraints and failure evidence.*

18.10 Closing synthesis for this section

We can now summarize Hyperseed's motivation stack in a single sentence: *values are stable patterns in paraconsistent evaluative fields; emotions are time-local readouts of value and resistance structure; goals are commitments that constrain action selection; and rationality is coherent action selection under value conflict and resource limits, optionally constrained by ethical universalization tests.*

To make the sentence operationally interpretable: calling values "stable patterns" emphasizes that they are not momentary appetites but recurrent, learned regularities in evaluation—regularities that can be detected, reinforced, revised, and composed. Calling the field *paraconsistent* is not rhetorical flourish: it signals that the system can simultaneously carry partially incompatible evaluations (e.g., valuing honesty and valuing loyalty in a way that yields genuine tension), without collapsing into triviality or requiring immediate resolution by enforcing global consistency. In this view, value conflict is not an anomaly to be eliminated at all costs; it is a structural feature of realistic minds embedded in complex social and ecological environments.

Likewise, describing emotions as "time-local readouts" is meant to place them between raw sensation and deliberative judgment: an emotion summarizes, at a moment, what the value-system is registering about the current trajectory of events and the current *resistance structure* (friction, cost, threat, uncertainty, or constraint) encountered in pursuing or maintaining valued patterns. This makes emotions informative even when they are not themselves endorsable as final verdicts: they are fast, lossy projections of a richer evaluative landscape, and their intensity can be interpreted as a proxy for urgency or constraint rather than as a proof of correctness.

Goals, in this stack, are not merely desires but *commitments* that change the decision landscape: once adopted, they restrict and shape action selection by introducing persistence, coordination across time, and explicit or implicit policies for allocating attention and resources. This provides a natural bridge between implicit goals (which may be embedded in default policies, habits, or learned heuristics) and explicit goals (which are linguistically or symbolically represented and can be negotiated, justified, or revised). It also clarifies why "goal" is not synonymous with "reward": reward is an episodic signal that can train or reinforce policies, while a goal is a longer-horizon constraint that can remain in force even when local reward is absent or noisy.

Finally, the definition of rationality given here is intentionally bounded: it is *coherent* action selection under value conflict and resource limits, not omniscient optimization. Coherence is the thread that connects the parts: it asks that chosen actions make sense relative to the system's currently operative values and commitments, while acknowledging that the system may be navigating incompatible pulls, incomplete information, and finite compute, time, and energy. Ethical universalization tests (e.g., categorical-imperative-style constraints) then appear as optional but principled filters on the space of coherent plans: they do not remove the need for bounded rational tradeoffs, but they can rule out classes of strategies whose general adoption would undermine the very social-pattern substrate that sustains trust, coordination, and long-run benefit.

Remark 1070. *A final connective thread: the entire construction is meant to compose with the earlier pattern-web view of mind [5] and with the broader Hyperseed ontology program [1]. Values are patterns; emotions are local projections; ethics is socially stabilized pattern constraint; and rationality is the art of steering through this web without demanding an impossible purity of consistency.*

One way to read this connective thread is as a compatibility claim across levels of description: the "pattern" language is meant to let us speak about neurocomputational regularities, cognitive-symbolic commitments, and socio-cultural norms using a common conceptual currency, without reducing one level into another. On this reading, ethical norms are neither arbitrary overlays nor purely private preferences; they are constraints that become stable insofar as they are reinforced by collective learning, institutional scaffolding, and repeated interaction, and they remain revisable insofar as the underlying pattern ecology changes. The emphasis on "impossible purity" is also methodological: it licenses approximate, context-sensitive resolutions of conflict (including compromise, prioritization, deferral, and exploratory action) while warning against the pathological demand that every tension must be globally resolved before any action is permissible.

This section has covered the Hyperseed concept bundle: *joy/woe, emotion, compassion; values/feelings/goals/reward; implicit/explicit goals; value paraconsistency; individuation/self-transcendence/open-ended intelligence/open-ended benefit; rationality criteria; categorical imperative and ethical decision; humility/grandiosity/ambition/humbition; evil and cultural morality.*

Taken together, this bundle is intended to be used as a vocabulary for diagnosing motivational dynamics in agents that learn and self-modify: it distinguishes what is being valued (stable evaluative patterns) from how valuation is being expressed moment-to-moment (emotional readouts), and from what is being actively maintained across time (goal commitments). It also highlights where failures can occur: paraconsistent value structure can be navigated skillfully (via rational coherence under constraints) or unskillfully (via denial, compulsive simplification, or culturally amplified rationalization). In that sense, terms like humility, grandiosity, ambition, and "humbition" are not decorative; they name characteristic stances toward uncertainty and self-assessment that can either support or sabotage coherent action under conflict, especially when universalization-style ethical constraints are invoked to arbitrate between short-term advantage and long-run pattern sustainability.

19 Life, energy, and genenergy

19.1 Why "life" belongs in a Hyperseed ontology

Hyperseed treats *mind* as a richly structured special case of a broader phenomenon: persistent, self-maintaining pattern-web dynamics occurring in a context/environment. This section isolates the "life layer" in between the generic pattern-process layer (Sections 9–12) and the mind/agency layers (Sections 13–21). Concretely, the "life layer" is the point at which pattern persistence becomes *normatively loaded*: the persistence is no longer merely a fact about which patterns tend to recur, but is constrained by a viability notion that distinguishes "acceptable" from "unacceptable" trajectories for the system. This is also where the ontology begins to require explicit bookkeeping of limited resources, because without such bookkeeping the difference between "maintaining itself" and "just happening to persist" is hard to formulate in a way that remains robust across contexts.

The key thesis is that "life" can be usefully reconstructed as a conjunction of:

- a *viability* requirement (homeostasis: staying within a viable range of states);
- a *resource* requirement (having and replenishing capacity-for-action);
- a *self-weaving* requirement (patterns that help sustain the web tend to be reinforced);
- and, in many cases, a *trans-generational persistence* requirement (reproduction within a species).

Each clause here functions as a "handle" that lets us talk about life without assuming any particular substrate (biological, artificial, social, or hybrid). The viability clause isolates a set of constraints that are *stateful* (they refer to where the system is), the resource clause isolates constraints that are *capacitive* (they refer to what the system can do next), the self-weaving clause isolates constraints that are *structural* (they refer to which patterns tend to amplify), and the trans-generational clause isolates constraints that are *lineage-based* (they refer to persistence across copies). Hyperseed does not treat these as all-or-nothing; rather, they provide dimensions along which a system can more or less instantiate what observers ordinarily call "life."

Hyperseed's term *genenergy* is used here for a context-indexed, observer-relative generalization of "energy" as capacity-for-action. The intent is not to replace physical energy, but to provide a single variable that can stand in for whichever "currency" of action is salient in the modeled context: metabolic free energy, battery charge, attention, time, money, permissions, social credit, error budget, spare parts, or other bottleneck resources. In particular, genenergy is meant to track (i) the *availability* of action, (ii) the *cost* of actions and repairs, and (iii) the *coupling* between system behavior and the replenishment/depletion of that availability. This makes it possible to state viability claims in a way that remains meaningful even when the system boundaries, units of measure, or the observer's coarse-graining change.

19.2 Complex interactive systems and viability

We use a deliberately minimal dynamical scaffold. For concreteness (and to keep the formalism aligned with the finite toy-model ethos of Section 5), we present definitions in discrete time with finite or countable spaces. Nothing essential depends on this choice. The discrete-time presentation should be read as a modeling convenience: it can represent sampled continuous-time dynamics, event-driven updates, or coarse-grained episodes of interaction. Likewise, finiteness/countability here is a stand-in for "bounded representational resolution"—a reminder that the observer/context O ultimately determines what distinctions are made and what variables are tracked.

Definition 273 (System, environment, and interaction history)**.** *A* system-in-environment *is specified by:*

- *a system-state space $\mathcal{S}$ and environment-state space $\mathcal{E}$;*
- *an action space $\mathcal{A}$ (the set of interventions available to the system);*
- *a (possibly stochastic) transition kernel*

$$P\big((s_{t+1}, e_{t+1}) \mid (s_t, e_t), a_t\big);$$

- *an initial distribution $P(s_0, e_0)$.*

A length-T interaction history *is the sequence*

$$h_{0:T} := (s_0, e_0, a_0, s_1, e_1, a_1, \ldots, s_T, e_T).$$

The factorization into (s_t, e_t) is not intended to assert a sharp ontological boundary; it is a modeling move that lets us speak about "internal" versus "external" variables at the granularity relevant to O. In many applications, e_t can be understood to include other agents, spatial context, exogenous shocks, or a reservoir from which resources can be drawn, while s_t includes the degrees of freedom that are treated as belonging to the system. Similarly, the action variable a_t is intentionally broad: it may represent physical acts, control signals, information-gathering, communications, or internal reconfiguration steps, provided these are the kinds of interventions the model attributes to the system.

Hyperseed's notion of a *complex interactive system* is intentionally broad and observer-indexed: it is about the structural richness of the interaction between system and environment. The point is to exclude degenerate cases in which apparent "life-like" persistence is merely an artifact of trivial dynamics (e.g., an absorbing state with no meaningful coupling), while still allowing many kinds of complexity measures depending on the observer's available descriptions and interests.

Definition 274 (Complex interactive system (structural complexity criterion))**.** *Fix an observer/context O and a representational scheme that assigns a description length (or, more generally, a weakness/clarity score) to histories. Let $\mathrm{SC}_O(h_{0:T})$ denote the structural complexity of an interaction history as assessed by O (see Sections 8 and 9 for weakness-based and compression-based complexity measures). A system-in-environment is called a* complex interactive system (for O) *if $\mathbb{E}[\mathrm{SC}_O(h_{0:T})]$ exceeds a context-dependent threshold over relevant time horizons T.*

The expectation $\mathbb{E}[\mathrm{SC}_O(h_{0:T})]$ is taken with respect to the distribution over histories induced by the initial distribution, the kernel, and (when present) the policy governing actions. The "relevant time horizons" clause allows complexity to be scale-sensitive: some systems are simple at short horizons but complex over long horizons (e.g., due to slow variables or rare events), and others are the reverse (locally complicated but globally repetitive). The threshold is context-dependent because complexity here is not posited as an absolute property of the world, but as an observer-relative measure of how much structured interaction must be tracked to predict, compress, or explain the history to an acceptable degree.

The first life-specific ingredient is a viability/homeostasis notion. This is where "mere persistence" becomes "persistence under constraints": a system may continue to exist in a literal sense while no longer counting as viable under the observer's criteria (e.g., a dead organism persists as matter, but not as a viable living process).

Definition 275 (Viability set and homeostatic constraint)**.** *Fix an observer/context O. A* viability set *is a subset*

$$\mathcal{V}_O \subseteq \mathcal{S} \times \mathbb{R}_{\geq 0}$$

whose elements (s, g) are interpreted as "system state s together with resource level g is viable." A system is said to satisfy a homeostatic constraint *on a time interval $\{0, \ldots, T\}$ if*

$$(s_t, g_t) \in \mathcal{V}_O \quad \textit{for most } t \in \{0, \ldots, T\}$$

in a sense made precise by a probability threshold (below) or by a paraconsistent evidence threshold (Section 3.2).

The inclusion of g directly in the viability set makes explicit that viability is not solely about "being in the right configuration," but also about possessing enough capacity to correct deviations, repair damage, and respond to disturbances. This prevents a common failure mode in purely state-based viability criteria: declaring a system viable even when it is in a brittle corner of state space where any small perturbation leads to collapse. In practice, $\mathcal{V}_O$ can encode multiple tolerances at once (e.g., temperature bounds, integrity constraints, and a minimum resource reserve), and can be chosen to reflect the observer's modeling goals: a biologist and an engineer may use different $\mathcal{V}_O$ for the same physical system.

Definition 276 (Homeostatic policy)**.** *Let g_t be a resource variable (to be defined in detail in Section 19.3). A (possibly stochastic)* policy *is a map π that assigns a distribution over actions given the currently available information (at minimum the current state, and possibly also history):*

$$\pi(\cdot \mid s_t, e_t, h_{0:t}) \in \Delta(\mathcal{A}).$$

Fix a horizon T and a target confidence level $1 - \delta$. A policy π is homeostatic for $(\mathcal{V}_O, T, \delta)$ *if*

$$P_\pi\Big((s_t, g_t) \in \mathcal{V}_O \textit{ for all } t = 0, \ldots, T\Big) \geq 1 - \delta.$$

The dependence on $h_{0:t}$ allows policies with memory, learned internal state, or belief-state tracking, without committing to any particular representation of that internal information. The confidence parameter δ expresses a robustness requirement: the smaller δ is, the more stringent the notion of "homeostasis" becomes, ruling out policies that succeed only under lucky environmental sequences. Also note that this definition is deliberately conservative ("for all t"): later sections may consider relaxed variants (e.g., allowing brief excursions, or optimizing expected time-in-viability), but the strict form makes clear what it means for a system to *reliably* stay within bounds.

Remark 1071 (Observer-relativity and fuzzy boundaries)**.** *Hyperseed permits that what counts as "the same system" and what counts as "viable" can be fuzzy. In the present mathematical layer, this is expressed by: (i) allowing $\mathcal{V}_O$ to depend on O (which distinctions and patterns define identity), and (ii) later (Section 19.6) replacing crisp predicates like "alive" with* p-bit*-valued evidence.*

A further consequence of observer-relativity is that even the choice of $\mathcal{S}$ and $\mathcal{E}$ can be contextually renegotiated: an observer may "move the boundary" (e.g., include a tool, a symbiont, or a niche-structure inside the system description) if doing so yields a simpler or more stable account of viability and resource flows. This is one reason Hyperseed emphasizes interaction histories and structural complexity rather than fixed ontological categories: the same physical process can be modeled as a single life-like system, a coalition of sub-systems, or a component of a larger organism-like process, depending on which decomposition best preserves explanatory and predictive power for the questions at hand.

19.3 Energy and genenergy as capacity-for-action

Hyperseed distinguishes (a) the folk notion of energy as "resources you can deploy to get things done," (b) the physics notion of energy as a specific conserved quantity in particular dynamical theories, and (c) an intended generalization, *genenergy*, designed to capture capability-for-action across diverse contexts (physical, cognitive, social, spiritual) in a single formal motif.

We formalize this by combining:

- an *effort cost* functional (Section 8), and
- an *effect/capacity* functional grounded in causal influence (Section 14) and information flow (Section 10).

19.3.1 Effort budgets and energy

Definition 277 (Effort cost and energy budget)**.** *Fix an observer/context O. An* effort cost *is a function $c_O : \mathcal{A} \to \mathbb{R}_{\geq 0}$. An* energy budget process *is a sequence $(g_t)_{t \geq 0}$ with $g_t \in \mathbb{R}_{\geq 0}$ such that actions must satisfy the feasibility constraint*

$$c_O(a_t) \leq g_t$$

(or more generally $\mathbb{E}[c_O(A_t)] \leq g_t$ under a stochastic policy).

Remark 1072 (Energy as the dual of effort)**.** *In this reconstruction, effort is an observer-relative cost of performing a process or representation, whereas energy is the available budget to pay for effort. This makes "energy" inherently context-indexed, which aligns with Hyperseed's insistence that many resource notions are observer-relative rather than absolute.*

19.3.2 Genenergy via control-capacity

To link "capability for action" to something mathematically crisp, we model the system as having a controllable influence channel from actions to future environment observations. The maximal information that can be transmitted through this channel (subject to constraints) is a natural quantitative proxy for causal impact.

Definition 278 (Observer-coarse-grained environment observation)**.** *Fix an observer/context O. Let $\mathcal{Y}_O$ be a finite set of environment* observations *available to O, and let $\phi_O : \mathcal{E} \to \mathcal{Y}_O$ be the coarse-graining map. Define the observed environment variable $Y_t := \phi_O(e_t)$.*

Definition 279 (Action-to-observation channel at time t)**.** *Fix time t and a realized history prefix $h_{0:t}$. The induced channel from action to next observation is*

$$K_{O,t,h}(y \mid a) \;:=\; P\big(Y_{t+1} = y \,\big|\, h_{0:t},\, A_t = a\big), \qquad y \in \mathcal{Y}_O,\; a \in \mathcal{A}.$$

Definition 280 (Single-step genenergy as constrained channel capacity)**.** *Fix $(O, t, h_{0:t})$ and an effort cost c_O. For a budget $g \geq 0$, define the* constrained capacity

$$\mathrm{Cap}_{O,t,h}(g) \;:=\; \max_{p \in \Delta(\mathcal{A})} \Big\{ I(A; Y_{t+1} \mid h_{0:t}) \;:\; \mathbb{E}_{A \sim p}[c_O(A)] \leq g \Big\},$$

where $I(\cdot\,;\cdot)$ is Shannon mutual information (Section 10.4). We call $\mathrm{Cap}_{O,t,h}(g)$ *the* genenergy available at $(t, h_{0:t})$ with budget g.

Remark 1073 (Interpretation)**.** $\mathrm{Cap}_{O,t,h}(g)$ *measures how strongly the system can steer what O will observe next, given a budget g to pay for effort. It is explicitly: (i) observer-relative (depends on ϕ_O), (ii) context-relative (depends on $h_{0:t}$), and (iii) resource-relative (depends on the constraint g).*

We can aggregate single-step genenergy over time/histories.

Definition 281 (Realizable genenergy of a system over a horizon)**.** *Fix a horizon T. Given a policy π that induces a joint distribution over histories and actions, define*

$$G_O(\pi; T) \;:=\; \mathbb{E}_{h_{0:T-1} \sim P_\pi} \left[\frac{1}{T} \sum_{t=0}^{T-1} \mathrm{Cap}_{O,t,h}(g_t) \right].$$

Define the realizable genenergy *of the system over horizon T as*

$$G_O^{\mathrm{real}}(T) \;:=\; \sup_{\pi} G_O(\pi; T),$$

where the supremum ranges over policies satisfying the system's feasibility constraints (including energy-budget dynamics and any structural constraints on what actions are possible).

Remark 1074 (Potential vs realizable genenergy)**.** *Hyperseed distinguishes potential genenergy (what could be achieved by some system built from the entity-set) from realizable genenergy (what is achievable given contextual constraints). Formally, one may treat "potential" as a supremum taken over a larger family of policies and/or contexts, and "realizable" as the supremum constrained by the system's actual embedding.*

19.3.3 Basic properties

Proposition 28 (Zero genenergy means no controllable influence at the given resolution)**.** *Fix* $(O, t, h_{0:t})$*. For any budget* $g \geq 0$*,*

$$\mathrm{Cap}_{O,t,h}(g) = 0 \quad \Longleftrightarrow \quad Y_{t+1} \perp A_t \mid h_{0:t} \text{ for all feasible action-distributions under budget } g.$$

Proof. For any feasible distribution $p(a)$, mutual information satisfies $I(A; Y_{t+1} \mid h_{0:t}) \geq 0$. Moreover, $I(A; Y_{t+1} \mid h_{0:t}) = 0$ if and only if A and Y_{t+1} are conditionally independent given $h_{0:t}$ under the induced joint distribution. Taking the maximum over feasible p yields: the maximum is zero exactly when every feasible p yields zero mutual information, i.e. when the channel output distribution does not depend on the action at the resolution of O within the feasible set. □

Proposition 29 (Monotonicity and concavity in the budget)**.** *For fixed* $(O, t, h_{0:t})$*, the map* $g \mapsto \mathrm{Cap}_{O,t,h}(g)$ *is nondecreasing and concave on* $\mathbb{R}_{\geq 0}$*.*

Proof. Monotonicity is immediate: if $g_2 \geq g_1$, then the feasible set $\{p : \mathbb{E}[c_O(A)] \leq g_1\}$ is contained in $\{p : \mathbb{E}[c_O(A)] \leq g_2\}$, so the maximum cannot decrease. Equivalently, enlarging the budget can only add admissible input distributions and never removes any previously admissible one, so the supremum over mutual informations is taken over a weakly larger domain.

For concavity, use time-sharing. Let $g_1, g_2 \geq 0$ and $\lambda \in [0, 1]$. Choose (approximately) optimal feasible distributions p_1, p_2 for budgets g_1, g_2. Concretely, for any $\varepsilon > 0$ pick p_1, p_2 such that $\mathbb{E}_{p_i}[c_O(A)] \leq g_i$ and $I_{p_i}(A; Y_{t+1} \mid h_{0:t}) \geq \mathrm{Cap}_{O,t,h}(g_i) - \varepsilon$ for $i \in \{1, 2\}$, so that the argument goes through even if the supremum is not attained. Define a mixture policy: first sample $B \sim \mathrm{Bernoulli}(\lambda)$, then sample $A \sim p_1$ if $B = 1$ and $A \sim p_2$ if $B = 0$. This mixture has expected cost $\mathbb{E}[c_O(A)] = \lambda \mathbb{E}_{p_1}[c_O(A)] + (1 - \lambda)\mathbb{E}_{p_2}[c_O(A)] \leq \lambda g_1 + (1 - \lambda) g_2$, so it is feasible for budget $\lambda g_1 + (1 - \lambda) g_2$. (Here we use linearity of expectation in the mixture; this is the operational sense in which the agent can "spend" a fraction λ of the time behaving according to policy p_1 and the remaining fraction according to p_2 while meeting the averaged cost constraint.) Mutual information is concave in the input distribution for a fixed channel, hence

$$\mathrm{Cap}_{O,t,h}(\lambda g_1 + (1 - \lambda) g_2) \;\geq\; I(A; Y_{t+1} \mid h_{0:t}) \;\geq\; \lambda I_{p_1}(A; Y_{t+1} \mid h_{0:t}) + (1 - \lambda) I_{p_2}(A; Y_{t+1} \mid h_{0:t}).$$

The first inequality holds because $\mathrm{Cap}_{O,t,h}(\cdot)$ is defined as a supremum over all feasible input distributions, and the constructed mixture distribution is one such feasible candidate at budget $\lambda g_1 + (1 - \lambda) g_2$. The second inequality is the standard concavity property of $p \mapsto I_p(A; Y_{t+1} \mid h_{0:t})$ when the conditional law of Y_{t+1} given A and $h_{0:t}$ is fixed; intuitively, randomizing between two input strategies cannot yield less information than the corresponding convex combination because mutual information can be written as a KL divergence that is jointly convex in the pair of distributions and becomes concave in the input when the channel is held fixed. Taking p_1, p_2 arbitrarily close to optimal yields concavity, i.e.,

$$\mathrm{Cap}_{O,t,h}(\lambda g_1 + (1 - \lambda) g_2) \;\geq\; \lambda \mathrm{Cap}_{O,t,h}(g_1) + (1 - \lambda) \mathrm{Cap}_{O,t,h}(g_2),$$

after letting $\varepsilon \to 0$. □

19.3.4 Entity-sets and monotone genenergy

Hyperseed speaks about genenergy not only for a particular instantiated system, but also for an *entity-set* E as "what systems buildable from E can do." We formalize this with a family-of-systems construction. The point of this shift is that the same component library E may admit many distinct system designs and couplings, and genenergy at the level of E should reflect the best achievable design consistent with the available entities.

Definition 282 (Systems buildable from an entity-set)**.** *Let* Ent *be a universe of entities (Section 6). For a finite entity-set* $E \subseteq \mathsf{Ent}$*, let* $\mathsf{Sys}(E)$ *denote the class of all systems-in-environment whose internal components are drawn from (a subset of)* E*, together with any admissible couplings to an environment. (Equivalently:* $\mathsf{Sys}(E)$ *is the set of implementable system models whose "parts list" is contained in* E*.) In particular, the definition permits using only a strict subset of* E *(unused components may simply be absent), and it separates the intrinsic availability of components from the extrinsic choice of environment/interface, which can matter for realized genenergy.*

Definition 283 (Potential genenergy of an entity-set)**.** *Fix an observer/context* O *and horizon* T*. Define the* potential genenergy *of* E *by*

$$g_O(E;T) \;:=\; \sup_{S \in \mathsf{Sys}(E)} G^{\mathrm{real}}_{O,S}(T),$$

where $G^{\mathrm{real}}_{O,S}(T)$ *denotes the realizable genenergy of system* S *over horizon* T *according to the definitions above. This supremum formalizes the idea of "capacity of the library": even if most systems assembled from* E *are ineffective,* $g_O(E;T)$ *records the best attainable realizable genenergy among all admissible assemblies and couplings. The explicit dependence on* O *emphasizes that what counts as realizable genenergy is observer-relative (via* ϕ_O*, costs, and the chosen functional), and the dependence on* T *encodes that some entity-sets may only exhibit their advantages over longer horizons (e.g., via learning or accumulation of state).*

Proposition 30 (Monotone genenergy)**.** *If* $E \subseteq E'$ *then* $g_O(E;T) \leq g_O(E';T)$*.*

Proof. If $E \subseteq E'$, then any system buildable from E is also buildable from E', so $\mathsf{Sys}(E) \subseteq \mathsf{Sys}(E')$. Taking suprema over nested sets yields $g_O(E;T) \leq g_O(E';T)$. Intuitively, enlarging the parts list cannot make previously feasible designs unavailable; at worst, the additional entities are ignored, and at best they enable new constructions whose realizable genenergy can exceed what was possible before. $\square$

Remark 1075 (Conservation and omniscient observers)**.** *At a fine-grained physical level, many dynamical theories admit a conserved energy. Hyperseed's "conserved genenergy" intuition can be rendered as a conditional statement: for a closed set of interacting systems, an observer whose coarse-graining does not lose information (so that entropy does not increase under observation) may see a conserved total genenergy-like quantity, while coarse-graining observers may see apparent creation/destruction of genenergy due to information loss. One way to read this is that, when the observer tracks a sufficiently rich microstate, changes in "capacity-for-action" may be explainable purely as transfers between subsystems (or between degrees of freedom) rather than as net creation; whereas under a many-to-one observation map, hidden correlations and inaccessible microstate detail can make the observer's effective description non-conservative. We treat this as a modeling principle rather than a theorem, because it depends on the chosen dynamics, the chosen observation map* ϕ_O*, and the chosen genenergy functional (capacity, divergence, etc.). In particular, even in deterministic Hamiltonian dynamics, conservation at the micro-level does not automatically imply conservation of any observer-defined genenergy unless that functional is invariant under the dynamics and the observation retains the relevant invariants; conversely, in open systems with external driving or dissipation, one should expect genuine non-conservation relative to the subsystem boundary, regardless of observer acuity.*

19.4 Metabolism as genenergy conversion

Genenergy as "capacity for action" becomes life-relevant only when it can be replenished. Metabolism is the archetypal replenishment mechanism: it converts environmental resources into usable genenergy, typically while exporting waste. In this sense, metabolism is not merely a source term in a budget equation; it is a structured interface between a system and its environment that (i) identifies what counts as "resource" at a chosen level of description, (ii) specifies the internal transformations that turn that resource into actionable capacity, and (iii) manages byproducts so that the same interface remains usable over time.

Definition 284 (Metabolic accounting model). *Fix an observer/context O. Let $r_t \in \mathbb{R}_{\geq 0}$ denote the amount of usable resource ingested from the environment at time t (at O's level of description), and let $w_t \in \mathbb{R}_{\geq 0}$ denote waste expelled. Let $\Gamma_O : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ be a conversion function mapping ingested resource to genenergy gain. Let $\lambda \geq 0$ be a leakage/decay rate. A simple budget dynamics is:*

$$g_{t+1} \;=\; (1-\lambda)g_t \;+\; \Gamma_O(r_t) \;-\; c_O(a_t).$$

The observer O matters twice in this model: first, through what is counted as an ingestible resource (the measurement of r_t), and second through what is counted as usable genenergy (the units and operational meaning of g_t). The conversion function Γ_O can be taken to encode both physical efficiency and descriptive coarseness: at a coarse level, many distinct micro-resources may be aggregated into a single scalar r_t, with Γ_O absorbing the aggregation and any saturation effects. In many applications one expects diminishing returns (e.g. bottlenecks or limited conversion capacity), so Γ_O may be concave, but the definition does not require this. Likewise, $c_O(a_t)$ plays the role of an action-dependent expenditure (maintenance, locomotion, sensing, planning, repair, etc.), and can be used to represent not only immediate energy draw but also wear or opportunity cost insofar as O treats those as budget-relevant.

Although w_t does not appear explicitly in the budget update, it is included because expelling waste is a constitutive part of metabolic coupling: waste handling can be modeled either by folding its costs into $c_O(a_t)$ (e.g. actions that perform filtration, excretion, garbage collection, heat export), by treating high w_t as required to keep λ low (failure to export waste increases effective decay), or by adding further state variables/constraints when the environment or internal compartments can saturate. The present scalar dynamics should be read as the simplest bookkeeping core around which richer constraints can be layered.

Definition 285 (Metabolism). *A system is said to carry out* metabolism *over a horizon T (for observer O) if, with nontrivial frequency over $t \in \{0, \dots, T-1\}$, it executes actions that:*

- *ingest resources (increase r_t relative to a baseline),*
- *expel waste (increase w_t relative to a baseline), and*
- *raise or sustain its genenergy budget via internal transformation, i.e. yield $g_{t+1} \geq g_t$ on average when maintenance is included.*

Here "baseline" can be understood as the counterfactual intake/expulsion rate that would occur without the system's organized activity at the same descriptive level (for example, passive diffusion, background inflow/outflow, or default operating mode). The requirement of "nontrivial frequency" is meant to rule out one-off charging events or purely accidental uptake: metabolism is a repeated, policy-shaped pattern of interaction rather than an isolated occurrence. The phrase "on average when maintenance is included" is also essential: a system may exhibit brief metabolic gains while still being non-metabolic in the relevant sense if those gains do not cover ordinary upkeep, or if they require unsustainable drawdown elsewhere (which, under O, would typically manifest either as an increase in λ or as rising costs $c_O(a_t)$).

Remark 1076 (Metabolism is a pattern-level notion)**.** *Metabolism need not be biochemical. Any system that reliably converts one form of resource into usable capacity-for-action counts as metabolic at the corresponding descriptive level. In a cognitive system, "metabolic resource" might be compute, time, attention budget, or social capital; in a physical organism, it might be chemical free energy; in an engineered robot, it might be battery charge and maintenance cycles.*

The pattern-level emphasis is important because it allows the same underlying substrate to support multiple metabolic descriptions depending on O. For instance, in an organism one may treat ATP production as the metabolic conversion (fine-grained O), or treat feeding and resting cycles as the conversion (coarser O); both can legitimately instantiate Γ_O, c_O, and λ, but they attribute different actions to intake versus expenditure. Similarly, for a social collective, "resource" may be funding or legitimacy, and "waste" may be churn, conflict, or reputational damage; the conversion function then summarizes the internal processes that turn inputs into coordinated capacity-for-action.

Proposition 31 (A minimal viability condition in the budget model)**.** *Assume there exists $\underline{g} > 0$ such that $(s, g) \in \mathcal{V}_O$ implies $g \geq \underline{g}$, and assume that there exists a policy producing a stationary resource-intake regime with*

$$\mathbb{E}[\Gamma_O(r_t)] \;\geq\; \mathbb{E}[c_O(a_t)] + \lambda \underline{g}$$

whenever $g_t \geq \underline{g}$. Then the expected budget $\mathbb{E}[g_t]$ can be maintained at or above $\underline{g}$ over arbitrarily long horizons (in expectation).

This condition has the natural interpretation that expected metabolic gains must cover (i) expected action costs and (ii) expected leakage at the minimal viable budget level. The "stationary regime" phrasing is doing conceptual work: it isolates a long-run, repeatable intake pattern rather than a transient windfall, and it permits stochasticity in both intake and cost while still requiring a nonnegative drift at the threshold $\underline{g}$. Note also that the statement is intentionally modest: it asserts invariance of a lower bound in expectation, not almost-sure non-ruin, and it does so within the scalar bookkeeping coordinate rather than the full state space.

Proof. Taking expectations in $g_{t+1} = (1 - \lambda)g_t + \Gamma_O(r_t) - c_O(a_t)$ gives

$$\mathbb{E}[g_{t+1}] \;=\; (1 - \lambda)\mathbb{E}[g_t] + \mathbb{E}[\Gamma_O(r_t)] - \mathbb{E}[c_O(a_t)].$$

Under the stated inequality, when $\mathbb{E}[g_t] \geq \underline{g}$ we have

$$\mathbb{E}[g_{t+1}] \;\geq\; (1 - \lambda)\mathbb{E}[g_t] + \lambda \underline{g} \;\geq\; (1 - \lambda)\underline{g} + \lambda \underline{g} \;=\; \underline{g}.$$

Thus $\underline{g}$ is an invariant lower bound in expectation. □

The final step can be read as a one-step inductive invariant: if $\mathbb{E}[g_t] \geq \underline{g}$ at some time t and the policy maintains the stated inequality whenever the system is above threshold, then the next expected budget also lies above threshold, and iterating yields the claimed "arbitrarily long horizons" result. When $\lambda = 0$, the condition reduces to the intuitive balance $\mathbb{E}[\Gamma_O(r_t)] \geq \mathbb{E}[c_O(a_t)]$; when $\lambda > 0$, it demands an additional margin proportional to the minimally viable stock $\underline{g}$.

Remark 1077 (From energy viability to pattern viability)**.** *Proposition 31 only protects the resource coordinate. A full "life" account also needs viability of the pattern-web structure itself (Section 12): metabolism must be coupled to repair, boundary maintenance, and habit stabilization so that the system-state s_t also remains in the viable region.*

In particular, keeping g_t above $\underline{g}$ does not prevent the system from drifting into states where conversion becomes impossible (e.g. loss of catalytic structure, broken sensors/actuators, degraded interfaces, or destabilized routines), which would correspond to changes in Γ_O, c_O, λ, or in the very mapping between micro-dynamics and the variables tracked by O. This is one reason "waste" and "maintenance" should be understood broadly: if waste accumulates and damages conversion machinery, the effective long-run condition for viability is not merely a budget inequality, but a coupled requirement that the mechanisms implementing Γ_O and controlling λ remain themselves within a self-sustaining pattern.

19.5 Reproduction, species, and lifeforms

Metabolism sustains an individual system; reproduction sustains a *type* of system over time. Hyperseed's definitions emphasize causal role and within-species reproduction. This distinction matters because many systems can maintain themselves for long periods (robust metabolism) without thereby generating any continuing lineage, while other systems can generate copies but only via external scaffolding that does not count as the system itself being the primary causal source. In the present stack, "type over time" is tracked by the persistence of structural/functional regularities in the pattern-web sense, rather than by any single material substrate.

19.5.1 Reproduction as a causal construction of a similar system

To define reproduction within our formal stack, we need (i) a similarity notion for systems and (ii) a causal notion of "plays a primary role in creating." Both are intentionally observer-relative: the same underlying physical process may or may not count as reproduction depending on which organizational features O treats as salient (e.g. genotype-level, phenotype-level, algorithm-level, institution-level), and depending on which causal granularity is used to attribute responsibility.

Similarity is naturally phrased using the pattern-web machinery: two systems are similar if their pattern webs are close under the pattern-web metric or under an approximate morphism (Section 11 and Section 12). This allows similarity to be defined at multiple descriptive levels: one may demand near-isomorphism of fine-grained internal mechanisms, or merely preservation of higher-level roles and interfaces. It also accommodates cases where there is no natural one-to-one component correspondence, as long as there exists an approximate structure-preserving map between organizational patterns.

Definition 286 (Pattern-web state of a system)**.** *Let $W_O(S,t)$ denote an observer-indexed summary of the system's internal organization at time t, e.g. a weighted graph/category whose nodes are salient patterns (Section 9) and whose edges represent compositional/probabilistic/causal relations (Section 11). We call $W_O(S,t)$ the* pattern-web state *of S at time t (relative to O).*

The point of $W_O(S,t)$ is not to insist that an agent (or scientist) literally constructs the entire graph, but that the ontology admits such a summary object as a target of distance/morphism comparisons. In practice, W_O may be realized implicitly by a learned representation, a mechanistic model, or a set of tests that jointly define what counts as "the same organization" for the observer/context at hand.

Definition 287 (Within-species similarity relation). *Fix an observer/context O. Let $d_O(\cdot,\cdot)$ be a distance (or dissimilarity) between pattern webs, for example a graph edit distance weighted by pattern intensities, or a metric derived from a Wasserstein-type distance between fuzzy pattern-sets. For $\epsilon > 0$, define*

$$S \approx_{O,\epsilon} S' \quad \Longleftrightarrow \quad \exists\, t, t' \text{ such that } d_O(W_O(S,t), W_O(S',t')) \leq \epsilon.$$

Allowing $\exists\, t, t'$ rather than fixing the same time index captures the idea that reproduction often relates different *life stages*: a parent at one phase and an offspring at another may be organizationally most comparable after development, bootstrapping, training, or maturation. The tolerance ϵ plays the role of a "species bandwidth": smaller ϵ yields narrower equivalence classes that require closer organizational match, while larger ϵ allows more drift, mutation, or implementation variation (e.g. different embodiments of the same algorithmic agent). Note also that $\approx_{O,\epsilon}$ need not be transitive for arbitrary d_O and ϵ; this is acceptable because the role of similarity here is to constrain reproduction events locally, while the species concept below supplies the lineage-closure structure.

Now define a reproduction event.

Definition 288 (Reproduction event). *Fix an observer/context O. A* reproduction event *from S to S' over a time window $[t_0, t_1]$ is an event in which:*

- *the existence/state of S and its actions in $[t_0, t_1]$ have a strong causal influence on the existence of S' at time t_1 (in the sense of predictive attraction / causal implication from Section 14), and*
- *$S \approx_{O,\epsilon} S'$ for a species-tolerance parameter ϵ.*

The time window formulation permits reproduction to be extended rather than instantaneous: copying may require a sequence of coordinated actions (construction, teaching, compilation, gestation, infection, fabrication) whose causal effect accumulates over $[t_0, t_1]$. The dependence on S's *actions* is important: it distinguishes reproduction from mere common-cause correlation (two similar systems produced by the same factory process) and from passive resemblance (unrelated convergent structures), by requiring that interventions on S (or on its relevant outputs) would substantially change the probability of S' existing as it does.

Remark 1078 (Primary causal role). *"Primary" can be formalized in multiple ways. One option is: among a set of candidate causal explanations for the existence of S', those that include S achieve strictly lower weakness (higher explanatory clarity). Another option is an information-flow criterion: conditional mutual information between S's actions and S''s formation is high after conditioning on other known factors. The ontology allows multiple instantiations; what matters is that reproduction is grounded in a quantitative causal contribution notion, not merely correlation.*

A useful intuition is that "primary" is meant to screen off background enabling conditions that are present in many contexts (ambient physics, general availability of matter/energy, a common environment), while retaining the particular causal pathway by which S helps bring about S'. In biological reproduction, the parent is primary even though the environment provides nutrients; in software reproduction, a running process may be primary even though the OS provides system calls. Conversely, if a system is merely a template stored in an archive and an external operator performs all the essential steps without dependence on the system's own organized activity, then the archive may fail to qualify as the primary causal source under many reasonable formalisms.

19.5.2 Species as a reproduction-closed set

Definition 289 (Species). *Fix an observer/context O and tolerance $\epsilon > 0$. Let $\to_O$ be the directed relation on systems given by*

$$S \to_O S' \iff \text{there exists a reproduction event from } S \text{ to } S' \text{ (within tolerance } \epsilon\text{)}.$$

A nonempty set $\mathcal{C}$ of systems is called a species (for O) *if:*

- *(closure) whenever $S \in \mathcal{C}$ and $S \to_O S'$, then $S' \in \mathcal{C}$; and*
- *(regeneration) for each $S' \in \mathcal{C}$, there exists $S \in \mathcal{C}$ with $S \to_O S'$ (except possibly for a designated "initial" subset, if one wishes to allow an origin event).*

This makes a species a lineage-stable class under the chosen reproduction relation: closure says that offspring remain in the class, while regeneration says that membership is not accidental but supported by incoming reproduction links from within the class (up to any explicitly granted origin boundary). The directedness of $\to_O$ allows asymmetric parent–offspring relations and accommodates cases where S can produce S' but not conversely (e.g. a mature organism producing a juvenile, or a trained model producing a distilled student). The definition is compatible with branching genealogies and with multiple parents, since $\to_O$ need not be functional. It also allows observer-dependent "species" notions such as: species by genetic organization, by morphology, by ecological role, or by algorithmic architecture, provided the similarity and causal criteria are specified.

One can view $\mathcal{C}$ as (approximately) a strongly connected component of the reproduction graph after contracting the optional initial subset: regeneration ensures incoming edges, while closure ensures outgoing edges stay inside. If the observer prefers a stricter biological notion, additional constraints (e.g. typical interbreeding, shared gene pool, or reproductive isolation) can be layered on top as refinements, without changing the core causal-closure idea.

Remark 1079 (Groups can reproduce too). *The ontology allows reproduction to be carried out by groups. Formally, one can replace S by a coalition object $\{S_1, \dots, S_k\}$ (or a composite system) and define a relation $\{S_1, \dots, S_k\} \to_O S'$. Nothing essential changes; it simply moves the reproduction arrow from individuals to composites.*

This group-level option covers cases like eusocial colonies, symbiotic consortia, cultural/institutional reproduction (where a coordinated group founds a new branch), and multi-agent systems that replicate via distributed protocols. It also supports "scaffolded" reproduction where no single component has enough causal influence alone, but the coalition does, matching many real-world cases where reproduction is inherently collaborative.

19.5.3 Lifeforms

We now combine the pieces into a lifeform notion. The intent is to separate (i) mere complex dynamics, (ii) self-maintenance (metabolism), and (iii) lineage continuation (reproduction), while keeping all three definable in a substrate-neutral way.

Definition 290 (Lifeform). *Fix an observer/context O. A system S is a* lifeform (for O) *if:*

- *S is a complex interactive system (Definition above),*
- *S routinely carries out metabolism (Section 19.4), and*

- *S routinely participates in reproduction events within some species $\mathcal{C}$.*

The species quantifier "within some species $\mathcal{C}$" is meant to ensure that reproduction is not a one-off coincidence but integrated into a reproduction-closed lineage class. Participation in reproduction events can be as a direct parent, as part of a coalition parent, or (in some contexts) as a necessary role in a structured reproductive process, depending on how O specifies the relevant causal attribution. This makes the lifeform concept robust across levels: an organism, a colony, or an engineered agent can qualify if it meets the metabolism and reproduction criteria at the chosen descriptive level.

Remark 1080 (Routine versus occasional)**.** *"Routinely" is intentionally graded. A crisp version would require reproduction and metabolism to occur with at least some frequency over long horizons; a fuzzy/paraconsistent version (below) treats routine-ness as evidence. This flexibility is essential for boundary cases (hibernation, spores, sterilized organisms, viruses).*

Graded routine-ness also handles time-scale mismatch: reproduction may be rare relative to metabolism (e.g. long-lived trees) but still a stable disposition, while metabolism may be intermittent relative to reproductive capability (e.g. dormant seeds). For sterilized organisms, the framework allows a nuanced classification: an individual may fail the "routinely participates" clause even if it is similar to members of a reproducing species, while the species itself remains well-defined via other members' reproduction links. For viruses and other borderline replicators, the causal-primacy condition can be tuned to decide whether the virus, the host, or the host–virus composite is the reproducing system, reflecting different observer commitments about what organization is doing the primary causal work.

19.5.4 Biological, synthetic, and evolved lifeforms

Hyperseed distinguishes lifeforms by substrate and origin. We encode this by adding labels/metadata on the realization of S. These labels are intended to be orthogonal to the core lifeform criteria: they classify *how* the organization is realized and *how* it arose, not whether it meets the metabolism/reproduction conditions.

Definition 291 (Lifeform subtypes: biological, synthetic, evolved)**.** *A lifeform S is:*

- biological *if its dominant implementation substrate is organic chemistry (at the relevant descriptive level);*
- synthetic *if its design/assembly was primarily guided by an intelligent engineering process (as opposed to arising via unguided population-level dynamics);*
- evolved *if it arose via evolutionary and self-organization processes without intentional design.*

These labels are not mutually exclusive at all descriptive levels (e.g. bio-engineered organisms), so we allow them to be multi-valued or p-bit*-valued when needed.*

At different descriptive levels, a single system may receive different subtype labels: a bio-engineered organism can be biological in substrate, synthetic in origin for particular modules, and evolved in the sense that its lineage later adapts via selection. Similarly, an artificial agent running on silicon may be synthetic in origin, but its later variants may be evolved if produced by an unguided evolutionary search or by an open-ended selection process. Allowing p-bit-valued labels supports intermediate or disputed cases where evidence is partial (e.g. uncertain origin), where the system contains a mix of components with different provenance, or where the observer treats "guidance" as a graded variable rather than a binary predicate.

19.6 Alive and dead as time-indexed (possibly paraconsistent) predicates

The ontology treats "alive" and "dead" as time-indexed properties and, crucially, as *boundary notions*: there are borderline cases, context dependence, and situations in which different evidential streams conflict. In particular, both predicates are intended to track *states of a system as reported through an observer/model interface*, not merely intrinsic microphysical facts: the same underlying system S at the same time t can receive different status assignments from distinct observers O because they use different sensors, different background theories, different coarse-grainings, or different practical decision thresholds.

We therefore define alive/dead predicates as p-bit-valued evidence fields (Section 3.2). Concretely, for any predicate P, a value $P(S,t) \in [0,1]^2$ is interpreted as a pair

$$P(S,t) = (P^+(S,t), P^-(S,t)),$$

where P^+ is the degree of *supporting* evidence and P^- is the degree of *counter*-evidence. The key point is that the framework does not require P^+ and P^- to sum to 1 (or to be otherwise complementary): simultaneously high P^+ and P^- represents an explicitly modeled evidential conflict, rather than an inconsistency that collapses the model.

Definition 292 (p-bit evidence for metabolism and reproduction)**.** *Fix an observer/context O. Let $\mathrm{Met}_O(S,t) \in [0,1]^2$ denote the* p-bit *evidence that S is metabolically active near time t, and let $\mathrm{Rep}_O(S,t) \in [0,1]^2$ denote the* p-bit *evidence that S is reproductively active (or participates causally in reproduction events) near time t.*

Both Met_O and Rep_O are meant to be operationally grounded: they may be produced by direct measurement (e.g. calorimetry, observed growth, molecular turnover), by inference from proxies, or by model-based attribution (e.g. participation of a viral genome in a host replication cycle). The phrase "near time t" allows the observer to use a small temporal neighborhood (e.g. a sampling interval), which is often necessary because metabolism and reproduction are rarely instantaneous at the resolution of observation.

Definition 293 (Alive predicate (paraconsistent))**.** *Fix weights $\alpha, \beta \geq 0$ with $\alpha + \beta > 0$. Define the alive evidence at time t by the monotone aggregation*

$$\mathrm{Alive}_O(S,t) \ := \ \Big(\min\{1, \tfrac{1}{\alpha+\beta}\big(\alpha\,\mathrm{Met}^+_O(S,t) + \beta\,\mathrm{Rep}^+_O(S,t)\big)\},\ \min\{1, \tfrac{1}{\alpha+\beta}\big(\alpha\,\mathrm{Met}^-_O(S,t) + \beta\,\mathrm{Rep}^-_O(S,t)\big)\}\Big).$$

We say S is alive for O at time t *if $\mathrm{Alive}^+_O(S,t)$ exceeds a chosen threshold; we say S is* not alive *if $\mathrm{Alive}^-_O(S,t)$ exceeds a chosen threshold. Both may occur simultaneously (paraconsistency).*

The normalization by $(\alpha+\beta)^{-1}$ makes the aggregation comparable across different weight choices, and the outer $\min\{1,\cdot\}$ ensures that the result remains within $[0,1]$ even if the underlying evidence sources are themselves already saturated. Allowing $\alpha = 0$ or $\beta = 0$ permits contexts in which one stream is judged irrelevant or unavailable; for example, an observer may treat reproduction as inapplicable to a particular entity type, or may lack reproductive data while still observing metabolic activity. Because the aggregation is componentwise monotone in each input coordinate, additional supporting evidence for metabolism or reproduction can never decrease Alive^+_O, and additional counter-evidence can never decrease Alive^-_O; this is important for ensuring that refinement of measurement (in the direction of more evidence) does not produce pathological reversals.

Thresholds may be chosen differently for the positive and negative components, and may depend on downstream use. For example, a safety-critical context might employ a low threshold for "not alive" (erring on the side of declaring non-viability), whereas a conservation context might use a low threshold for "alive" (erring on the side of continued protection). Nothing in the formalism forces a unique threshold policy; the intent is to separate the evidential field $\mathrm{Alive}_O(S,t)$ from the eventual binary (or multiway) decision rule applied to it.

Definition 294 (Dead predicate (time-indexed))**.** *Fix a lookback window length $\tau \in \mathbb{N}$. Define the "was-alive" evidence by*

$$\mathrm{WasAlive}_O(S,t) \;:=\; \bigoplus_{u\in\{t-\tau,\ldots,t-1\}} \mathrm{Alive}_O(S,u),$$

where $\oplus$ is the p-bit *join (componentwise max) from Section 3.4. Define*

$$\mathrm{Dead}_O(S,t) \;:=\; \mathrm{WasAlive}_O(S,t) \;\otimes\; \neg\mathrm{Alive}_O(S,t),$$

using the p-bit *negation and monoidal product from the core.*

The use of a lookback window encodes the idea that "dead" presupposes a recent history of life-like functioning, and thereby avoids classifying as dead entities for which there was never meaningful evidence of being alive (relative to O). The join $\bigoplus$ implements an existential-style temporal summary ("alive at some time in the window") rather than an averaging summary; this matches ordinary usage where a single sufficiently strong period of life in the recent past is enough to make subsequent non-life plausibly "death." The choice of τ is a modeling parameter that can be tuned to the timescales relevant to the organism or system class: for fast-lived microorganisms it may be short, while for long-lived organisms or slow metabolic processes it may be longer.

The monoidal product $\otimes$ in $\mathrm{Dead}_O(S,t)$ enforces a conjunctive structure: strong dead-ness requires both strong "was alive" evidence and strong present "not alive" evidence (expressed via $\neg\mathrm{Alive}_O(S,t)$). Because the underlying logic is paraconsistent, it is possible for $\mathrm{Dead}_O(S,t)$ to coexist with nontrivial $\mathrm{Alive}_O(S,t)$ when evidence streams disagree about current status; this is a feature rather than a bug in contexts such as partial observability, sensor failure, or disputes about what counts as metabolic activity.

Remark 1081 (Interpretation of dead-ness)**.** *$\mathrm{Dead}_O(S,t)$ is high when there is strong evidence that S was alive recently and strong evidence that it is not alive now. This captures the intended asymmetry: "dead" is not merely "not alive"; it is "not alive now, but was alive before."*

One can also read the construction as imposing a temporal directionality that is commonly implicit in practice: evidence of a prior living state changes the semantic category of subsequent inactivity. For example, a rock is ordinarily classified as "not alive" rather than "dead" because $\mathrm{WasAlive}_O$ remains low, while a recently functioning organism with a sudden cessation of activity yields high $\mathrm{WasAlive}_O$ and can therefore support high Dead_O if present non-life evidence is also high.

Example 16 (Boundary cases: viruses, spores, and cryopreservation)**.** *A virus may have high Rep^+_O (it participates in reproduction events) but low Met^+_O (it lacks autonomous metabolism). Depending on α, β and the observer's modeling choices, one may obtain: (i) borderline alive (moderate positive and negative evidence), or (ii) paraconsistent alive/not-alive (strong but conflicting evidence). Similarly, spores or cryopreserved organisms may have low current metabolic evidence but strong evidence for persistence of the underlying pattern web and strong evidence of future metabolic resumption; this pushes naturally toward a graded, time-indexed alive predicate rather than a crisp one.*

A further class of boundary cases arises from observational granularity and delayed reporting. For instance, an intensive-care monitor may show no detectable respiration (pushing Met_O^- upward) while other tests indicate ongoing cellular activity (pushing Met_O^+ upward), yielding simultaneous support for alive and not-alive at the same time index. In such cases, the time-indexing prevents the model from forcing an irreversible commitment: later evidence can be incorporated without retroactively rewriting earlier evidential states, while the paraconsistent representation preserves the fact that the earlier state was genuinely conflicted rather than merely unknown.

19.7 Life as self-weaving under resource constraints

We can now restate the intended Hyperseed synthesis succinctly: The aim of the synthesis here is not to propose an additional "vital" ingredient, but to make explicit how the already-introduced pattern-level dynamics acquire a concrete directionality once we acknowledge that maintaining any organized web requires ongoing throughput. In other words, the same self-weaving mechanism that can in principle elaborate arbitrarily rich structure becomes sharply selective when it must continually pay the costs of continuing to exist.

- The *self-weaving webs* of Section 12 provide the pattern-level mechanism: patterns that contribute to the persistence of the web tend to be reinforced (habit-taking), and those that undermine it tend to be suppressed (habit-reversal), potentially including cross-context coupling via morphic resonance. This can be read as an abstract selection process operating *within* an individual or system over time: reinforcement is not merely "learning" in the cognitive sense, but any dynamical bias that causes certain configurations to recur and stabilize. Likewise, suppression is not merely forgetting, but an active reduction in the probability that destabilizing configurations will be re-instantiated. The possible role of cross-context coupling highlights that stabilization may draw upon correlations that are not localized to a single immediate environment, so that persistence can be influenced by regularities that span situations, timescales, or nested sub-webs.
- The present section adds the *resource bottleneck*: self-weaving requires the continual availability of genenergy, replenished by metabolism and allocated via policies that manage effort. The bottleneck framing matters because it converts "could persist" into "must compete for limited continuation capacity": even if many patterns are in principle compatible with persistence, only those compatible with the available genenergy budget can actually be maintained. By "metabolism" we mean any process that converts environmental gradients, stored reserves, or external inputs into a usable internal currency, so that the web can repeatedly pay the costs of sensing, acting, repairing, and coordinating. The allocation "policies" can be explicit (deliberate choice, executive control) or implicit (homeostatic set-points, reflexive gating, priority dynamics); in either case they implement a distribution of effort across maintenance, exploration, exploitation, and reconfiguration. Under this view, life is not only a web that reinforces itself, but a web that must continually decide what to *fund*, what to *defer*, and what to *terminate* as conditions fluctuate.
- Reproduction provides a route for pattern-web persistence that exceeds the lifespan of a single instance, yielding species-level continuity. This adds an inter-instance channel for stabilization: patterns that cannot be sustained indefinitely within one bounded embodiment may nonetheless persist by being re-instantiated in successors. Importantly, reproduction need not be construed narrowly as biological replication; it can be treated more generally as any mechanism that transfers enough of the web's organization (or its generative constraints) to seed a new instance that can resume self-weaving. Species-level continuity then reflects the persistence of a *family* of webs

that share a core set of self-maintaining motifs while still permitting variation, adaptation, and drift across generations.

This prepares the ground for the next layers: knowledge and belief systems (Section 20) can be seen as specialized pattern-web regimes that manage genenergy allocation by compressing experience into reusable models, and intelligence/agency (Section 21) can be seen as the discovery and exploitation of high-transfer, high-capacity genenergy pathways across contexts. To "compress experience" here is to reduce the ongoing costs of prediction and control by replacing repeated costly inference with amortized structure (schemas, categories, causal expectations) that can be cheaply invoked. Such regimes therefore act as budgeting tools: they steer attention, simplify decision spaces, and pre-commit effort toward interventions that have historically yielded good persistence returns. In the same spirit, "high-transfer" pathways are those whose benefits generalize beyond the narrow situation in which they were learned (e.g., representations or skills that remain useful across tasks), while "high-capacity" pathways are those that can reliably sustain large flows of genenergy (e.g., robust metabolic routes, stable social coordination, or scalable tool-use) without collapsing under noise, scarcity, or complexity. The overall picture is that resource constraints do not merely limit life; they help define what counts as viable organization by making persistence an ongoing, budgeted achievement rather than a passive property.

20 Knowledge, belief systems, and science

20.1 Why an epistemic layer is needed

Sections 9–19 treated minds as pattern-using, energy-limited systems: observers make (and fail to make) distinctions, quantify simplicity via weakness/effort, and organize patterns into webs whose dynamics include attention and habit formation. In that framing, pattern webs already carry a great deal of structure, but they do not yet distinguish between (i) merely having an internal regularity that happens to correlate with the world and (ii) having a *normatively usable* internal regularity that can be recruited as an answer, criticized as an error, or improved via deliberate inquiry. The epistemic layer is introduced to make that distinction explicit: it adds mechanisms for *evaluation* (when is a pattern treated as a commitment?), *interrogation* (what question is a pattern answering?), and *revision* (how are commitments updated under limited time, compute, and evidence).

Hyperseed then takes an additional step: it treats *knowing* and *thinking* not as mysterious extras but as *structured dynamics on pattern webs.* The key move is operational:

- A system *knows* something to the extent that it can *answer a question* in a way that reliably reduces uncertainty and supports effective action.
- A system *thinks* to the extent that it can *generate, select, and refine* questions, answers, and the beliefs that connect them.

Here "question" and "answer" are not treated as purely linguistic objects. They are taken to be templates and constraints that can be instantiated in perception, planning, explanation, or social exchange. Reliability is likewise operationalized: an "answer" counts as reliable insofar as it remains usable across a relevant range of contexts (or can signal its own limits), rather than merely fitting a single episode. This connects directly to the earlier emphasis on attention and habit formation: attention provides a way to allocate limited resources across competing questions, while habits provide cached answer-patterns whose reuse is efficient but whose brittleness must be monitored.

Remark 1082. *Philosophically, this treats epistemology as a species of control theory: the point of "knowing" is not to mirror the world in some metaphysically immaculate way, but to compress and stabilize action-relevant distinctions in the face of uncertainty and limited resources. On this view, "uncertainty reduction" is not an abstract goal but a means of improving control: it is valuable insofar as it sharpens the system's ability to choose interventions, anticipate outcomes, and recover from error. This also implies that a system may rationally tolerate local inconsistency when the cost of immediate global reconciliation outweighs the benefit, or when conflicting evidence supports different actions in different regimes. This stance aligns with Hyperseed's broader pattern-centric view of cognition [5, 1] and with explicitly social and computational pictures of scientific practice [20]. In the Hyperseed core-concept set, this section primarily elaborates Knowing and Thinking (Hyperseed-Concept* **??***), Questions (Hyperseed-Concept 144), and Answers (Hyperseed-Concept 56).*

In this section we formalize:

(a) template patterns, questions, and answers;

(b) beliefs and axiom systems as paraconsistent, resource-sensitive commitments;

(c) question networks as (possibly cyclic) dependency structures;

(d) belief systems as coherent epistemic sub-webs within a community; and

(e) science and state-dependent science as belief-system dynamics with explicit empirical coupling.

The ordering reflects a build-up from local representational machinery (templates, questions, answers) to increasingly global organization (axioms, dependency networks, and community-level stabilization). In particular, allowing question networks to be cyclic is not an incidental complication: real inquiry often contains feedback loops (e.g., a hypothesis suggests a measurement protocol, whose results reshape the hypothesis space, which in turn changes what counts as a relevant measurement). The epistemic layer aims to model such loops without requiring idealized acyclic rational reconstructions.

Throughout, we reuse the paraconsistent p-bit domain and the quantale operations from Section 3. This reuse is intended to keep epistemic dynamics continuous with the earlier "weakness/effort" theme: epistemic commitments are treated as patterns with strengths that can be composed, competed, and updated, rather than as all-or-nothing propositions that instantly force global consistency.

Remark 1083 (Notation reminder: p-bit, $\mathbb{V}$, $\oplus$, $\otimes$)**.** *We write* $\mathbb{V} = [0,1]^2$ *for the paraconsistent evidence domain (a "p-bit"), where an element* (v^+, v^-) *is interpreted as* positive *and* negative *evidence held simultaneously (Hyperseed-Concept 65 and Hyperseed-Concept 198). The binary operation* $\oplus$ *denotes the componentwise join (so it* aggregates *evidence), and* $\otimes$ *denotes the quantale product used to* compose *strengths along a rule/premise chain. These choices are aligned with Hyperseed's broader quantale-weakness emphasis [3, 2] and with paraconsistent logics designed to avoid explosion [23, 24]. Interpreting beliefs in* $\mathbb{V}$ *makes it straightforward to represent common epistemic states that are awkward in purely consistent formalisms, such as "there are good reasons for and against," "the data are mixed," or "I have strong supporting evidence but also a salient defeater." In later formalizations, this will let question-answer dynamics treat conflict as a first-class signal (something to be routed, localized, or investigated) rather than as an immediate catastrophe that trivializes inference.*

20.2 Template patterns, questions, and answers

Hyperseed defines questions and answers in terms of *template patterns*. We will model a template pattern as a pattern with a fixed "frame" plus variable "slots".

Definition 295 (Template pattern)**.** *Fix a universe of discourse X. Let S be a finite set of* slots *and let $F \subseteq S$ be the subset of* fixed slots*. A* template *is a map*

$$\tau : S \to X \cup \{*\},$$

where $\tau(s) \in X$ for $s \in F$ and $\tau(s) = *$ (a placeholder) for $s \in S \setminus F$. An instantiation *of τ is a map $\iota : S \to X$ such that $\iota(s) = \tau(s)$ for all $s \in F$. We write $\mathrm{Inst}(\tau) \subseteq X^S$ for the set of instantiations.*

Remark 1084. *In practice, S corresponds to argument positions of a predicate or roles in a schema. The set $\mathrm{Inst}(\tau)$ is the space of candidates the system is trying to narrow down.*

Remark 1085. *It is often useful to view τ as specifying an* equivalence class *of fully specified patterns: two instantiations $\iota, \iota' \in X^S$ are equivalent with respect to the current frame if they agree on the fixed slots F. From this perspective, the placeholder symbol $*$ does not denote an element of X; it denotes* underdetermination *relative to a task or context. This makes explicit why templates are naturally context-sensitive: changing which slots are treated as fixed (i.e., changing F) changes which distinctions among candidates are currently meaningful.*

Remark 1086 (Intuition and examples)**.** *A template pattern is a disciplined way of saying: "I recognize the* form *of what I am looking for, but not all of its content." The slots S are the places where content may vary; the fixed set F pins down what is already determinate, and the symbol $*$ marks what is still open. The set X^S denotes all assignments of elements of X to each slot in S, and $\mathrm{Inst}(\tau) \subseteq X^S$ carves out those assignments that agree with the fixed frame.*

A simple example: let X be a set of people, $S = \{1, 2\}$ represent the two roles in a binary relation, and let $F = \{1\}$ with $\tau(1) = \mathsf{Alice}$ and $\tau(2) = *$. Then $\mathrm{Inst}(\tau)$ is the set of pairs (Alice, x) with $x \in X$. In a more schematic setting, S might index semantic roles like agent, $\mathsf{patient}$, $\mathsf{instrument}$, etc., matching Hyperseed's emphasis on patterns as re-usable structures (Hyperseed-Concept 130; see also [5]).

This definition is useful because it makes questions and answers mathematically comparable: a question will be about restricting $\mathrm{Inst}(\tau)$, and an answer will be anything that narrows, reweights, or otherwise simplifies the candidate space. Thus, the epistemic layer is expressed in the same language as the pattern layer: distinctions made among *instantiations are the concrete content of "learning."*

Remark 1087. *This template formalism also connects directly to familiar computational mechanisms such as pattern matching and unification. A fixed frame corresponds to a partially instantiated structure (e.g., a term with variables), and an instantiation corresponds to a substitution assigning concrete values to the remaining slots. In this light, $\mathrm{Inst}(\tau)$ can be read as the solution set of a constraint satisfaction problem induced by the fixed slots, with later evidence adding additional constraints or weights.*

Definition 296 (Question)**.** *A* question *for a system S is an action (or action policy) whose intent is to obtain information about $\mathrm{Inst}(\tau)$ for some template τ. Formally, we model a question as a pair (τ, Exp) where*

- *τ is a template pattern, and*

- Exp *is an* experiment/interaction *channel that produces data d which can be used to update beliefs about* $\mathrm{Inst}(\tau)$.

Remark 1088 (Intuition and examples)**.** *A question is not, in this formalism, merely a string of words; it is an* intervention into the world (or into ones own cognitive dynamics) *chosen to discriminate among candidate instantiations. The experiment channel* Exp *embodies the pragmatic fact that information is obtained through interaction: one measures, queries, probes, introspects, simulates, or otherwise acts to produce data.*

Example: if X is a set of possible diagnoses, a template might fix the patient identity and leave the diagnosis slot open; then Exp *might be a lab test producing an outcome that shifts the candidate set. Example: if X is a set of physical parameter values,* Exp *might be a measurement protocol. By treating questions as actions/policies, this section aligns the epistemic layer with the control machinery of Section 14 and with Hyperseed's general view that cognition is closed-loop (cf. [19]). In the Hyperseed core-concept set, this is precisely Questions as information-seeking actions (Hyperseed-Concept 144) interacting with Contexts and Aspects (Hyperseed-Concept 86).*

Remark 1089. *The pair* (τ, Exp) *separates two logically distinct components that are often conflated in informal discourse: (i)* what *is being asked (the target template τ), and (ii)* how *the system proposes to find out (the interaction channel* Exp*). Different experiments can address the same template (e.g., multiple tests for the same diagnosis), and the same experiment can serve multiple templates depending on which slots are being treated as open. This separation also makes room for internal questions:* Exp *may be an introspective or computational procedure (e.g., running a simulation, retrieving from memory, or checking a proof) rather than an external sensorimotor action.*

Definition 297 (Answer)**.** *An* answer *to a question* (τ, Exp) *is any artifact that reduces uncertainty about* $\mathrm{Inst}(\tau)$*. Concretely, an answer may be:*

- *a particular instantiation* $\iota \in \mathrm{Inst}(\tau)$*;*
- *a constraint* $C \subseteq \mathrm{Inst}(\tau)$ *that prunes candidates;*
- *a distribution (or* p-bit*-valued scoring) over* $\mathrm{Inst}(\tau)$*; or*
- *any representation that yields an entropy reduction or computational simplification relative to baseline inference.*

Remark 1090 (Intuition, examples, and usefulness)**.** *An answer is defined by its* function *rather than its format: it is whatever makes the space of candidates smaller, sharper, or cheaper to search. If the question is "which ι is correct?", then a complete answer is a single* $\iota \in \mathrm{Inst}(\tau)$*. But many answers are partial: a constraint C might say "the unknown is in this region" or "the unknown satisfies these invariants," and a distribution might say "these candidates are plausible, these are not."*

Remark 1091. *The four bulleted forms above intentionally mix* set-based *and* probabilistic/graded *answers. The set-based view corresponds to elimination and deduction (hard constraints), while the graded view corresponds to abduction and induction (soft evidence). In particular, the* p-bit*-valued scoring option is meant to cover situations in which the system uses bounded or many-valued belief representations rather than full real-valued probabilities, while still supporting the same conceptual role: ranking or weighting elements of* $\mathrm{Inst}(\tau)$ *so that resources are allocated toward more promising candidates.*

Remark 1092. *The phrase "entropy reduction or computational simplification" is meant broadly. In the probabilistic case, one can formalize the effect of an answer as moving from a prior $P(\iota)$ on* $\mathrm{Inst}(\tau)$ *to a posterior $P(\iota \mid d)$ after observing data d from* Exp, *with uncertainty reduction measured (for example) by $H(P)-H(P(\cdot \mid d))$ or by mutual information between ι and d. In the computational case, an answer can be a* compiled *representation—a rule, model, proof sketch, cached sufficient statistic, or program fragment—that makes subsequent inference over* $\mathrm{Inst}(\tau)$ *cheaper even if it does not drastically reduce the candidate set outright. This matches the operational notion that "knowing" often means being able to answer quickly or with fewer resources, not merely being able to exclude possibilities in principle.*

Remark 1093. *For example, if* $\mathrm{Inst}(\tau)$ *is large, then a constraint C may be vastly more valuable than a single guessed instantiation: it changes the computational geometry of the problem by pruning whole subspaces. In other words, a constraint acts like a* structural *answer: instead of selecting one element of* $\mathrm{Inst}(\tau)$*, it alters the shape of the remaining search landscape so that many candidate instantiations become unreachable or irrelevant under C, often turning an intractable exploration into a manageable one. The parenthetical reference to "entropy reduction" can be understood in several compatible ways: Shannon-style uncertainty reduction, logical-entropy reduction [17], or algorithmic description-length reduction [16]. On a Shannon view, the answer increases concentration of probability mass on fewer instantiations; on a logical-entropy view, it increases the rate at which pairs of distinct instantiations are distinguished by the system's predicates; on an algorithmic view, it permits a shorter effective description of the candidate set by exploiting regularities introduced by C or by the refined model. Hyperseeds point is not to legislate a single measure, but to assert that "answerhood" is tightly bound to* distinction-making *(Hyperseed-Concept 98) and* effort *(Hyperseed-Concept 100). Put informally, what makes an answer an answer is that it induces new discriminations the system can actually use, and that these discriminations are achieved at some nontrivial computational or experimental cost that must be justified by the resulting pruning or re-weighting of possibilities.*

Remark 1094 (Answer quality as weakness reduction)**.** *Let* Π *be the system's current "candidate set" representation for* $\mathrm{Inst}(\tau)$*. If an answer refines this representation (by removing candidates or sharpening scores), then the system has effectively* added distinctions *among instantiations. Here "representation" is meant broadly:* Π *could be an explicit set, a constraint-satisfaction encoding, a posterior distribution, a scoring function over candidates, or any other data structure that supports selection and elimination, and refinement can include either hard exclusion or merely making some candidates decisively less plausible. In the weakness formalism (Section 3.7), adding distinctions corresponds to* reducing *the set of undistinguished pairs, hence decreasing weakness. Equivalently, when fewer candidate pairs remain interchangeable with respect to the system's current tests, predicates, and internal symmetries, the system is less "weak" because it has more leverage to act differently depending on which instantiation is true. Thus, in a minimal formal sense, answering a question is "weakness reduction on a candidate space." This framing also clarifies why merely producing a token output is insufficient: an output counts as a higher-quality answer only insofar as it produces a measurable refinement of* Π *relative to the system's prior state, ideally in a way that is stable under re-encoding of the same candidate space.*

Remark 1095. *This remark is one of the key bridges in the document: it identifies epistemic progress with the same primitive currency used earlier (weakness/effort) [3, 2]. In particular, it treats "learning" and "problem-solving" as variations of a single underlying operation: investing effort in order to produce distinctions that make the environment (or the task space) less confusable to the system. Seen in this light, a "good question" is one that admits actions likely to yield* *high weakness reduction per unit effort, and a "good answer" is one that actually delivers such reduction. This makes explicit the normative direction implicit in the earlier sections: questions and answers are evaluated not only by truth-apt content, but by their capacity to reconfigure the system's candidate space so that subsequent decisions can be made with fewer costly ambiguities. This also echoes Hyperseed's general pattern-emergence framing [5]. Concretely, asking the right question can be understood as selecting a partition of* $\mathrm{Inst}(\tau)$ *that aligns with available tests and interventions, so that the system is nudged toward discovering compressive patterns (regularities) rather than merely accumulating isolated facts.*

20.3 Beliefs as paraconsistent valuations

We treat a belief state as a p-bit-valued valuation of a language of claims. The language can be instantiated in many ways (logical formulas, pattern claims, type assertions, causal rules, etc.). For this section it suffices to treat it abstractly. In particular, we do not assume that $\mathcal{L}$ comes equipped with a fixed proof system or semantics; the purpose of the abstraction is to separate (i) what the agent *takes itself* to have evidence for or against from (ii) whatever background logic one might later use to relate claims to each other. This separation is useful when comparing ordinary reasoning, scientific inference, and socially stabilized belief systems, since these often share *claims* while disagreeing about the sanctioned *derivations* between them.

Definition 298 (Claim language and belief state)**.** *Let $\mathcal{L}$ be a set of* claims*. A* belief state *is a function*

$$\beta : \mathcal{L} \to \mathbb{V} = [0,1]^2, \qquad \beta(\varphi) = (\beta^+(\varphi), \beta^-(\varphi)).$$

$\beta^+(\varphi)$ is positive evidence for φ and $\beta^-(\varphi)$ is negative evidence. No consistency constraint is imposed.

A useful way to read $\beta(\varphi) \in [0,1]^2$ is as recording two *independently accumulating* quantities: one channel aggregates support and one channel aggregates counterevidence. The absence of a constraint such as $\beta^+(\varphi) + \beta^-(\varphi) \le 1$ is deliberate: it allows the model to represent both partial information (both small) and conflicted information (both large) without forcing an artificial reconciliation step. When later reasoning requires a single scalar "credence-like" quantity, one can introduce derived summaries (e.g. a net-support score $\beta^+(\varphi) - \beta^-(\varphi)$ or an information-mass score $\beta^+(\varphi) + \beta^-(\varphi)$), but these are *projections* of the underlying state rather than the state itself.

Remark 1096 (Intuition and examples)**.** *This definition says: a minds epistemic posture is not a single probability distribution nor a set of crisp truths, but a paraconsistent field of* evidence *(Hyperseed-Concept 65). The same claim can be supported and opposed at once; this matches ordinary cognition, where we can have strong reasons both for and against a proposition without immediately dissolving into nonsense. Formally, allowing $\beta^+(\varphi)$ and $\beta^-(\varphi)$ to both be large blocks the classical principle that inconsistency entails triviality, aligning with paraconsistent traditions [23, 24].*

A simple example: let φ be "this medicine is safe." One may have clinical-trial support (large β^+) and also anecdotal reports of adverse events (nontrivial β^-). The usefulness of the definition is compositional: once belief is a function into $\mathbb{V}$, we can apply the same quantale operations used elsewhere to aggregate testimony, compose rules, and propagate constraints through networks of claims.

It is also helpful to connect the p-bit representation to familiar logical and epistemic categories. At the crisp extremes, $(1,0)$ behaves like "accepted," $(0,1)$ like "rejected," $(0,0)$ like "no information," and $(1, 1)$ like "inconsistent but maximally evidenced on both sides." Intermediate values allow graded versions of these four corners, so the model can represent "weakly supported," "mostly disconfirmed," or "strongly contested" claims without deciding prematurely which side must win. This graded, paraconsistent stance is especially important in scientific contexts where evidence streams arrive asynchronously, instruments disagree, or different experimental setups pull in different directions.

Definition 299 (Direct and indirect belief (operational form))**.** *Fix a temporal scaffold* $(T, \preceq)$ *as in Section 7. Let* $\mathcal{P}$ *be a set of pattern-claims of the form "pattern* P *holds at time* t*".*

(a) A direct belief *is a belief about* persistence*: a claim that an observed or inferred pattern will continue to hold at later times along some timeline relative to some world/context.*

(b) An indirect belief *is a belief about* belief production*: a claim that some cognitive content (rule, schema, procedure) will be used by the system's inference to generate (or modify) future direct beliefs.*

Operationally, one can think of direct beliefs as assigning p-bit-valuations to temporally indexed claims in $\mathcal{P}$ (e.g. $\beta(P@t)$), while indirect beliefs assign p-bit-valuations to higher-order claims about transitions, updates, and rule applications (e.g. that certain kinds of observations will be treated as reliable, or that certain inference steps will be applied when premises are present). The definition does not require that indirect beliefs be infallible or even consistent with one another: a system can simultaneously treat a source as "generally reliable" while also treating it as "often biased" in specific contexts, and this tension can be represented as nontrivial β^+ and β^- on the corresponding indirect claim.

Remark 1097 (Intuition and why the distinction matters)**.** *Direct beliefs are about how the world is expected to continue: they are, so to speak, commitments about the* trajectory *of pattern (Hyperseed-Concept 130) through time. Indirect beliefs are about the minds own machinery: which rules, sources, and internal procedures will shape those commitments. This split is philosophically significant: the mind not only predicts the world; it predicts itself as an epistemic actor, and it does so under resource constraints.*

Example: "the sun will rise tomorrow" is a direct belief about persistence. "my measurement instrument is reliable" or "modus ponens is a valid inference move" are indirect beliefs: they govern how new evidence becomes new direct belief. In Hyperseed terms, indirect beliefs are often stabilized socially as part of a shared practice, foreshadowing belief systems and science (Hyperseed-Concept 64; see also [20, 19]).

The direct/indirect split also clarifies how disagreement can persist even when agents share much of the same first-order data. Two agents may have similar direct beliefs about many immediate patterns while differing sharply in indirect beliefs about which models are admissible, which measurements are trusted, or which inference rules are appropriate under uncertainty. In such cases the conflict is not (only) over φ but over the mechanisms that generate future $\beta(\varphi)$, so resolution requires addressing the indirect layer (e.g. by calibration, methodological critique, replication practices, or negotiating shared standards).

Remark 1098. *In practice, indirect beliefs correspond to the "rules of the game" a mind uses in thinking: trusted inference patterns, trusted sources, and stable modeling biases. In a community, many indirect beliefs are socially maintained.*

20.4 Axiom systems and hypothetical reasoning

Hyperseed emphasizes that an axiom system, *as held by an agent*, is psychological/pragmatic: axioms are interrelated indirect beliefs. We model this as a designated subset of claims with high commitment. In particular, what makes a claim "axiomatic" in this sense is not a metaphysical property of the sentence, but the agent's stance that it will be treated as a stable inferential anchor while the agent reasons, explains, and plans. This framing is meant to cover both explicit axiom lists (as in formal mathematics) and tacit, practice-level commitments (as in scientific methodology or everyday reasoning).

Definition 300 (Axiom system)**.** *An* axiom system *is a pair* (A, θ) *where* $A \subseteq \mathcal{L}$ *is a set of claims and* $\theta \in (0, 1]$ *is a commitment threshold. A belief state* β treats (A, θ) *as axiomatic if*

$$\beta^+(\varphi) \geq \theta \quad \textit{for all } \varphi \in A.$$

It is important that this definition is intentionally one-sided: it constrains the positive commitment $\beta^+(\varphi)$ but does not require that $\beta^-(\varphi)$ be small. This is consistent with the paraconsistent stance of the framework: an agent may, for pragmatic reasons, proceed *as if* some φ is fixed for the purposes of a project, while still registering countervailing evidence in the background (e.g., unresolved anomalies or known edge cases). Likewise, A is not required to be deductively closed, consistent, or minimal; it is merely the set the agent has earmarked as "treated as fixed" at the given threshold. In practice, A may include redundant items, mutually supporting principles, and even explicitly recognized tensions (for example, idealizations in a model that are acknowledged not to be literally true).

Remark 1099 (Intuition and examples)**.** *An axiom system here is not a claim about eternal certainty; it is a policy-like stance: "within this context, I will treat these claims as fixed points around which inference turns." The threshold* θ *makes this explicit: axiomatic status is a* degree *of commitment, not an ungraded categorical mark. This matches the everyday phenomenon that even mathematical axioms are, psychologically, held with a certain kind of firmness that is stronger than ordinary conjectures, yet still situated within a practice.*

Example: in Euclidean geometry, A might contain the parallel postulate; in a physical theory, A might contain symmetry principles or conservation laws; in a social epistemology, A might contain methodological commitments like "randomized trials matter." The definition is useful because it gives a clear handle on how fixed assumptions enter a paraconsistent inference system without requiring global consistency, and it allows axiom change to be modeled as a continuous shift in evidence rather than an abrupt collapse.

A useful way to read θ is as a floor on "how hard it is to dislodge" an axiom within the relevant context: the closer θ is to 1, the more nearly the axiom behaves like a hard constraint for the agent's positive stance, whereas smaller θ corresponds to a looser, working-commitment notion of axiomaticity. Because $\theta \in (0, 1]$ rather than $\theta = 1$, the model can represent cases where an agent is highly committed but not maximally committed—for example, when the agent treats a principle as "good enough" for engineering design or for a particular line of argument, while conceding that future evidence could still rationally lower the commitment. Conversely, the definition also separates two roles often conflated in informal talk: (i) a claim's importance as an inferential premise, and (ii) the agent's total evidential situation about that claim, including recorded objections.

Definition 301 (Entertaining a hypothesis)**.** *Fix a belief state* β *and a claim* $h \in \mathcal{L}$*. To* entertain the hypothesis h at strength $s \in \mathbb{V}$ *is to form the hypothetically augmented state*

$$\beta \uparrow_s h \;:=\; \beta \oplus \delta_{h,s},$$

where $\delta_{h,s}(h) = s$ and $\delta_{h,s}(\varphi) = (0,0)$ for $\varphi \neq h$, and $\oplus$ is the componentwise join from Section 3.4. One then runs an inference/closure operator (defined below) to see what follows.

Here $s \in \mathbb{V}$ may itself be mixed, e.g. $s = (s^+, s^-)$ with both coordinates nonzero, so "entertaining" can represent not only a pure pro-assumption (boosting h) but also a controlled stress-test in which one injects both supportive and adverse weight and then observes which downstream commitments are robust. This is particularly relevant in domains where hypotheses are rarely adopted as crisp binaries, and instead come in graded forms (e.g. "h is approximately true," "h holds in the regime of interest," or "h is a useful idealization"). The fact that $\delta_{h,s}$ is concentrated at h is also deliberate: it isolates the direct hypothetical move from any additional modeling choices about how the rest of the network should be updated, leaving that propagation to the closure operator and the background inferential structure.

Remark 1100 (Notation unpacking and intuition)**.** *The map $\delta_{h,s}$ is an "evidence spike" concentrated on the single claim h: it assigns the chosen strength $s = (s^+, s^-)$ to h and contributes no evidence elsewhere. The operation $\beta \oplus \delta_{h,s}$ then means: add this hypothetical evidence to the current belief state, componentwise, without deleting prior evidence. This is the paraconsistent analogue of the classical act "assume h and derive consequences," but it is deliberately less brittle: one can entertain h while still retaining negative evidence for h in the background.*

Example: one might entertain h = "a new particle exists" at strength $(0.6, 0.0)$ to explore downstream predictions, even if current data yields some negative evidence. This definition is useful because it turns counterfactual reasoning into a standard operator on belief states, enabling systematic exploration of question networks (Section 20.6) and also clarifying how cycles can be temporarily "cut" by hypotheses.

A further point is that $\uparrow_s$ is designed to be compositional: in later use, one can entertain several hypotheses by successive applications (or by joining several spikes) and then compare the resulting closures. This makes the operation suitable not only for "what if h?" reasoning but also for controlled scenario analysis: one can vary s and watch which conclusions change continuously and which change only when certain thresholds are crossed. In that sense, $\uparrow_s$ plays a role analogous to parameter sweeps in modeling: it supplies a uniform interface for probing the sensitivity of an inferential system to hypothetical adjustments.

Remark 1101. *This implements the Hyperseed description: to assume an axiom is to explore what would be implied if a truth value were very different than currently believed. The paraconsistent setting allows the exploration to coexist with contradictory evidence rather than forcing an all-or-nothing toggle.*

One can also view this as separating two questions that are often run together: (i) what the agent currently believes, and (ii) what the agent would be prepared to infer under a stipulated supposition. By treating the supposition as an explicit, additive modification of the evidence state, the model makes room for disciplined hypothetical reasoning even when the agent's baseline state is already nonclassical (e.g. contains tensions, exceptions, or domain-limited rules). This becomes especially important when axioms are treated as context-sensitive commitments: the same agent may legitimately run different inferential closures from the same underlying β by entertaining different axiom-like hypotheses at different strengths, corresponding to different projects, explanatory aims, or modeling idealizations.

20.5 Weighted inference and closure

To connect beliefs to question answering we need a minimal notion of inference. We use a general "weighted rule" scheme compatible with the quantale operations. In particular, we treat inference as an evidence-transforming operation on belief states, so that the same algebraic primitives used for composing partial evidence elsewhere also govern derivations.

Definition 302 (Weighted inference rules)**.** *A* weighted inference rule *is a triple $r = (\Gamma, \psi, \lambda_r)$ where $\Gamma \subseteq \mathcal{L}$ is a finite set of premises, $\psi \in \mathcal{L}$ is a conclusion, and $\lambda_r \in \mathbb{V}$ is a rule strength. Given a belief state β, define the rule's contribution to ψ by*

$$\mathrm{contrib}_r(\beta) \;:=\; \lambda_r \otimes \bigotimes_{\varphi \in \Gamma} \beta(\varphi),$$

using the p-bit *quantale product $\otimes$ from Section 3.4.*

It is often helpful to read Γ as a conjunction-like bundle of requirements: all premises must be supported to some extent for the rule to fire with nontrivial strength, and the degree to which the premises jointly hold is computed by the iterated product. When $\Gamma = \{\varphi_1, \ldots, \varphi_k\}$, the expression $\bigotimes_{\varphi \in \Gamma} \beta(\varphi)$ is shorthand for $\beta(\varphi_1) \otimes \cdots \otimes \beta(\varphi_k)$; the finiteness of Γ ensures this is well-defined without additional limiting assumptions. In the special case $\Gamma = \emptyset$, the iterated product is understood as the $\otimes$-unit, so an "axiom rule" $(\emptyset, \psi, \lambda_r)$ contributes λ_r directly to ψ.

Remark 1102 (Intuition and examples)**.** *This definition formalizes inference as "strength flows through a rule." The premises Γ are a finite subset of claims; ψ is the claim supported by the rule; and λ_r is the intrinsic reliability (or methodological authority) of the inference pattern. The iterated product $\bigotimes_{\varphi \in \Gamma} \beta(\varphi)$ composes the evidence values for all premises, and then $\lambda_r \otimes (\cdots)$ scales that combined support by the rule strength.*

Example: a probabilistic-logic-inspired rule "from φ infer ψ" might use a large λ_r if it is a trusted implication, while a heuristic analogy rule might use a smaller λ_r. The usefulness is that all inference becomes a special case of the same algebra used for composing patterns and influences elsewhere: rules are patterns with weights, and applying a rule is pattern-composition [5, 3].

A further point is that λ_r can be used to encode more than "truth-preservation." It may reflect experimental reproducibility, the historical reliability of an instrument, the domain-of-applicability of an approximation, or even a social/organizational trust score. Because $\mathbb{V}$ is paraconsistent, the framework does not require that high support for ψ forces low support for $\neg\psi$; rather, it records how multiple strands of reasoning contribute (possibly in tension) to the evolving state. Thus, the notion of "rule strength" is closer to evidential warrant than to a classical entailment guarantee.

Definition 303 (One-step inference operator)**.** *Let $\mathcal{R}$ be a set of weighted inference rules. Define $F_{\mathcal{R}} : \mathbb{V}^{\mathcal{L}} \to \mathbb{V}^{\mathcal{L}}$ by*

$$F_{\mathcal{R}}(\beta)(\psi) := \beta(\psi) \oplus \bigoplus_{(\Gamma,\chi,\lambda)\in\mathcal{R}:\ \chi=\psi} \Big(\lambda \otimes \bigotimes_{\varphi\in\Gamma} \beta(\varphi)\Big).$$

By construction, $F_{\mathcal{R}}$ performs a form of weighted forward chaining: each rule computes a candidate increment for its conclusion, and then all such increments are aggregated by $\oplus$. The definition allows $\mathcal{R}$ to be large (even infinite) as long as the relevant joins exist in $\mathbb{V}$; this is exactly where the completeness assumptions on the quantale become operationally meaningful.

Remark 1103 (Notation unpacking and intuition)**.** *Here $\mathbb{V}^{\mathcal{L}}$ denotes the set of all belief states (all functions $\mathcal{L} \to \mathbb{V}$). For each conclusion $\psi \in \mathcal{L}$, the operator $F_{\mathcal{R}}$ keeps the current evidence $\beta(\psi)$ and joins it (via $\oplus$) with the evidence contributed by* every *rule whose conclusion is ψ. The symbol $\bigoplus$ denotes iterated join over that (possibly finite) set of rules.*

Intuitively: one inference step means "apply all rules once in parallel and add their conclusions to what you already believe." This is a deliberately extensional view of inference, compatible with different internal implementations (symbolic proof search, neural approximations, probabilistic programming), so long as their net effect can be summarized as evidence aggregation.

Two additional structural properties are worth keeping in mind when interpreting $F_{\mathcal{R}}$. First, it is *inflationary* (or extensive): for all β and ψ one has $\beta(\psi) \leq F_{\mathcal{R}}(\beta)(\psi)$ because $F_{\mathcal{R}}(\beta)(\psi)$ is defined as $\beta(\psi) \oplus (\cdots)$. This matches the intended reading that one-step inference accumulates consequences rather than retracting beliefs. Second, because different rules for the same conclusion are combined by $\oplus$, the operator treats rules as independent sources of support whose effects are merged in a commutative, associative way (as governed by the join structure of the quantale). In practice, this "all-at-once" aggregation is a semantic idealization; algorithmically one may schedule rules in any order, and the theorem below justifies that repeated application still converges to an appropriate closure under mild conditions.

Theorem 18 (Existence of inference closure)**.** *The operator $F_{\mathcal{R}}$ is monotone on the complete lattice $\mathbb{V}^{\mathcal{L}}$. Hence it has a least fixed point above any initial state β_0, given by*

$$\mathrm{Cl}_{\mathcal{R}}(\beta_0) := \bigoplus_{n \geq 0} F_{\mathcal{R}}^{n}(\beta_0),$$

where F^0 is the identity and $F^{n+1} = F \circ F^n$. If, additionally, all values that can arise belong to a finite subquantale $W \subseteq \mathbb{V}$ (e.g. a finite rational grid closed under $\oplus$ and $\otimes$), then for finite $\mathcal{L}$ the ascending chain stabilizes after finitely many steps.

The expression "least fixed point above β_0" should be read as: among all belief states $\beta \in \mathbb{V}^{\mathcal{L}}$ such that $\beta_0 \leq \beta$ and $F_{\mathcal{R}}(\beta) = \beta$, there is a smallest one in the pointwise order. This is the natural notion of closure for an accumulating (inflationary) inference step: closure must preserve the initial evidence and must be stable under further rule application. In settings where $\mathcal{L}$ or the effective range of β is finite (as in the theorem's second clause), the iterative characterization as a finite-stage saturation is especially literal: one can view $F_{\mathcal{R}}^{n}(\beta_0)$ as "beliefs derivable in at most n rounds," and the stabilization index N as a bound on the depth of rule-chaining needed to reach closure.

Remark 1104 (What the theorem is saying, in plain language)**.** *The theorem asserts that if one repeatedly applies the one-step inference operator $F_{\mathcal{R}}$—adding in all consequences, then consequences of consequences, and so on—this process has a well-defined "limit" belief state: the least state that contains the initial evidence and is closed under the rules. Mathematically, it is the least fixed point of $F_{\mathcal{R}}$ above β_0.*

This result is important because it guarantees that "run inference to closure" is not merely a metaphor but a legitimate construction in the paraconsistent quantale setting. It connects the epistemic layer to the document's broader use of fixed-point constructions for stability and self-consistency (compare Knaster–Tarski usage in other contexts, e.g. [10]). It also complements the earlier weakness-based view: closure is one way of operationalizing how indirect beliefs generate direct beliefs through repeated pattern application [5].

An additional intuition is that $\mathrm{Cl}_{\mathcal{R}}(\beta_0)$ is the smallest "saturated" belief state compatible with the rules, analogous to the least Herbrand model in logic programming, but with truth values in $\mathbb{V}$ rather than $\{0,1\}$. Because joins aggregate rather than choose, closure can be seen as a conservative way to incorporate *all* derivable support without committing to a single proof path. This is especially relevant in paraconsistent settings: if there are rules deriving both ψ and $\neg\psi$, closure records both streams of support, instead of forcing explosion or global inconsistency.

Proof. Monotonicity: $\oplus$ and $\otimes$ are monotone in each argument (componentwise on $[0,1]^2$). Therefore each $\mathrm{contrib}_r(\beta)$ is monotone in β, and the join over rules preserves monotonicity, so $F_{\mathcal{R}}$ is monotone.

The poset $\mathbb{V}^{\mathcal{L}}$ is a complete lattice under pointwise order, so by Knaster–Tarski, $F_{\mathcal{R}}$ has fixed points and the least fixed point above β_0 is the join of the iterates. For the finiteness claim, assume $\mathcal{L}$ is finite and values are restricted to a finite subquantale $W \subseteq \mathbb{V}$. Then $W^{\mathcal{L}}$ is a finite poset, and the ascending chain $\beta_0 \le F_{\mathcal{R}}(\beta_0) \le F_{\mathcal{R}}^2(\beta_0) \le \cdots$ cannot strictly increase forever. Hence it stabilizes at some finite stage N, yielding a fixed point. $\square$

It is also worth observing that the chain displayed in the proof is ascending not only because $F_{\mathcal{R}}$ is monotone, but because $F_{\mathcal{R}}$ is inflationary: $\beta \le F_{\mathcal{R}}(\beta)$ holds pointwise by definition. Thus the iterative process never loses evidence already present in β_0; it only accumulates additional support as rules fire on newly strengthened premises. In computational terms, when $\mathcal{L}$ and the effective value set are finite, one can implement closure as a standard saturation loop: repeatedly update β by $F_{\mathcal{R}}(\beta)$ until no coordinate changes.

Remark 1105 (Proof sketch and intuition)**.** Proof sketch. *The strategy is standard: show $F_{\mathcal{R}}$ is order-preserving, then invoke the fixed-point theorem for monotone maps on complete lattices. In the present setting, the relevant complete lattice is the space of valuations $\beta\colon \mathcal{L} \to [0,1]^2$ ordered pointwise by the product order on $[0,1]^2$, so that $\beta \le \beta'$ means $\beta(\varphi)^+ \le \beta'(\varphi)^+$ and $\beta(\varphi)^- \le \beta'(\varphi)^-$ for all $\varphi \in \mathcal{L}$. Joins in this lattice are computed componentwise (pointwise suprema), which is exactly what makes the iterative construction below well-behaved.*

The closure $\mathrm{Cl}_{\mathcal{R}}(\beta_0)$ is obtained by iterating $F_{\mathcal{R}}$ starting from β_0 and taking the join of all iterates; monotonicity ensures this is an ascending chain. Equivalently, one may view $\mathrm{Cl}_{\mathcal{R}}(\beta_0)$ as the least fixed point of $F_{\mathcal{R}}$ above β_0*: it is the smallest valuation extending the initial evidence that is stable under all rule applications. The usual fixed-point theorem guarantees existence of such fixed points and characterizes the least one as the join of the iterates (or, more abstractly, as the join of all post-fixed points above β_0).*

If the value domain and language are finite, the ascending chain must stabilize in finitely many steps. More concretely, finiteness implies there are only finitely many distinct valuations reachable by repeatedly applying $F_{\mathcal{R}}$ starting from β_0, and since each step can only increase evidence in the product order, no valuation can repeat without having stabilized; hence convergence occurs after at most that finite number of strict increases. (When the domain is infinite, the same monotone-iteration construction still makes sense, but the stabilization may require a limit stage and is then captured by taking the supremum of the chain.) $\square$

The key step is that $\oplus$ and $\otimes$ are monotone componentwise on $[0,1]^2$; thus any expression built from them by composition and joins is monotone. Here "componentwise monotone" means that increasing either the positive coordinate or the negative coordinate of any input cannot decrease the corresponding coordinate of the output, so rule-aggregation never retracts previously accumulated support. Since the rule operator $F_{\mathcal{R}}$ is assembled from these primitives by applying them pointwise across $\mathcal{L}$ (and then taking joins over applicable rules), the order-preservation of $F_{\mathcal{R}}$ follows by straightforward structural induction on the way rule conclusions are computed.

Geometrically, one may imagine each claim $\varphi \in \mathcal{L}$ carrying a point in the unit square (the (β^+, β^-) plane), and an inference step moving these points "upward" in the product order (never decreasing either component). The pointwise nature of the order is important: different formulas may move at different rates, and closure is reached only when every *formula has become stable under further applications of the rules. In particular, the "upward" motion is not along a single axis but in a partial order, so there can be incomparable intermediate states; nevertheless, the iteration from β_0 produces a chain because each iterate is obtained from the previous one by a uniform application of the same monotone operator.*

Closure is then the least stable configuration under repeated application of these monotone transformations: a fixed point reached by taking the supremum of all successive improvements. This least fixed point represents the minimal amount of evidence that must be assigned, given β_0 and $\mathcal{R}$, to satisfy the closure condition "all rule conclusions are already accounted for." In this sense, $\mathrm{Cl}_{\mathcal{R}}(\beta_0)$ functions as a weighted analogue of deductive closure: it is not merely a set of consequences, but a saturation of the initial valuation by all rule-supported increases in (β^+, β^-).

Remark 1106 (Non-explosion by design)**.** *The scheme above does not include any special rule of the form "from φ and $\neg\varphi$ conclude anything." Thus inconsistency does not automatically produce arbitrary conclusions: a claim receives evidence only if there is a rule path that contributes to it. This is the minimal operational sense in which the framework is* paraconsistent*. Put differently, even if both φ and $\neg\varphi$ carry high positive evidence, this fact by itself does not act as a universal trigger; only explicitly provided rules can propagate information from those premises to further conclusions. One may still choose to include rules whose premises mention both φ and $\neg\varphi$ (for example, to model specific forms of diagnostic reasoning), but any such propagation is then local, controlled, and weight-sensitive rather than automatic and unbounded.*

Remark 1107. *This remark highlights a design choice: paraconsistency is not an add-on but a consequence of what is* omitted*. In particular, since inference is mediated by explicit weighted rules, contradictions can persist locally without turning the entire lattice of beliefs into maximal evidence everywhere. The absence of explosion means that the closure operator does not collapse all formulas to a top element merely because some formula has both kinds of support; instead, the fixed-point computation preserves the distinction between "having conflicting evidence about φ" and "having evidence for an unrelated ψ." This aligns with the paraconsistent motivations developed in [23, 24]. It also clarifies how inconsistency interacts with graded evidence: tension between β^+ and β^- for a given claim is represented explicitly in the valuation, and closure propagates only what the rule base $\mathcal{R}$ licenses, thereby preventing a single inconsistency from saturating the entire language unless the rules themselves encode such saturation.*

20.6 Question networks and the dynamics of thinking

Hyperseed allows question networks whose answers are further questions, potentially without a well-founded base. We model this as a directed graph (or category) of question dependencies. In this framing, the "shape" of an inquiry matters: two agents may share the same local inference rules yet differ radically in what they can reach because their networks present different routes for evidence to enter and propagate.

Definition 304 (Question network)**.** *A* question network *is a directed graph $\mathsf{Q} = (V, E)$ where nodes $v \in V$ are questions and an edge $v \to w$ means "answering v requires (or strongly benefits from) answering w." Cycles are permitted.*

It is useful to keep in mind that the edge label "requires (or strongly benefits from)" can cover multiple epistemic relations. For instance, $v \to w$ may mean (i) w supplies a missing variable needed to even state a candidate answer to v, (ii) w supplies calibration/validation needed to treat v's data as trustworthy, or (iii) w supplies a model-selection choice without which v is ill-posed. In practice, one can regard the graph as a compressed summary of a richer structure (e.g., typed questions, dependence modalities, or weighted edges expressing how strong the benefit is), but the directed graph already captures the core phenomenon: the nontrivial ordering constraints induced by epistemic dependency.

Remark 1108 (Intuition and examples)**.** *A question network is an explicit representation of the structure of inquiry. Edges express epistemic dependency: to answer one question, you may need answers to others (or at least to reduce them sufficiently). Permitting cycles is essential: real inquiry often involves mutually supporting questions, like "what counts as a reliable instrument?" depending on "what theory of measurement do we accept?" and vice versa. This is the formal shadow of a familiar philosophical fact: inquiry is not always well-founded on indubitable primitives; it is often stabilized by a coherent web.*

Example: in a research program, one node may be "estimate parameter θ," another "validate the measurement protocol," another "choose a model class," and dependencies may loop. In the Hyperseed core-concept set this corresponds directly to Question Networks (Hyperseed-Concept 145) and also to Dependency (Hyperseed-Concept 93).

A further perspective is graph-theoretic: the strongly connected components (SCCs) of Q identify clusters of questions that mutually depend on one another. In a well-founded tree-like inquiry, SCCs are trivial; in realistic inquiry, SCCs often correspond to methodological "packages" (measurement standards, modeling assumptions, interpretive norms) that are revised together. This helps separate two issues: (i) what is locally answerable given current methods, and (ii) what is globally stabilized by coherence constraints across a loop.

One may also read the parenthetical "(or category)" literally. If we interpret each edge $v \to w$ as a generating morphism $v \to w$, then composites correspond to indirect dependence paths: if answering v benefits from w and w benefits from u, then there is a composite dependence of v on u. On this view, reachability in the underlying graph expresses the transitive closure of "benefits from," and SCCs correspond to objects mutually connected by morphisms in both directions. Nothing in what follows requires category theory, but the categorical reading aligns with the idea that inquiry is a process of composing partial reductions rather than merely accumulating facts.

Definition 305 (Thinking as controlled closure)**.** *Fix a question network Q, a belief state β, and an inference rule set $\mathcal{R}$. A* thinking episode *is a finite sequence of operations of the form:*

(a) choose a question node v (possibly based on goals/values and attention);

(b) obtain data via the question's experiment channel, producing an evidence increment e_v;

(c) update beliefs (e.g. $\beta \leftarrow \beta \oplus e_v$) and propagate by closure $\beta \leftarrow \mathrm{Cl}_{\mathcal{R}}(\beta)$; and

(d) optionally entertain hypotheses to break cycles or explore counterfactual branches.

The finiteness of the episode is important as an idealization of bounded agency: even if $\mathrm{Cl}_{\mathcal{R}}$ is defined as a least fixed point of rule application, an actual agent typically approximates it under time/attention constraints, and the "controlled" part of the loop determines where approximation error accumulates. Thus, a thinking episode is not assumed to be complete inference, but rather a bounded sequence of actions that can be repeated and interleaved with further data collection.

It is also helpful to make explicit a minimal set of closure-operator intuitions that motivate $\mathrm{Cl}_{\mathcal{R}}$. In many logical and computational settings, closure operators are (at least approximately) extensive, monotone, and idempotent:

$$\beta \preceq \mathrm{Cl}_{\mathcal{R}}(\beta), \qquad \beta \preceq \beta' \Rightarrow \mathrm{Cl}_{\mathcal{R}}(\beta) \preceq \mathrm{Cl}_{\mathcal{R}}(\beta'), \qquad \mathrm{Cl}_{\mathcal{R}}(\mathrm{Cl}_{\mathcal{R}}(\beta)) = \mathrm{Cl}_{\mathcal{R}}(\beta),$$

where $\preceq$ is an information ordering ("contains no more commitments than"). Hyperseeds paraconsistent stance suggests that $\preceq$ should be read as an ordering of evidence or commitments that need not collapse under inconsistency, so "extensive" means "adds what the rules license" rather than "forces global consistency."

Remark 1109 (Intuition and connections)**.** *This definition casts thinking as a controlled alternation between* active inquiry *(choose and perform a question) and* passive propagation *(apply closure to distribute the consequences through the belief web). The "controlled" aspect is crucial: the system does not apply all questions, but selects them under constraints of attention and value (Sections 18 and 14), echoing the cognitive-synergy and resource-allocation motifs in [19].*

Conceptually: inquiry supplies new distinctions (new evidence increments e_v), and closure turns these into a revised global stance by pushing them through indirect beliefs (rules, trusted sources, schemas). Thus thinking is neither pure perception nor pure deduction; it is the iterative weaving together of questions and inference.

One can read step (a) as a *policy* over nodes: a mapping from the current epistemic/valuational state to a choice of which question to invest in next. This makes explicit why networks matter: two networks with the same set of nodes but different edge structure can lead the same policy to very different trajectories of belief change, because different dependencies alter which questions become bottlenecks. In scientific practice, this corresponds to the familiar dynamic where an entire research program can be stalled by a single unresolved methodological node (e.g., an instrument calibration or a missing dataset), even when many downstream theoretical questions are already articulated.

Step (b) also deserves a slightly richer reading: the "experiment channel" of a question need not be a physical experiment. It may be an observation procedure, a simulation, a database query, an expert consultation, or even an introspective probe, so long as it yields an evidence increment e_v that the agent treats as relevant to updating β. This makes the notion of question nodes compatible with both empirical and conceptual inquiry: some nodes are primarily settled by measurement, others by argument, and many by a mixture of both.

Remark 1110 (Bottoming out cyclic dependencies)**.** *If Q has cycles (non-well-founded "questions about questions"), then an agent can still operate by (i) choosing a cut set of hypotheses that temporarily resolves the cycle, (ii) exploring the induced consequences, and (iii) revising the hypotheses or the network itself. This is a natural reading of Hyperseed's remark that one can "force bottoming out" by entertaining a hypothesis.*

A useful way to see this operationally is to treat the chosen hypotheses as provisional "anchors" that permit local progress. For example, if "is the instrument reliable?" depends on "does the theory predict stable readings?" and that depends on "are the readings trustworthy?", then one can temporarily posit a calibration prior or a simplified theory to obtain provisional predictions, then use discrepancies to revise the anchors. In other words, the cycle is not eliminated in principle; rather, the agent chooses a temporary direction of fit to obtain traction.

Remark 1111. *The "cut set" intuition is graph-theoretic: one chooses a set of nodes whose provisional assignment breaks the cycle, analogous to choosing boundary conditions for a differential* *equation. The paraconsistent mechanism makes this psychologically plausible: entertaining a hypothesis need not annihilate contrary evidence; it simply injects additional evidence that can later be retracted (or counterbalanced) without global collapse.*

In graph terms, the cut set can be compared to a feedback vertex set: removing (or temporarily "pinning") those nodes makes the remaining dependency structure acyclic, enabling a staged evaluation from upstream to downstream. In epistemic terms, the pinned nodes function like methodological stipulations or default assumptions, which can later be relaxed. This also clarifies why paraconsistency is not merely a technical convenience: if hypotheses can be introduced and later revised without forcing explosive inference, then the agent can explore multiple competing "boundary conditions" in parallel, retaining incompatible lines of investigation long enough to see which ones pay off.

Finally, the possibility of revising "the network itself" is not an afterthought: inquiry often changes what counts as a question, what counts as an experiment channel, and what counts as an acceptable dependency. For instance, learning that a measurement process is systematically biased can introduce a new node ("estimate bias parameters") and rewire edges so that previously "downstream" theoretical nodes now depend on bias correction. Thus, the dynamics of thinking are not only dynamics on β but also dynamics on Q and on the effective rule set $\mathcal{R}$ that governs closure.

20.7 Belief systems and productive belief systems

Hyperseed defines a belief system as a coherent network of beliefs held within a community of minds, with a characteristic "mutual implication" property. We capture this by combining (i) community aggregation, (ii) inference closure, and (iii) a complexity-sensitive notion of "surprising strength." In this subsection, "belief" is treated as a graded semantic attitude toward sentences of a shared language $\mathcal{L}$, and a "system" is not merely a set but a pattern of mutual evidential support as mediated by an explicit rule set $\mathcal{R}$.

Definition 306 (Community belief aggregation)**.** *Let M be a finite set of agents, each with a belief state $\beta_i : \mathcal{L} \to \mathbb{V}$. Define the* community aggregate *belief state by*

$$\beta_{\mathsf{M}}(\varphi) := \bigoplus_{i \in \mathsf{M}} w_i \otimes \beta_i(\varphi),$$

where weights $w_i \in \mathbb{V}$ model trust/authority/attention and the operations are those of the p-bit *quantale. In particular, $\otimes$ should be read as "evidence scaling" (how much an agent's attitude counts after weighting), while $\bigoplus$ is the quantale join that pools the contributions into a single community-level valuation.*

Remark 1112 (Intuition and examples)**.** *This is a minimal formalization of intersubjective knowledge: we take individual belief states and combine them into a community stance by (i) scaling each agents contribution by a weight w_i and (ii) joining the results. If w_i is high (in positive evidence), agent i has more epistemic influence; if w_i has a negative component, one can even represent distrust or systematic adversariality in a graded way.*

Example: in a lab group, a senior experimentalist might have higher weight on measurement-related claims, while a theoretician might have higher weight on model-selection rules. The usefulness of this definition is that it makes social epistemology compositional: a community is not a mysterious supra-mind but an aggregation operator on individual minds' evidence valuations (Hyperseed-Concept **??** *and Hyperseed-Concept 170).*

Two further points are worth making explicit. First, the aggregation is performed pointwise in φ: the community may defer to different agents on different claims, depending on how $\beta_i(\varphi)$ interacts with w_i under $\otimes$. Second, the weights w_i need not be normalized in the probabilistic sense; rather, their meaning is fixed by the algebra of $\mathbb{V}$ and by the intended operational semantics (e.g. "whose judgment is heeded" vs. "how much independent evidence is added"). This leaves room for modeling phenomena such as epistemic division of labor, institutional gatekeeping, and domains of recognized expertise within a single uniform operator.

Definition 307 (Coherence score)**.** *Fix β and a rule set $\mathcal{R}$. For $\varphi \in \mathcal{L}$ define the "leave-one-out" state*

$$\beta^{\setminus\varphi} := \text{the state equal to } \beta \text{ except with the value at } \varphi \text{ replaced by } (0,0).$$

Define the coherence score *of B (relative to β and $\mathcal{R}$) as*

$$\mathrm{Coh}_{\mathcal{R}}(B;\beta) := \frac{1}{|B|}\sum_{\varphi\in B}\pi\big(\mathrm{Cl}_{\mathcal{R}}(\beta^{\setminus\varphi})(\varphi)\big),$$

where $\pi(p,q) = (1+p-q)/2$ is the plausibility projection (cf. Section 14). When B is understood from context, $\mathrm{Coh}_{\mathcal{R}}(B;\beta)$ can be read as a single-number summary of how "self-explanatory" the set B is under the inferential practices encoded by $\mathcal{R}$.

Remark 1113 (Notation unpacking and intuition)**.** *The leave-one-out state $\beta^{\setminus\varphi}$ deletes the community's direct evidence for φ by setting it to $(0,0)$ while keeping all other claims unchanged. Then $\mathrm{Cl}_{\mathcal{R}}(\beta^{\setminus\varphi})(\varphi)$ asks:* how much support for φ can be reconstructed from the rest of the belief web, via inference rules? *Finally, $\pi(p,q) = (1+p-q)/2$ collapses a* p-bit *into a single plausibility scalar, increasing with positive evidence p and decreasing with negative evidence q.*

Thus $\mathrm{Coh}_{\mathcal{R}}(B;\beta)$ measures, on average over $\varphi \in B$, how well each belief is supported by the others*. This makes "mutual implication" precise without demanding classical consistency: coherence is about reconstructability under closure, not about absence of conflict.*

Operationally, this is a counterfactual test: if we "blank out" the community's explicit stance on φ while leaving its other stances intact, does the remaining web (together with $\mathcal{R}$) recover φ anyway? A belief set with high coherence is therefore one in which many beliefs are not epistemically isolated; they are downstream of shared principles, background assumptions, or explanatory constraints captured by the closure operator. Conversely, if many $\varphi \in B$ cannot be reconstructed once removed, then B behaves more like a mere list of stipulations than an integrated system.

Note that averaging over $\varphi \in B$ makes coherence sensitive to the "typical" member of the set, rather than to a single highly implied cornerstone claim; one can also consider variants such as a minimum-over-φ (worst-case) coherence or a distributional profile of the individual summands, but the mean is the simplest global proxy for networked support.

Remark 1114. Coh *is high when each belief in B is well supported by the others via the community's inference rules. This is a formalization of "on average, each belief is strongly implied by the other beliefs." Because we use $\pi \circ \mathrm{Cl}$, coherence is allowed to coexist with contradiction: a belief may be well supported and also well opposed.*

It is also worth emphasizing what coherence is not*. A high score does not imply that B is true, empirically adequate, or even stable under future evidence; it only indicates that, relative to $\mathcal{R}$ and β, the beliefs in B form an inferentially entangled cluster. This is one reason coherence is useful in a pluralistic setting: competing communities can each exhibit high internal coherence while disagreeing, and the framework can then ask additional questions (e.g. about predictive performance, causal control, or openness to revision) to distinguish productive belief systems from merely self-reinforcing ones.*

Definition 308 (Complexity cost and "surprise-adjusted" implication)**.** *Let* $\mathrm{Comp} : \mathcal{L} \to [0, \infty)$ *be a complexity cost (e.g. description length, or an order reversal of weakness). Fix* $\lambda > 0$ *and define a simplicity-biased prior weight*

$$\mathrm{Prior}(\varphi) := e^{-\lambda\,\mathrm{Comp}(\varphi)}.$$

For $\varphi \in \mathcal{L}$ *define the* surprise-adjusted implication score

$$\mathrm{SAI}(\varphi; \beta, \mathcal{R}) := \frac{\pi\big(\mathrm{Cl}_{\mathcal{R}}(\beta^{\setminus\varphi})(\varphi)\big)}{\mathrm{Prior}(\varphi)}.$$

Remark 1115 (Intuition, and relation to simplicity/weakness)**.** *The complexity cost* $\mathrm{Comp}(\varphi)$ *quantifies how "expensive" a claim is to represent or to search for: it could be a description length in the sense of algorithmic information theory [16], or a transformation of weakness/effort as developed earlier [3]. The parameter* $\lambda > 0$ *controls how strongly the community prefers simplicity.*

The score SAI *then formalizes a familiar epistemic phenomenon: a complex statement, if strongly implied by the rest of what we accept, is more noteworthy than a simple one. Dividing by* $\mathrm{Prior}(\varphi)$ *ensures that a claim with low prior weight must be especially well supported by the network to achieve a high* SAI*. In Hyperseed-concept terms, this is the interaction of Simplicity (Hyperseed-Concept 169), Weakness (Hyperseed-Concept 202), and Uncertainty (Hyperseed-Concept 195).*

Interpreting SAI *as a "productivity"-leaning signal is natural: the numerator rewards inferential integration (via closure), while the denominator penalizes gratuitous complexity. Thus, when two claims are equally implied by the rest of the system, the one with smaller* $\mathrm{Comp}(\varphi)$ *is treated as less epistemically surprising; conversely, a high-complexity claim must earn its keep by being tightly constrained by the rest of the web. The exponential form of* Prior *is convenient because it turns additive complexity into multiplicative penalties; however, the framework is compatible with other monotone decreasing mappings from complexity to prior weight if a different calibration is desired.*

Remark 1116 (Matching the Hyperseed phrasing)**.** *Hyperseed describes a belief as something "held true to a degree that is surprising given the complexity of the belief." The prior* $\mathrm{Prior}(\varphi)$ *makes complex claims a-priori unlikely. A large* SAI *means the community implies* φ *strongly despite its low prior.*

Equivalently, SAI *distinguishes between "easy" implications (those that follow from many simple, high-prior patterns) and "hard" implications (those that emerge as nontrivial consequences of the system). In this sense,* SAI *operationalizes the idea that an integrated belief system is not merely a heap of assertions: it can generate relatively unexpected consequences, and those consequences can be ranked by how much inferential pressure the rest of the system exerts on them relative to their complexity.*

Definition 309 (Belief system and productive belief system)**.** *A* belief system *(for a community* M*) is a pair* $(B, \mathcal{R})$ *where* $B \subseteq \mathcal{L}$ *is a focal belief set and* $\mathcal{R}$ *is a rule set, such that* $\mathrm{Coh}_{\mathcal{R}}(B; \beta_{\mathsf{M}})$ *exceeds a chosen threshold. Here "focal" is meant to emphasize that* B *is not the entire doxastic state of* M*, but a distinguished subfamily of commitments that are tracked as a unit (e.g. a theory, paradigm, doctrine, platform, or research program) and whose internal relations are evaluated using* $\mathcal{R}$*. Likewise,* $\mathcal{R}$ *is not only a list of inference schemata, but can also encode allowed explanatory moves, defeasible reasoning patterns, methodological norms, and admissible forms of updating; it is part of what makes* B *into a system rather than a mere set. The threshold requirement is intended to exclude arbitrarily assembled collections of propositions: a community may hold many beliefs, but only some coherent sub-webs are stable enough to function as objects of collective inquiry, pedagogy, and transmission.*

A belief system is productive *if, in addition:*

(a) (Individuation) there exists a "core" subset $B_{\text{core}} \subseteq B$ *that remains stable under typical evidence updates (high persistence of key commitments), and*

*(b) (Self-transcendence) the system regularly generates new high-*SAI *beliefs or new questions whose answers lead to novel patterns, without collapsing coherence.*

The two additional clauses should be read as constraints on the dynamics *of the pair* $(B, \mathcal{R})$ *as the community encounters new data, arguments, and social pressures. In particular, "typical evidence updates" can be understood as those updates that occur with non-negligible frequency in the epistemic environment of* M *(the ordinary course of observation, experiment, testimony, and criticism); the individuation requirement then says that some subset functions as a robust identity condition for the system across such ordinary perturbations. Similarly, the "without collapsing coherence" proviso rules out a degenerate kind of novelty in which the system generates ever more claims only by loosening* $\mathcal{R}$ *or fragmenting* B *so that* $\mathrm{Coh}_{\mathcal{R}}(B; \beta_{\mathsf{M}})$ *no longer remains above threshold.*

Remark 1117 (Intuition and why "productive" needs two constraints)**.** *A belief system is, on this definition, a coherent epistemic sub-web in a community (Hyperseed-Concept 64). But a merely coherent web can be sterile: it might resist novelty so strongly that it never learns, or it might be so plastic that it dissolves under every perturbation. The definition of "productive" therefore combines two tensions that recur throughout Hyperseed:* individuation *(a stable identity across time) and* self-transcendence *(ongoing creation of new structure).*

The individuation clause says there is a persistent core (Hyperseed-Concept **??***) that survives ordinary evidence fluctuations. One way to think of* B_{core} *is as the subset of commitments that play a high-"load-bearing" role in the community's reasoning: they constrain many other beliefs, are invoked across many contexts, and are not easily abandoned without a substantial reconfiguration of* B*. This does not require infallibility; it requires that, at the time-scale of ordinary inquiry, the system has enough internal continuity to accumulate results, train newcomers, and coordinate collective action. Conversely, if* no *such* B_{core} *exists, then the "system" behaves more like a shifting coalition of claims than a persisting object, and it becomes difficult to interpret its apparent successes (or failures) as attributable to anything stable.*

The self-transcendence clause says inquiry continues to generate surprising, complexity-defying implications (Hyperseed-Concept 167) and new Questions (Hyperseed-Concept 144) leading to Emergence (Hyperseed-Concept **??***). Here "generates" is meant in the constructive sense: the system, by applying* $\mathcal{R}$ *to* B *and to incoming evidence, yields new commitments, conjectures, models, predictions, or problem-statements that were not trivially present at the outset. The reference to high-*SAI *is intended to separate mere proliferation of claims from epistemically meaningful novelty: a productive system does not simply add ad hoc patches, but tends to add beliefs (or questions) that integrate with and reorganize the web in a way that increases understanding, explanatory reach, or compressive power while still maintaining coherence. In philosophical terms, one might hear an echo of process views in which stability is a maintained pattern rather than a static substance [15]. In the intended application to science, the pair of constraints approximates a familiar phenomenon: research traditions preserve enough continuity to be identifiable across time, yet are also compelled to generate new results, new measurement regimes, and new conceptual distinctions in response to anomalies and opportunities.*

A useful way to see why both constraints are needed is to consider two failure modes. If a system has individuation without self-transcendence, it may become a well-defended "museum" of doctrine: highly coherent and highly stable, but systematically unresponsive to the kinds of questions that would extend or revise it. If a system has self-transcendence without individuation, it may behave like a perpetual brainstorming session: many novel outputs, but little cumulative structure, making *it hard to distinguish progress from drift. The productive regime is the narrow corridor in which novelty is* assimilated *rather than merely* accumulated *or* repelled*.*

Remark 1118. *The individuation/self-transcendence pair mirrors Hyperseed's use of those terms in other contexts. The present definition is intentionally schematic; later sections can specialize "typical evidence" and "regularly generates" to concrete learning dynamics and novelty measures. In particular, one can operationalize "typical evidence" by specifying a distribution over evidence-events relevant to* M *(experiments, observations, counterarguments, replications, testimony streams), and then measuring persistence of candidate cores under the corresponding update rule. Likewise, "regularly generates" can be rendered as a rate condition (e.g. expected production of high-*SAI *outputs per unit time, per unit research effort, or per cycle of deliberation), together with a constraint that* $\mathrm{Coh}_{\mathcal{R}}(B;\beta_{\mathsf{M}})$ *does not fall below threshold after incorporation. On this reading, productivity becomes a property that can in principle be compared across communities or across historical phases of a single community: the same belief system may be productive during one era (when it opens fertile question-spaces) and less productive in another (when it mainly stabilizes and defends its inherited core).*

It is also worth noting that the definition does not presuppose that productive systems are always "true" in any final sense; rather, it characterizes a kind of epistemic fitness *for generating structured, coherent novelty. This allows the framework to distinguish (i) coherent but stagnant systems, (ii) inventive but unstable systems, and (iii) systems that exhibit cumulative inquiry. In later applications, one can ask which additional constraints (e.g. calibration to external feedback, robustness across subcommunities, or sensitivity to adversarial testing) connect productivity more tightly to truth-tracking or scientific reliability.*

20.8 Science as empirically coupled belief-system dynamics

Hyperseed defines science as a community belief system that generates predictive and causal models about observation sets accepted broadly by members of the community. We model this as a special case of the thinking loop where questions are experiments and answers are shared observations. This framing makes explicit that "scientific knowledge" is not a single agent's internal state but a coupled multi-agent process: the community stabilizes a repertoire of experimental questions, a shared interface for what counts as an answer, and a rule-governed method for turning those answers into durable belief updates. In particular, the "predictive and causal" emphasis is meant to distinguish scientific models from purely interpretive narratives: the central outputs of the belief system are claims that constrain what should be observed under specified conditions, and (when available) how observations would change under interventions.

Definition 310 (Observation set)**.** *Fix a community* M *and a context class of experiments* E*. An* observation set *is a set* O *together with an observation map*

$$\mathsf{Obs} : E \to \mathsf{O},$$

possibly stochastic and observer-indexed. An observation set is accepted broadly *by* M *if, for a large fraction of agents and a large fraction of eligible experiments, the induced observations are mutually consistent up to the community's tolerance thresholds. The phrase "context class of experiments" is intended to include not only the abstract experimental design but also the admissible range of protocols, instrument configurations, and background conditions that the community treats as "the same kind" of experiment for purposes of comparison. Likewise, "tolerance thresholds" should be read as including both quantitative tolerances (e.g., error bars, confidence intervals, calibration* *margins) and qualitative tolerances (e.g., coding reliability or procedural compliance in observational sciences).*

Remark 1119 (Intuition and examples). *An observation set is a formalization of what a community can "jointly see". The map* $\mathsf{Obs} : E \to \mathsf{O}$ *abstracts the full measurement pipeline into an input-output channel: an experiment* $e \in E$ *yields an observation in* O*, perhaps with stochasticity due to noise, differing instruments, or contextual effects. Broad acceptance is not metaphysical certainty; it is a social-epistemic stability condition: most relevant observers running the relevant protocols obtain compatible outcomes. Put differently,* Obs *is not assumed to be infallible, but it is assumed to be sufficiently well-behaved (under the community's standards) that disagreement is attributable to identifiable sources such as sampling variability, instrument drift, experimenter degrees of freedom, or genuine context sensitivity, rather than to arbitrary observer idiosyncrasy. The "observer-indexed" allowance captures cases where the observation pipeline includes human judgment (e.g., labeling, clinical assessment, ethnographic interpretation) while still permitting intersubjective convergence through training, rubrics, and reliability checks.*

Example: in physics, E *could be a class of experimental setups and* O *numerical readouts. In psychology,* O *might be survey responses or behavioral measures. In biology,* O *could be sequencing reads or microscopy counts; in astronomy,* O *could be processed spectra; in economics,* O *could be aggregated indicators computed from raw data. This makes explicit the dependence of "empirical truth" on intersubjective agreement and protocol, linking to Logical/Empirical Truth (Hyperseed-Concept 104) and Intersubjective Reality (Hyperseed-Concept* **??***), and aligning with social-computational accounts of science [20]. The point is not to reduce truth to consensus, but to specify the operational substrate by which a community can treat some claims as empirically constrained: without broadly accepted observation sets, "evidence" cannot enter the communal belief dynamics in a stable, reproducible way.*

Definition 311 (Scientific model class and predictive claims). *A* scientific model class *is a set* $\mathcal{M}$ *of candidate models. Each model* $m \in \mathcal{M}$ *induces:*

- *a family of predictive claims* $\mathrm{Pred}_m(e)$ *about observations* $\mathsf{Obs}(e)$*, and*
- *optionally a family of causal claims* Cause_m *about how interventions change predictions.*

The community treats these as elements of the claim language $\mathcal{L}$*. Here "predictive claims" should be read broadly to include point predictions, distributional predictions (e.g., likelihoods over* O*), conditional predictions given auxiliary variables, and robust qualitative constraints (e.g., monotonicity, invariances, sign predictions). Similarly, "causal claims" range from fully specified structural equations to weaker claims about directionality or invariance under a class of interventions; the definition leaves room for multiple grades of causal expressiveness within* $\mathcal{L}$*.*

Remark 1120 (Intuition and connection to earlier machinery). *A model class* $\mathcal{M}$ *is the space of representational hypotheses the community is willing to consider. The induced claims* $\mathrm{Pred}_m(e)$ *and* Cause_m *are then just ordinary claims in* $\mathcal{L}$*, so they can receive* p-bit *evidence and participate in closure with the same rule machinery as any other belief. This makes model comparison and theory choice instances of general belief management: models do not sit outside the belief state but are represented through the claims they entail and the support they accumulate via the update mechanisms. In particular, competing models may share some induced claims while differing on others; closure then propagates evidence to all logically or methodologically connected claims, which is how localized experimental outcomes can have global effects on a theory network.*

This is important structurally: science is not a separate kind of reasoning; it is a particular configuration of question/answer dynamics where questions are experiments and answers are shared *observations. Causal claims connect directly to Section 14's intervention viewpoint, and the pluralistic model-class stance aligns with Hyperseed's broader engineering orientation toward families of methods rather than single privileged formalisms [19]. The explicit model-class framing also clarifies why scientific communities invest in tool-building: new instruments, new statistical methods, and new representational languages expand E, enrich O, and enlarge (or restructure) $\mathcal{M}$, thereby changing what questions can be asked and what answers can count as decisive.*

Definition 312 (Empirical update operator)**.** *Let $e \in E$ be an experiment and $o = \mathsf{Obs}(e)$ its (shared) observation. An* empirical evidence increment *is a map $\epsilon_{e,o} : \mathcal{L} \to \mathbb{V}$ that assigns positive/negative evidence to those predictive/causal claims that agree or disagree with (e, o). A scientific update step is*

$$\beta \leftarrow \mathrm{Cl}_{\mathcal{R}}\big(\beta \oplus \epsilon_{e,o}\big),$$

where $\mathcal{R}$ includes both domain rules and methodological rules (statistics, measurement models, etc.). The definition is intentionally agnostic about the internal structure of $\mathbb{V}$ and the operator $\oplus$: different scientific subcultures can implement "evidence addition" by log-likelihood accumulation, score-based updates, hypothesis-test-like penalties, or other evidential bookkeeping, so long as the result can be represented as a belief-state update followed by rule closure. The phrase "agree or disagree" should be interpreted through $\mathcal{R}$: agreement may mean a high probability assigned to o under $\mathrm{Pred}_m(e)$, or satisfaction of a qualitative constraint, or being within a prespecified tolerance band after correction for known measurement error.

Remark 1121 (Intuition: why this captures "empirical coupling")**.** *Empirical coupling is represented by the fact that observations enter as an evidence increment $\epsilon_{e,o}$, which is then integrated into the belief state and propagated by closure. The methodological rule set $\mathcal{R}$ is where the community encodes its indirect beliefs about how to translate raw observations into support for claims (measurement error models, statistical tests, calibration conventions, etc.). Thus the empirical loop is: act (choose e), observe (o), translate to evidence, then infer. This highlights that "data" are not self-interpreting: the same (e, o) can produce different $\epsilon_{e,o}$ under different methodological commitments (e.g., different priors, different preprocessing pipelines, different correction procedures), and scientific disagreement can therefore be located either in the observation interface* Obs *or in the rule system $\mathcal{R}$.*

In Hyperseed terms, this is a controlled flow from Answers (Hyperseed-Concept 56) into Beliefs (Hyperseed-Concept 65), guided by Indirect Beliefs and stabilized socially as a Belief System (Hyperseed-Concept 64). The "controlled" aspect is precisely what distinguishes scientific coupling from mere exposure to experience: the community engineers reproducible questions (standardized experiments), shareable answers (broadly accepted observation sets), and disciplined update rules (methodological norms) so that belief change is not arbitrarily sensitive to individual perspective.

Proposition 32 (Occam bias from simplicity-weighted priors)**.** *Fix $\lambda > 0$ and a complexity cost* $\mathrm{Comp} : \mathcal{M} \to [0, \infty)$*. Define* $\mathrm{Prior}(m) = e^{-\lambda\,\mathrm{Comp}(m)}$*. Suppose two models $m_1, m_2 \in \mathcal{M}$ receive equal empirical support in the sense that the community assigns equal plausibility to their predictive adequacy. If* $\mathrm{Comp}(m_1) < \mathrm{Comp}(m_2)$ *then* $\mathrm{Prior}(m_1) > \mathrm{Prior}(m_2)$*, so any posterior weight proportional to (support) $\times$ (prior) will prefer m_1.*

Remark 1122 (What the proposition is saying and why it matters)**.** *The proposition states a minimal Occam principle: if two models fit the data equally well, the simplicity-biased prior assigns higher weight to the simpler model, so any Bayesian-like update that multiplies support by prior will prefer it. Nothing subtle is being claimed about the world; the point is that* a preference for simplicity is already present in the choice of prior*. In practice,* Comp *can proxy for many different* *simplicity notions: description length, number of parameters, circuit size, degrees of freedom, or norm-based regularity; different choices encode different methodological values, and communities can (and do) argue about which complexity measure best captures "simplicity" for their domain. The proposition also clarifies a common interpretive confusion: the Occam effect here is not an extra rule tacked onto inference after seeing data, but a consequence of committing (in advance) to a simplicity-penalizing representation of model plausibility. From the belief-system viewpoint, such priors are part of the community's methodological rule set: they are indirect beliefs about which hypotheses are worth taking seriously before evidence arrives, and they influence how quickly a community converges or fragments when empirical support is ambiguous.*

Remark 1123. *This connects directly to the earlier weakness preference: if* Comp *is taken as a form of description length or weakness-derived effort, then scientific model selection becomes a special case of the general Hyperseed bias toward lower effort representations [3, 2]. It also resonates with classic algorithmic justifications of Occam-style priors [16]. In particular, when* $\mathrm{Comp}(m)$ *is identified (up to an additive constant) with a code length for describing* m*, the weight* $e^{-\lambda \mathrm{Comp}(m)}$ *can be read as a softness-controlled analogue of assigning higher prior mass to shorter descriptions;* λ *then calibrates how aggressively the agent trades empirical fit against representational economy.*

Proof. Immediate from monotonicity of the exponential: $\mathrm{Comp}(m_1) < \mathrm{Comp}(m_2)$ implies $-\lambda\,\mathrm{Comp}(m_1) > -\lambda\,\mathrm{Comp}(m_2)$, hence $e^{-\lambda\,\mathrm{Comp}(m_1)} > e^{-\lambda\,\mathrm{Comp}(m_2)}$. Equivalently, taking logs shows $\log w(m) = -\lambda\,\mathrm{Comp}(m)$ is strictly increasing as $\mathrm{Comp}(m)$ decreases, so the ordering of weights is exactly the reverse ordering of complexities. □

Remark 1124 (Proof sketch and intuition)**.** Proof sketch. *The proof is a one-line order argument: since* $x \mapsto e^{-\lambda x}$ *is strictly decreasing for* $\lambda > 0$*, smaller complexity yields larger prior weight. Then equal empirical support implies the posterior preference is determined by the prior. More explicitly, if two models* m_1, m_2 *have the same likelihood for the observed data* D*, i.e.* $p(D \mid m_1) = p(D \mid m_2)$*, then Bayes' rule gives*

$$\frac{p(m_1 \mid D)}{p(m_2 \mid D)} = \frac{p(D \mid m_1)}{p(D \mid m_2)} \cdot \frac{p(m_1)}{p(m_2)} = \frac{p(m_1)}{p(m_2)},$$

so any posterior preference comes solely from the prior ratio $p(m_1)/p(m_2) = e^{-\lambda(\mathrm{Comp}(m_1)-\mathrm{Comp}(m_2))}$*.*
□

Geometrically, one may view $\mathrm{Comp}(m)$ *as a coordinate measuring where a model lies along a "simplicity axis." The prior* $e^{-\lambda \mathrm{Comp}(m)}$ *is then a decaying density along that axis; the proposition just states that this density is higher at smaller coordinates. One can also view* λ *as setting the "length scale" along this axis: for large* λ *the density drops sharply (strong simplicity pressure), whereas for small* λ *it decays slowly (weak simplicity pressure), so that empirical likelihood differences must be correspondingly larger to override the simplicity bias.*

Remark 1125 (Hyperseed reading)**.** *This is the epistemic analogue of weakness preference: among models consistent with observations, prefer the weaker/simpler one. When combined with paraconsistent evidence handling, "anomalies" do not force immediate abandonment; they become negative evidence that can coexist with positive evidence until a better model emerges. In this reading, the exponential prior plays the role of a continuously valued "default conservatism": it rewards models that require fewer special-case commitments, fewer auxiliary hypotheses, or less representational machinery to maintain internal coherence with what has already been learned. Thus, scientific change is not modeled as a brittle, all-or-nothing refutation step, but as a gradual reweighting in which anomalies reduce support without necessarily driving the posterior to zero in the presence of coexisting, partially conflicting evidential constraints.*

Remark 1126 (Additional clarification: coupling to empirical adequacy)**.** *The above preference statement is most informative when made relative to empirical coupling. In standard Bayesian terms, model selection compares posteriors $p(m \mid D) \propto p(D \mid m)\, p(m)$, so that the simplicity term $p(m) \propto e^{-\lambda \mathrm{Comp}(m)}$ acts as a regularizer rather than a substitute for data fit. Accordingly, if m_2 fits the data substantially better than m_1, then a higher* $\mathrm{Comp}(m_2)$ *can be compensated by a sufficiently larger likelihood $p(D \mid m_2)$; the present proposition isolates the limiting case where the likelihoods are equal (or, more generally, when the Bayes factor is near* 1*), so that the complexity penalty becomes the deciding factor. On the "belief-system dynamics" interpretation, this corresponds to cases where multiple explanatory stories accommodate the same observational constraints, and the update rule resolves the tie by favoring the representation that is cheaper to maintain, communicate, and integrate with the agent's existing web of commitments.*

20.9 State-dependent science

Hyperseed proposes that some observation sets are accessible (and intersubjectively stabilizable) only when the community is in particular states of consciousness. We model this by indexing the observation channel by a state parameter. Concretely, the role of the state parameter is to treat "the observer" (and the social/ritual/technical context that sustains the observer) as part of the experimental apparatus: changing the sustained cognitive–affective–attentional configuration can change which distinctions can be enacted, and hence which experimental questions are even well-posed. This is not merely an appeal to private experience; it is an attempt to express, in the same formal slot as an instrument model, the idea that observer-training and observer-context can be constitutive of measurement.

Definition 313 (State-indexed observation)**.** *Let* S *be a set of community-accessible states (meditative, "I–Thou", oceanic, etc.). A* state-indexed observation set *consists of* O *and maps*

$$\mathsf{Obs}_s : E_s \to \mathsf{O}, \qquad s \in \mathsf{S},$$

where E_s is the set of experiments that are performable/meaningful in state s.

In this definition, E_s plays a logically important role: it allows that the relevant difference between states is not only that they yield different outcomes for the *same* experimental description, but that some experimental descriptions may fail to be executable, intelligible, or stablely interpretable outside a given state. Equivalently, the state index can change both the "domain" (what can be asked) and the "channel" (how answers are produced). One can also package the same idea as a single partial map $\mathsf{Obs} : \bigcup_{s \in \mathsf{S}} (\{s\} \times E_s) \to \mathsf{O}$ with $\mathsf{Obs}(s, e) = \mathsf{Obs}_s(e)$; the present notation simply emphasizes that the observation channel itself is conditioned on state.

Remark 1127 (Intuition and conceptual placement)**.** *The new ingredient is the index $s \in \mathsf{S}$: what counts as an admissible experiment E_s and what observations result via Obs_s may depend on the cognitive/affective/attentional state of the agents performing the protocol. This operationalizes the idea that certain distinctions may be* state-gated*: one must become a certain kind of observer to stably enact certain observational couplings.*

Examples range from mundane to speculative: altered attentional regimes can change perceptual discrimination thresholds; disciplined contemplative practices may yield reproducible reports within a trained community; more conjectural proposals (e.g. morphic resonance) would also, if made protocol-stable, fit this formal slot [13]. In the Hyperseed core-concept set, this subsection touches States of Consciousness (Hyperseed-Concept 178) and Oceanic Consciousness (Hyperseed-Concept 123), and it is consonant with state/location taxonomies for individuals and collectives [4, 12].

A practical reading is that the "state" variable is itself something a community can (to some degree) prepare, verify, and maintain. In the same way that many laboratory instruments require calibration and controlled environmental conditions, a state-dependent protocol may require training regimes, selection criteria, social norms, and environmental supports that keep the community within an operational envelope corresponding to s. This suggests separating three layers: (i) a *state-preparation* procedure (how s is reached), (ii) a *state-verification* procedure (how membership in s is checked or at least bounded), and (iii) the *in-state* experimental protocol $e \in E_s$ (what is done once in s). The formalism above directly models (iii) and implicitly absorbs (i)–(ii) into the background conditions defining the domain E_s and the effective channel Obs_s.

Definition 314 (State-dependent science)**.** *A* state-dependent science *is a family of belief-system dynamics* $(B_s, \mathcal{R}_s, \mathsf{Obs}_s)$ *indexed by* $s \in \mathsf{S}$*, such that within each state:*

- *observations are broadly accepted by the in-state community;*
- *predictive/causal models are updated by the empirical loop of Section 20.8; and*
- *the resulting beliefs are stable under small perturbations of protocols within that state.*

The phrase "belief-system dynamics" here is intended to be read in the same sense as earlier sections: B_s is the in-state belief-state (or set of admissible belief-states), $\mathcal{R}_s$ is the in-state revision/update dynamic, and Obs_s is the in-state observation channel. Nothing in the definition requires that the beliefs be *true* in a metaphysical sense; the requirement is that they be generated and maintained by an empirically coupled, self-correcting loop relative to the state-conditioned access channel. In particular, one can allow that $\mathcal{R}_s$ includes explicit procedures for handling disagreement, uncertainty, and inter-observer variability, provided these procedures themselves are part of the stable in-state practice.

Remark 1128 (Intuition and why this remains "science" in the formal sense)**.** *The definition says: for each s, there is a coherent, empirically coupled belief-system dynamic. Thus state-dependent science is not defined by abandoning empirical discipline, but by acknowledging a further contextual variable that affects what can be observed and how. From a process perspective, the observer is not an inert point but a temporally extended pattern of capacities; changing that pattern changes the observation channel [15].*

The stability-under-perturbation clause is the analogue of experimental robustness: within a given state s, small variations of protocol should not wildly change the observation map. This is what blocks the notion from degenerating into "anything goes" subjectivism: reproducibility is enforced, but only relative to the state-indexed context.

To make the robustness clause more concrete, one may think of perturbations as spanning (at least) (i) "technical" perturbations (minor differences in timing, phrasing, apparatus configuration), (ii) "social" perturbations (minor differences in group composition or facilitation), and (iii) "state" perturbations that remain within the tolerance region of s (e.g. small fluctuations in attention, affect, or absorption that do not constitute leaving s). The intent is not to demand zero variability, but to demand that the in-state observation channel have a stable core: outcomes cluster, calibration is possible, and error models can be learned. This is also the point at which standard concerns about expectancy effects and demand characteristics must be treated as first-class methodological issues: if such effects dominate, then the purported Obs_s is not stable in the required sense, or else the channel being measured is actually "suggestibility under protocol" rather than the target phenomenon.

Remark 1129 (Why this is not automatically "unscientific"'). *The formal difference from ordinary science is not the absence of empirical coupling, but the presence of an additional context variable* s*. If a community can reliably enter a state* s *and reproduce observation protocols within* s*, then* $(\mathsf{Obs}_s, \mathcal{R}_s)$ *can support a genuine (state-indexed) empirical discipline. Cross-state translation and public accessibility become separate questions, not prerequisites.*

Public accessibility can then be treated as a spectrum rather than a binary. Some states may be widely reachable with modest training, making the resulting discipline closer to ordinary science in sociological character; other states may require long training horizons or unusual life conditions, making the resulting discipline closer to an expert craft (but still potentially empirical within that expert community). In either case, the formalism invites a "meta-scientific" layer: communities can study which state-preparation procedures are reliable, what the failure modes are, how long it takes to stabilize observers, and how intersubjective agreement scales with training. In that sense, even when s is hard to reach, claims about s can remain tethered to evidence about reachability, reliability, and robustness.

Remark 1130 (Normative feedback). *Hyperseed also suggests a feedback loop: if a state-indexed science pertains to states of extraordinary well-being, then the discipline can serve as a community-level control policy that helps shift the community toward those states. Within our formalism this is naturally expressed by letting states be reachable nodes in a policy-controlled Markov process, with "scientific practice" as an action that increases transition probabilities toward desirable states.*

The Markov framing also makes explicit that "doing the science" can have dual roles: it both (i) produces observations (epistemic output) and (ii) shifts the distribution over states (pragmatic/ethical output). This dual role is already present in many ordinary scientific institutions (e.g. training, credentialing, lab culture), but here it becomes central because the observation channel itself is state-conditioned. Accordingly, evaluation criteria can be layered: one may assess a practice by the coherence and predictive power of its in-state models, and separately assess it by the value profile of the states it tends to induce, while still keeping these assessments analytically distinct.

Remark 1131. *This remark connects epistemology back to values and control: inquiry is not merely descriptive but can become prescriptive insofar as a practice reliably induces states with preferred value profiles (Section 18). In Hyperseed language, this is an instance of Control (Hyperseed-Concept 87) operating on States of Consciousness (Hyperseed-Concept 178) via socially stabilized practice, which also relates naturally to community-level notions of culture and collective mind systems developed later (Section 22).*

20.10 Micro-example: paraconsistent transitivity in a question network

We conclude with a tiny instance showing how questions, axioms, and paraconsistent inference fit together. In this setting, it is helpful to read each claim $p \in \mathcal{L}$ as a node in a small question/answer graph, and to read the rule set as edges that transport evidential support between nodes. The purpose of the example is not to argue that "same for the current task" is literally transitive in every domain, but to show how a familiar schema can be represented and evaluated even when the inputs are partially contradictory.

Example 17 (Three entities and a transitivity rule). *Let* $X = \{a, b, c\}$*. Consider the claim language*

$$\mathcal{L} = \{p_{ab}, p_{bc}, p_{ac}\},$$

where p_{uv} abbreviates "u and v should be treated as the same (for the current task)." In many applications, one might imagine u, v as records, hypotheses, categories, or agents; the notation is intentionally minimal so that the only moving parts are (i) a rule schema and (ii) a paraconsistent treatment of evidence.

Let the community's rule set contain a weighted "transitivity" rule

$$r: \{p_{ab}, p_{bc}\} \to p_{ac} \quad \textit{with strength } \lambda_r = (0.8, 0.0).$$

Here the strength has two components, meant to encode (respectively) how strongly the community treats the rule as supporting its conclusion and how strongly it treats the rule as opposing *its conclusion. Thus, $\lambda_r = (0.8, 0.0)$ says "we have substantial positive license to apply this rule, and no explicit negative license attached to the rule itself."*

Suppose an agent has evidence

$$\beta(p_{ab}) = (0.9, 0.4), \qquad \beta(p_{bc}) = (0.7, 0.1), \qquad \beta(p_{ac}) = (0.0, 0.0).$$

It is useful to read $\beta(p) = (\beta^+(p), \beta^-(p))$ as a pair of nonnegative weights, where $\beta^+(p)$ measures degree of support for p and $\beta^-(p)$ measures degree of support for $\neg p$ (or, more generally, for "reasons against accepting p"). The evidence for p_{ab} is explicitly conflicted: both positive and negative support are present. In particular, nothing in the representation forces $\beta^+(p_{ab}) + \beta^-(p_{ab}) \leq 1$, so the framework can record "mixed signals" without first reconciling them into a single probability-like quantity.

Compute the one-step inference contribution:

$$\mathrm{contrib}_r(\beta) = (0.8, 0.0) \otimes (0.9, 0.4) \otimes (0.7, 0.1) = (0.8 \cdot 0.9 \cdot 0.7,\ 0.0 \cdot 0.4 \cdot 0.1) = (0.504, 0.0).$$

This multiplication-style $\otimes$ can be read as an "and-like" aggregation: a rule application is strong only to the extent that each ingredient (the rule license and each premise) is strong, and the particular choice here treats the positive and negative channels independently by multiplying like with like. In other words, for this illustrative $\otimes$, the positive component of the contribution depends only on the positive components of the inputs, and the negative component depends only on the negative components. Thus

$$F_{\mathcal{R}}(\beta)(p_{ac}) = \beta(p_{ac}) \oplus (0.504, 0.0) = (0.504, 0.0).$$

The $\oplus$ operation is acting as the accumulator for multiple sources of evidence (for instance, multiple rules or observations targeting the same claim); in this toy step there is only one contributing rule, so the update is transparent. The agent now has positive evidence for p_{ac}, derived from the transitivity schema, while the conflict in p_{ab} did not "explode" into arbitrary conclusions. Concretely, the presence of $\beta^-(p_{ab}) = 0.4$ does not force $\mathrm{contrib}_r(\beta)$ *to become negative, nor does it automatically block the positive pathway; it is simply recorded as a coexisting counter-weight on the premise node.*

If the agent wishes to "bottom out" a cycle in a larger question network, it may entertain a hypothesis such as p_{ac} at high strength, propagate by closure, and compare the resulting conflicts to decide whether the hypothesis is coherent with other commitments. In that broader usage, one can think of the hypothesis injection as an explicit, inspectable intervention: rather than silently assuming a fixed point exists and is unique, the agent tests candidate stabilizers and then evaluates how much inconsistency they induce elsewhere in the network.

Remark 1132 (What to notice in the computation)**.** *The crucial feature is that negative evidence in a premise does not automatically negate the ability to infer something; nor does it entail everything. This is the operational point of the paraconsistent setup: local inconsistency is permitted as a first-class datum, and inference is engineered so that inconsistency does not trivialize the entire theory.*

The rule strength $\lambda_r = (0.8, 0.0)$ carries only positive support, and (in the product used in this example) the negative component of the contribution becomes 0 because the rules negative component is 0. Equivalently, with this $\otimes$, a rule application can contribute negative evidence to its conclusion only if the rule itself (or, in other designs, some premise) carries negative evidence in the channel that is wired to generate negative output. This makes the "audit trail" of negativity explicit: one can point to exactly which pieces of the system are responsible for introducing counter-support for a claim.

Thus we obtain a derived positive claim without any requirement that the premises be consistent. In a network with multiple rules, an agent might simultaneously accumulate positive and negative evidence for the same conclusion (e.g., $F_{\mathcal{R}}(\beta)(p_{ac}) = (\alpha^+, \alpha^-)$ with both components nonzero), in which case the system records that tension rather than forcing an immediate collapse to either acceptance or rejection.

As a toy illustration, this mirrors the intended "conflict without explosion" behavior discussed throughout the paraconsistent parts of the document [23, 24]. The key methodological point is that the ability to proceed in the presence of conflict is not a purely informal principle; it is enforced by the algebra of $\otimes, \oplus$ and by the way rules are allowed to contribute to conclusions.

In a fuller implementation, alternative $\otimes$ choices could allow negative evidence to propagate in more nuanced ways; the point here is that the algebraic interface makes such choices explicit and auditable. For example, one could choose an $\otimes$ in which the negative component of a premise partially attenuates (rather than nullifies) the positive contribution, or in which a strongly negative premise injects explicit negative mass into the conclusion; the present micro-example simply exhibits the cleanest "separation of channels" behavior so that the mechanics can be read off directly from the numbers.

Hyperseed concepts covered

- Knowing and Thinking as structured dynamics on question/answer graphs (Hyperseed-Concept **??**).
- Template Patterns; Questions as information-seeking actions about instantiations; Answers as instantiations or other uncertainty-reducing artifacts (Hyperseed-Concept 130, Hyperseed-Concept 144, Hyperseed-Concept 56, Hyperseed-Concept 195).
- Beliefs (direct and indirect); Axiom Systems; "entertaining a hypothesis" as hypothetical belief injection followed by closure (Hyperseed-Concept 65, Hyperseed-Concept 64).
- Question Networks, including cyclic/non-well-founded dependencies and "bottoming out" by hypothesis (Hyperseed-Concept 145, Hyperseed-Concept 93).
- Belief System as a coherent network of beliefs held in a community; "productive" belief systems via individuation and self-transcendence constraints (Hyperseed-Concept 64, Hyperseed-Concept **??**, Hyperseed-Concept 167).
- Science as empirically coupled belief-system dynamics; State-Dependent Science as a state-indexed family of observation sets and update loops (Hyperseed-Concept 104, Hyperseed-Concept 178).

21 Intelligence, tasks, and agency

21.1 Motivation: from mind concepts to task competence

Sections **??**–20 built a picture of minds as pattern-using, resource-limited systems: they represent (some) distinctions, update paraconsistent beliefs, allocate attention, and exert control to shape future perception while negotiating value conflicts. In this framing, "mind" names an internal organization: a way of building and reusing structured regularities under bounded computation, bounded time, and bounded sensing. What remains missing at this stage is an *operational* connector between internal organization and externally checkable performance, i.e., a way to say not only what a system *is like* internally but what it can *reliably accomplish* when coupled to an environment.

Hyperseed's "intelligence" layer adds two commitments:

- *Tasks* provide an operational bridge from internal pattern webs to externally checkable competence.
- *Agency* is persistent closed-loop control; *autonomy* is the capacity to generate, sustain, and revise goals from within (rather than merely executing imposed objectives).

The first commitment is deliberately methodological: it treats performance as something that can be posed, repeated, and audited. In particular, a task statement is meant to pin down (i) what information is available to the system, (ii) what interventions are permitted, (iii) what counts as success or failure, and (iv) what resource budgets and time horizons apply. This makes it possible to distinguish "the system sometimes produces a desired outcome" from "the system is competent at a specified interaction pattern," and to separate one-off luck from stable capability. It also forces clarity about *interfaces*: what is observed, what is acted upon, and how feedback is delivered.

The second commitment clarifies a persistent ambiguity in informal discussions of intelligent behavior. Many systems can execute a goal when the goal is supplied from outside, yet do not select, maintain, or renegotiate goals under changing conditions. Hyperseed therefore separates (a) being an agent in the minimal cybernetic sense of maintaining a control loop over time, from (b) being autonomous in the stronger sense of owning a goal-management process. The distinction matters for evaluation: two systems might solve the same benchmark task while differing radically in how brittle their goal pursuit is when the task is perturbed, reframed, or partially underspecified.

This section formalizes tasks (and families of tasks), defines intelligence measures as transfer and generalization across task sets, and makes "agent," "autonomous agent," "intent," and the action primitives "stimulate"/"inhibit" mathematically explicit. We also introduce a compact notion of "engineered" as an ontological tag on artifacts produced by intelligent action. A further motivation for these formalizations is comparability: once tasks are explicit objects, one can speak precisely about when two seemingly different problems share a structure (hence belong to a common family), when a solution method transfers, and when improvement reflects genuine generalization rather than memorization of a narrow interaction script.

In particular, the move to *families* of tasks is meant to encode variation: different initial conditions, different noise realizations, different objective weights, different environments drawn from a distribution, or even different representational encodings of the same underlying problem. This is the natural setting in which "generalization" and "transfer" are not slogans but statements about performance stability under controlled shifts. A system that performs well on a single fixed instance may be competent at that instance; a system that performs well across a family demonstrates robustness to variation. Likewise, a system that learns within one family and then reliably improves performance on a related family exhibits transfer in a sense that can be measured and compared across architectures.

The emphasis on action primitives such as "stimulate"/"inhibit" is also explanatory rather than decorative: many agent models tacitly assume a rich action alphabet. By naming minimal primitives, Hyperseed aims to make clear what sort of causal interface is being assumed between an agent and its world. In this view, complex actions can be built compositionally from simpler primitives, while the core semantics remains grounded in how interventions modulate downstream dynamics (amplifying, suppressing, enabling, blocking). This keeps later notions of "intent" tied to concrete control structure: intent is not merely a post-hoc interpretation, but a commitment expressed through persistent selection of actions that shape trajectories toward goal conditions under feedback.

Finally, the "engineered" tag is introduced to mark a distinction that will matter later when discussing artifacts, tools, and constructed sub-agents. The tag is not meant to imply a specific material substrate or manufacturing process; rather, it indicates provenance: the object exists in its present functional organization *because* intelligent action brought it about (possibly via long chains of intermediate artifacts and delegation). This provenance marker becomes useful when reasoning about ecosystems that mix naturally occurring structures with designed ones, or when tracking how competence can be externalized into tools that then feed back into later task performance.

Remark 1133. *Philosophically, the move from "mind" to "intelligence" in Hyperseed is a move from* being a web of patterns *to* being assessable by what one can reliably do*. A task is not merely an external test: it is a formalized interface between an agent's internal organization and an environment that can answer back. This is why tasks belong to the Hyperseed core-concept set as an explicit bridge concept (Hyperseed-Concept 186), and why task families become the natural stage on which transfer learning is defined (Hyperseed-Concept 192; see also [19, 7]). The key word in "environment that can answer back" is* counterfactual responsiveness*: when the agent changes what it does, the world changes what it returns. This prevents collapsing "task" into a static dataset query and keeps the emphasis on interaction, feedback, and control. Reliability then refers not only to average success but to stability under repeated trials, bounded resources, and specified perturbations—a notion aligned with competence rather than isolated performance.*

21.2 Tasks as interaction specifications

We work with an intentionally lightweight task formalism: a task is an interaction channel plus an evaluation functional. This is compatible with classical decision theory (MDPs/POMDPs) but keeps the paraconsistent value layer explicit. In particular, we separate (i) the *interface* that generates observation streams in response to actions from (ii) the *evidence-bearing evaluation* attached to transitions, and we do so without assuming that the agent has access to any privileged "true state" variable beyond what the interaction itself provides.

Definition 315 (Histories)**.** *Fix finite sets O (observations) and A (actions). For $t \geq 0$ define the set of length-t histories by*

$$H_t := O \times (A \times O)^t = \{(o_0, a_0, o_1, \dots, a_{t-1}, o_t)\}.$$

Let $H := \bigcup_{t \geq 0} H_t$ be the set of all finite histories.

Remark 1134. *The notation here is deliberately explicit: O is the alphabet of percepts the task presents, and A is the alphabet of interventions the agent may select. A history in H_t is thus an alternating record*

$$(o_0)\ (a_0, o_1)\ (a_1, o_2)\ \cdots\ (a_{t-1}, o_t),$$

and H is simply the set of all such finite records of arbitrary length. This is the minimal object needed to define policies without assuming Markovian state access: a policy may depend on the entire past, not merely on the current observation.

As a simple example, if $O = \{0,1\}$ and $A = \{\mathsf{L}, \mathsf{R}\}$, then an element of H_2 is a quintuple $(o_0, a_0, o_1, a_1, o_2)$ such as $(1, \mathsf{L}, 0, \mathsf{R}, 0)$. Such strings are the "raw material" out of which an agent constructs patterns and habits (Hyperseed-Concept 130, 155; cf. [5]).

Two small technical conventions are worth keeping in mind for later sections. First, the set H includes the "time 0" history $(o_0) \in H_0$, so an agent may condition its very first action on an initial percept. Second, H is a disjoint union of H_t over t, so "history length" is always well-defined: a history is not merely a sequence but a sequence together with its time index.

Definition 316 (Policies)**.** *A (possibly stochastic)* policy *is a map*

$$\pi : H \to \Delta(A),$$

where $\Delta(A)$ is the probability simplex on A. A deterministic policy is the special case $\pi : H \to A$.

Remark 1135. *The symbol $\Delta(A)$ denotes the set of all probability distributions on the finite set A. Thus $\pi(h)$ is not an action but a distribution over actions, from which an action may be sampled. This is the standard way to model randomized decision-making; it is also the cleanest way to model bounded or exploratory control without changing the rest of the mathematics.*

For a concrete illustration, if $A = \{\mathsf{L}, \mathsf{R}\}$, then $\Delta(A)$ can be identified with $[0,1]$ by $p \mapsto (p, 1-p)$, and a policy returns a coin-bias conditioned on the history. In many later constructions, one can restrict attention to deterministic policies without changing the conceptual point; allowing stochasticity simply keeps the formalism honest about uncertainty.

It is also useful to note the modeling stance implicit in $\pi : H \to \Delta(A)$: the agent is not assumed to have a compact internal "state" that summarizes the past. Of course, real agents often compute summaries (belief states, feature maps, recurrent memories), but those are implementations *of a history-dependent policy rather than prerequisites of the task definition.*

Definition 317 (Task)**.** *A* task *is a tuple*

$$T = (O, A, P, r, \gamma),$$

where O and A are finite, $P : O \times A \to \Delta(O)$ is a transition kernel over observations, $r : O \times A \times O \to \mathbb{V}$ is a p-bit*-valued immediate evaluation (reward/penalty evidence), and $\gamma \in (0,1)$ is a discount factor.*

Remark 1136. *This definition should be read as a deliberately "interface-only" cousin of the standard MDP/POMDP framework: instead of positing a hidden state space, we treat the observation process itself as the primary object. The transition kernel $P(o,a)$ is a distribution over next observations o' given current observation o and action a. The immediate evaluation $r(o,a,o')$ is not a single real number but a value in $\mathbb{V} = [0,1]^2$, i.e. a* p-bit *of positive and negative evidence.*

A simple example is a bandit-like task where P ignores o and a and always returns the same distribution on O, while r assigns $(1,0)$ to "good" outcomes and $(0,1)$ to "bad" ones. More generally, this setup can encode tasks whose feedback is noisy, socially contested, or internally conflicted (Hyperseed-Concept 198), which is one reason Hyperseed avoids reducing value to a single scalar too early (cf. [19]).

Two clarifications help relate this "observation-level" formalism to more familiar ones. First, a classical MDP $(S, A, \tilde{P}, \tilde{r}, \gamma)$ induces a task of the present form by taking $O = S$, letting P be $\tilde{P}$

(viewed as a kernel on observations), and letting r be an evidence-valued lift of the scalar reward $\tilde{r}$ (for instance by mapping $\tilde{r} > 0$ to positive evidence and $\tilde{r} < 0$ to negative evidence, if one wishes). Second, a POMDP with latent state S and observation kernel Z can also be viewed through this lens by taking O to be the observation alphabet and absorbing the latent state into the induced observation-to-observation dynamics; in general this produces a non-Markov observation process, so the present Markov kernel $P : O \times A \to \Delta(O)$ is best seen as a simplifying interface choice rather than a claim that observations are always Markov in reality.

If one wishes to drop even this Markov-in-O simplification, the minimal generalization is to allow a history-dependent environment kernel $P : H \times A \to \Delta(O)$, i.e. $P(h, a)$ is a distribution over the next observation given the entire past. We do not need that generality for the constructions in this section, but it is conceptually aligned with the earlier point that the agent's policy may be fully history-dependent.

Remark 1137 (Why p-bit-valued evaluation)**.** *The evaluation r is allowed to be conflicted: it may assign both positive and negative evidence to a transition. This matches Hyperseed's value paraconsistency (Section 18) and supports tasks whose feedback is ambiguous, socially contested, or internally conflicted. In particular, allowing $r(o, a, o') = (p, n)$ with both $p > 0$ and $n > 0$ makes room for "mixed" events (e.g. actions that succeed on one criterion while failing on another, or actions that are praised by one evaluator while condemned by another) without forcing an early reconciliation into a single numerical tradeoff.*

Definition 318 (Trajectory value via discounted salience join)**.** *Write an infinite trajectory as $\omega = (o_0, a_0, o_1, a_1, \ldots)$. Define the* discount factor p-bit $\delta_t := (\gamma^t, \gamma^t) \in \mathbb{V}$ *and the trajectory value*

$$\mathrm{Val}_T(\omega) := \bigoplus_{t \geq 0} \delta_t \otimes r(o_t, a_t, o_{t+1}),$$

using the p-bit *quantale operations $\oplus$ and $\otimes$ from Section 3.4.*

Remark 1138. *A few symbols deserve a first-reading gloss. The infinite sequence ω is the full unfolding of interaction: observation, action, observation, action, and so on. The discount $\gamma \in (0, 1)$ yields weights γ^t that shrink with time, and the pair $\delta_t = (\gamma^t, \gamma^t)$ discounts positive and negative evidence symmetrically in $\mathbb{V}$. The operation $\otimes$ plays the role of "scaling" evidence by salience (here, discount), while $\oplus$ plays the role of an "accumulation" operator, which in the* p-bit *quantale is a componentwise maximum (Section 3.4; Hyperseed-Concept 143, 202; see [3, 2] for broader discussion of weakness).*

As an example, suppose along a trajectory there is one highly salient positive event early on with $r = (1, 0)$ and all later events have smaller discounted magnitude; then $\mathrm{Val}_T(\omega)$ will retain that early strong evidence. Conversely, a single striking failure early on will dominate the negative component. This reflects a bounded-attention reading: what is remembered and acted upon is often the most salient evidence, not the sum of all evidence.

The choice of $\bigoplus_{t \geq 0}$ (a join/max-like accumulation) also sidesteps the usual convergence questions that arise with infinite-horizon summation: because $\oplus$ is idempotent and bounded in $\mathbb{V}$, the expression is well-defined as soon as each discounted term $\delta_t \otimes r(o_t, a_t, o_{t+1})$ is defined. Intuitively, the value records the strongest *discounted positive evidence encountered and the* strongest *discounted negative evidence encountered, rather than aggregating all evidence into a single scalar.*

For readers who prefer to see the mechanics in a finite prefix, consider the first two transitions of ω with evidence $r_0 := r(o_0, a_0, o_1)$ and $r_1 := r(o_1, a_1, o_2)$. Then the two-step salience-joined evidence is

$$(\delta_0 \otimes r_0) \;\oplus\; (\delta_1 \otimes r_1),$$

so whichever transition carries more salient positive evidence will set the positive coordinate of the result, and likewise for the negative coordinate. This makes explicit the sense in which the formalism models "what stands out" rather than "what adds up" over time.

Remark 1139. *Because $\oplus$ is a componentwise maximum,* Val_T *emphasizes the most salient discounted success/failure signals along the trajectory. This matches an attention-like reading: a bounded agent may be driven primarily by the strongest evidence-laden events rather than by a fully additive cumulative utility. Other aggregators can be substituted if desired; the present choice keeps the link to the core quantale explicit. In particular, since $\oplus$ acts like a (discounted) supremum,* Val_T *behaves more like a* "peak evidence" *semantics than a* "sum of evidence" *semantics: once a decisive success signal has occurred, additional smaller successes do not further increase the positive component, and analogously for failures. This makes the evaluation robust to long stretches of low-level noise, while remaining sensitive to rare but high-confidence events (e.g. a single catastrophic failure state, or a single decisive achievement of a goal condition). It also clarifies why discounting interacts naturally with $\oplus$: discounting controls how much salience is granted to evidence as it recedes in time, while $\oplus$ controls how evidence is pooled across time once discounted.*

Definition 319 (Policy value and plausibility scalarization)**.** *Let $\mathbb{E}_\pi[\cdot]$ denote expectation over trajectories induced by P and π. Define the* p-bit*-valued policy value*

$$J_T(\pi) := \mathbb{E}_\pi\big[\mathrm{Val}_T(\omega)\big],$$

where expectation is taken componentwise in $[0,1]^2$*. Define the* plausibility projection $\mathrm{pl} : \mathbb{V} \to [0,1]$ *by*

$$\mathrm{pl}(v^+, v^-) := \frac{1 + v^+ - v^-}{2}.$$

The scalar score $\mathrm{pl}(J_T(\pi))$ *is interpreted as "net plausibility of success." In this reading, v^+ can be viewed as graded support for success, v^- as graded support for failure, and the affine centering at $\frac{1}{2}$ treats "no salient evidence either way" as epistemically neutral rather than as either success or failure.*

Remark 1140. *Componentwise expectation means: if* $\mathrm{Val}_T(\omega) = (V^+(\omega), V^-(\omega))$*, then* $J_T(\pi) = (\mathbb{E}_\pi[V^+], \mathbb{E}_\pi[V^-])$*. The projection* pl *then converts the evidence-pair into a single number in* $[0,1]$ *by treating positive evidence as increasing plausibility and negative evidence as decreasing it. The affine form $\frac{1+v^+-v^-}{2}$ is chosen so that $(1,0) \mapsto 1$, $(0,1) \mapsto 0$, and $(0,0) \mapsto \frac{1}{2}$ as a neutral baseline.*

One should not mistake pl *for a metaphysical collapse of value into one scalar; it is a pragmatic device for defining competence comparisons and breadth measures. The underlying* p-bit *value $J_T(\pi) \in \mathbb{V}$ retains the information about conflict (Hyperseed-Concept 198) even when one temporarily projects down to a real score. It is also useful to note some basic structural properties of* pl*: it is monotone nondecreasing in v^+, monotone nonincreasing in v^-, and* 1*-Lipschitz with respect to the ℓ_1-distance on* $[0,1]^2$ *up to a factor of $\frac{1}{2}$, i.e. changing (v^+, v^-) by (Δ^+, Δ^-) changes* pl *by at most $\frac{1}{2}(|\Delta^+| + |\Delta^-|)$. Thus, while* pl *is a lossy map, it behaves continuously and predictably under small changes in evidential components. Moreover,* $\mathrm{pl}(v^+, v^-) = \frac{1}{2} + \frac{1}{2}(v^+ - v^-)$ *makes explicit that the scalarization is equivalent to taking a signed "evidence balance" $v^+ - v^- \in [-1,1]$ and rescaling it into* $[0,1]$*; in particular,* pl *treats equal positive and negative evidence as neutral regardless of the absolute magnitudes, reflecting the intended paraconsistent stance that conflict should not be silently resolved without a modeling decision.*

Definition 320 (Task sets)**.** *A* task set *is any collection $\mathcal{T}$ of tasks (often equipped with a distribution* D *for sampling tasks). We will refer to* $(\mathcal{T}, \mathsf{D})$ *as a* task environment*. In the typical* *case where* D *is present, one can regard* D *as encoding both prevalence (which tasks occur) and importance (which tasks matter more) within the ecology.*

Remark 1141. *A task set* $\mathcal{T}$ *plays the role of an "ecology of challenges." A single task can be solved by memorization or brittle specialization; a distribution over tasks forces the question of generalization and transfer (Hyperseed-Concept* **??**, *118, 192; cf. [19, 7]).*

As a simple example, $\mathcal{T}$ *might be the set of all two-armed bandits with varying payoff probabilities, and* D *a prior over those probabilities. Then an "intelligent" agent is one that does not merely excel on one bandit instance, but does well on typical draws from the family. This example also highlights a distinction between* in-task *uncertainty (stochastic rewards within a fixed bandit instance) and* across-task *uncertainty (not knowing which instance will be drawn); task environments make the latter explicit and thereby separate adaptivity/learning from mere execution. In settings where tasks share structure (e.g. common latent parameters), good performance on* D*-typical tasks can be interpreted as evidence that the policy (or agent) has captured that structure rather than overfitting to idiosyncrasies of a single task. Finally, note that* $\mathcal{T}$ *need not be "small" or even countable: it may be a parametrized family (e.g. all MDPs in a class), and* D *may be a continuous distribution; the definition is intentionally agnostic about representation so that later breadth notions can range from finite benchmarks to open-ended task generators.*

21.3 Task morphisms and compositional transfer

Hyperseed treats intelligence as pattern discovery that *transfers* across contexts. A minimal formalization of transfer is: one task can be reduced to another by translating observations/actions while preserving evaluation.

Definition 321 (Task reduction / simulation morphism)**.** *Let* $T = (O, A, P, r, \gamma)$ *and* $T' = (O', A', P', r', \gamma)$ *share the same discount* γ*. A* reduction *(or* simulation morphism*)* $F : T \to T'$ *consists of maps*

$$f_O : O \to O', \qquad f_A : O \times A' \to A,$$

such that for all $o \in O$ *and* $a' \in A'$ *with* $a = f_A(o, a')$*:*

*(a) (*Dynamics compatibility*) The pushforward of* $P(o, a)$ *under* f_O *equals* $P'(f_O(o), a')$*, i.e.*

$$(f_O)_*\big(P(o, a)\big) = P'(f_O(o), a') \in \Delta(O').$$

*(b) (*Evaluation compatibility*) For all* $o_+ \in O$*,*

$$r(o, a, o_+) = r'\big(f_O(o), a', f_O(o_+)\big).$$

Remark 1142. *The notation* $(f_O)_*$ *denotes pushforward of a distribution along a function: if* $\nu \in \Delta(O)$ *and* $f_O : O \to O'$*, then* $(f_O)_*(\nu) \in \Delta(O')$ *is the distribution of* $f_O(X)$ *when* $X \sim \nu$*. Thus condition (a) says: if one observes* o *only through* $f_O(o)$ *and acts via an abstract action* a' *which is decoded into a concrete action* a*, then the next abstract observation has exactly the distribution prescribed by* T'*.*

The decoder $f_A : O \times A' \to A$ *is allowed to depend on the concrete observation* o*. This models a common phenomenon in representation transfer: the same abstract action token may be implemented differently depending on the finer-grained concrete context. In transfer-learning language,* F *is an exact semantics-preserving interface between tasks (Hyperseed-Concept 192, 157; see [7] for a related framework emphasizing compositional transfer).*

Remark 1143. *A reduction says: by observing o only through $f_O(o)$ and choosing an abstract action a' (which is then decoded into a concrete action a), the agent experiences a task equivalent to T'. This is a precise encoding of "reusing a solution by changing representation."*

Proposition 33 (Reductions compose)**.** *If $F : T \to T'$ and $G : T' \to T''$ are reductions (in the sense of Definition 321), then there is a composite reduction $G \circ F : T \to T''$.*

Remark 1144. *Intuitively, this proposition says that "doing one representation change after another" is itself a representation change of the same kind. This matters because transfer in realistic settings is rarely a single leap; it is often a chain of abstractions: raw perception to mid-level features to task-specific summaries. The proposition is a small but essential step toward treating transfer as a compositional algebra rather than a bag of tricks (cf. [7]).*

Proof. Write $F = (f_O, f_A)$ and $G = (g_O, g_A)$. Define $(g \circ f)_O := g_O \circ f_O$ and define the composite action decoder by

$$(g \circ f)_A(o, a'') := f_A\big(o,\ g_A(f_O(o), a'')\big),$$

so that an abstract a'' is first decoded to an a' using g_A (at the abstract observation $f_O(o)$), then decoded to a concrete a using f_A (at the concrete observation o). Dynamics compatibility follows from functoriality of pushforward of measures and the two given compatibility conditions; evaluation compatibility follows by substitution. □

Proof sketch. The strategy is to define the only composite maps one could reasonably mean: observations are re-encoded by composing the encoders, and actions are decoded in two stages. The two compatibility axioms are then checked by "plugging in" these definitions. Pushforward is functorial, so the dynamics condition composes automatically; reward preservation is a direct substitution. □

Remark 1145. *The key step is recognizing that actions must be decoded with awareness of the correct observation granularity at each stage: g_A expects an O'-observation (namely $f_O(o)$), while f_A expects the original O-observation o. Geometrically, one can picture a commutative diagram of stochastic kernels: the composite reduction ensures that the "abstract" observation process induced from T matches the observation process of T'' exactly.*

Corollary 3 (Category of tasks)**.** *There is a (small) category* Task *whose objects are tasks and whose morphisms are task reductions; identities are given by $f_O = \mathrm{id}_O$ and $f_A(o, a) = a$.*

Remark 1146. *This corollary says that tasks and exact transfer maps between them form a mathematical world in which one can speak of equivalence, composition, and invariants. The philosophical gain is that "transfer" becomes something one can reason about structurally, rather than narratively: an agent that discovers a morphism has discovered a re-description that preserves what matters for evaluation.*

In later developments (outside the strict setting here), one often relaxes exact equality to approximation and moves to enriched or higher-categorical variants; the point of beginning with an ordinary category is to make clear which parts of transfer are purely structural (cf. [7]).

Proposition 34 (Transfer by reduction)**.** *Let $F : T \to T'$ be a reduction. Given any policy $\pi' : H' \to \Delta(A')$ for T', there is an induced policy π for T such that*

$$J_T(\pi) = J_{T'}(\pi').$$

Remark 1147. *In plain terms: if you know how to act in the abstract task T', and you have an exact interface F telling you how to* view *T as T', then you can act in T with exactly the same expected value. This is the formal skeleton of "solving a new problem by translating it into a known one". It connects directly to the later breadth and intellectuality definitions: a large part of what makes an agent appear generally intelligent is not raw skill on each task, but the ability to locate such interfaces quickly (Hyperseed-Concept 192, **??**). In particular, the interface supplies both an* observation coding *(what the agent is allowed to treat as the "same situation") and an* action decoding *(how an abstract decision is realized as a concrete intervention). When such a translation is exact, there is no room for performance loss: the agent is not merely approximating T by T' but inhabiting T' as an isomorphic informational perspective on T.*

Proof. Define the encoded history map $\widehat{(\cdot)} : H \to H'$ by applying f_O to each observation in the history and leaving action slots as abstract placeholders. More explicitly, if a history in T has the form $h = (o_0, a_0, o_1, a_1, \ldots, o_t)$, then $\widehat{h} = (f_O(o_0),\ \square_0,\ f_O(o_1),\ \square_1,\ \ldots,\ f_O(o_t))$, where each $\square_i$ denotes an "action position" to be filled by an abstract action from A' when π' is executed. This separation emphasizes that π' is evaluated only on the information it expects in T', namely its own past abstract actions and the coded observations. At history $h \in H$ with current observation o, sample $a' \sim \pi'(\widehat{h})$ and execute $a = f_A(o, a')$ in T. This defines a policy π on T by the composite procedure $h \mapsto \widehat{h} \mapsto a' \mapsto a$; under the usual measurability assumptions on f_O, f_A, this induced π is a valid stochastic policy. By construction, the resulting encoded observation process matches the T' dynamics, and the step evaluation matches exactly; therefore the induced trajectory value distribution matches, hence the expected p-bit value matches. Concretely, one can couple the two rollouts so that at every time t the coded observation in the T-run equals the observation in the T'-run, and the abstract action sampled by π' in T' is the same abstract action used (via f_A) to generate the concrete action in T. The reduction axioms are precisely what make this coupling consistent across time: the transition law for $f_O(o_{t+1})$ given the past agrees with the T' transition law given $(\widehat{h}, a')$, and the evaluation functional applied to (o_t, a_t, o_{t+1}) agrees with the evaluation in T' applied to the corresponding coded transition. Under this coupling, the per-trajectory p-bit values coincide almost surely, so taking expectations over the common randomness yields equality of expected p-bit. ☐

Proof sketch. One defines π by "running π' on the encoded history" and decoding its chosen abstract action back into a concrete one. The reduction axioms guarantee that (i) the encoded observation stream has the same law as in T', and (ii) each step's evaluation agrees under encoding. Therefore trajectory values, and hence their expectations, coincide. Equivalently, the map F behaves like a semantics-preserving compiler from T-interaction traces to T'-interaction traces: the agent computes in the T'-space while the environment evolves in T, and the axioms ensure these two views remain synchronized. ☐

Remark 1148. *The proof works because the reduction conditions are exactly the two places where a mismatch could enter: in the stochastic evolution of observations or in the evaluation of transitions. Visually, one can imagine an agent living in T while wearing "glasses" that apply f_O to every observation; the world seen through the glasses behaves like T', and the decoded actions ensure the world is acted upon in the correct way to maintain the illusion. Said differently, the agent's internal state need not represent T directly: it can represent the coded process, plan there, and rely on the decoder to realize those plans faithfully in T. If either condition failed, transfer could break in a sharply identifiable way: the agent might see a process that no longer follows the assumed T' dynamics (model mismatch), or it might be optimizing the wrong objective because coded transitions are evaluated differently (reward/value mismatch).*

Remark 1149 (Where groupoids enter)**.** *If two tasks reduce to each other, they are equivalent objects in* Task*; the invertible reductions form a groupoid of task equivalences. In later sections, more flexible (approximate) morphisms can be handled by V-enrichment and higher-categorical structure, but the strict case above already captures the core transfer idea. Here "groupoid" means that every morphism regarded as an equivalence has an inverse and that these equivalences compose: if $T \to T'$ and $T' \to T''$ are invertible reductions, then their composite is an invertible reduction $T \to T''$, with identities given by the trivial "do nothing" interface. From the agent's perspective, equivalence identifies tasks that differ only by a change of representation: any optimal (or more generally any) policy can be transported across the equivalence without changing its induced value distribution. This categorical viewpoint separates questions of* capability *(what can be solved up to equivalence) from questions of* search *(how quickly an agent can find the relevant reduction).*

21.4 Competence, intellectuality, and intelligence measures

We now define task competence and several derived quantities that capture Hyperseed's distinction between narrow and general intelligence.

Definition 322 (Agent as a policy-producing process)**.** *Fix an interface (O, A). An* agent Ag *is any procedure that, when coupled to a task T on (O, A), produces a policy $\pi_{\mathsf{Ag},T} : H \to \Delta(A)$. (We make the internal state explicit in Section 21.5.)*

Remark 1150. *This definition intentionally abstracts away implementation details: it treats an agent as a* policy factory *whose output depends on the task it is placed in. The point is to allow many realizations (neural, symbolic, hybrid, social) under a single rubric (Hyperseed-Concept 111, 106, 80). Only later do we constrain the internal structure to express persistent agency.*

As an example, a table-lookup procedure that maps each history to a fixed action is an agent in this sense (though not an interesting one); a reinforcement learning system that updates its policy as it interacts is also an agent.

Remark 1151. *A few clarifications help avoid category errors later. First, the dependence $\pi_{\mathsf{Ag},T}$ on T is meant to include whatever coupling information is available when the agent is "placed in" the task: the task's observation and action semantics, any provided training corpus or simulator access, the interaction protocol, and (when relevant) the agent's own randomization. Second, writing $\pi_{\mathsf{Ag},T} : H \to \Delta(A)$ keeps open whether Ag is deterministic or stochastic: a deterministic agent yields point-mass distributions in $\Delta(A)$, whereas an exploratory learner yields non-degenerate distributions. Finally, the interface (O, A) matters: the same underlying decision-maker may induce very different policies depending on how information is represented in O or which interventions are available in A; later comparisons should therefore be understood as being made within a fixed interface unless explicitly stated otherwise.*

Definition 323 (Task competence)**.** *Given agent Ag and task T, define the competence*

$$\mathrm{Comp}(\mathsf{Ag}; T) := \mathrm{pl}\big(J_T(\pi_{\mathsf{Ag},T})\big) \in [0, 1].$$

Remark 1152. *Competence is the scalarized "how well did it do" number, obtained by first computing the* $\mathsf{p\text{-}bit}$ *policy value $J_T(\pi)$ and then projecting to $[0, 1]$ by* pl*. It is thus a derived quantity, suitable for aggregation and comparison, not the foundational notion of value itself.*

In the simplest non-paraconsistent case where r always has the form $(u, 1-u)$ for a real $u \in [0, 1]$, the projection pl *recovers u (up to an affine reparameterization). But in the general case, competence is merely a pragmatic summary of conflicted evidence.*

Remark 1153. *Because competence is defined via a projection* pl*, it should be read as an* ordinally *meaningful score unless further structure on* pl *is imposed: the same underlying* p-bit *value can map to different numerical scales depending on how cautious or optimistic* pl *is about inconsistency. In particular, if two tasks T and T' have very different reward-generating processes (different noise models, different degrees of inconsistency, or different ranges before scalarization), then* $\mathrm{Comp}(\mathsf{Ag}; T)$ *and* $\mathrm{Comp}(\mathsf{Ag}; T')$ *are comparable only to the extent that J_T and $J_{T'}$ have been normalized in a commensurate way. This is one reason the present section treats competence as a* measurement layer *on top of the task semantics rather than as a fundamental axiom of preference.*

Definition 324 (Capability profile)**.** *For a task set $\mathcal{T}$, the* capability profile *of* Ag *is the function*

$$\kappa_{\mathsf{Ag}} : \mathcal{T} \to [0, 1], \qquad \kappa_{\mathsf{Ag}}(T) := \mathrm{Comp}(\mathsf{Ag}; T).$$

Remark 1154. *The capability profile κ_{Ag} is a map from the ecology of tasks to measured performance. It is conceptually useful because it reframes intelligence as a* landscape *rather than a point: an agent may be strong in one region of $\mathcal{T}$ and weak in another, and questions about generalization become questions about the geometry of this function (Hyperseed-Concept* **??***, 118).*

For instance, a chess engine may have κ near 1 *on tasks involving legal chess positions and near* 0 *on tasks involving language understanding.*

Remark 1155. *The capability profile viewpoint also makes explicit what is sometimes implicit in informal discussions of "intelligence tests": any scalar score is necessarily an aggregation over (explicit or latent) sub-tasks. In this paper's terms, an "intelligence measure" corresponds to (i) a chosen task set $\mathcal{T}$, (ii) a way of sampling or weighting tasks (often a distribution* D*), and (iii) a rule for collapsing the resulting function κ_{Ag} (or learning curves derived from it) to one or a few summary numbers. Put differently, κ_{Ag} is the object that carries the most information; the various aggregates introduced below intentionally discard information in order to gain interpretability and comparability.*

Definition 325 (Breadth at tolerance ε)**.** *Let* D *be a probability distribution on $\mathcal{T}$. For $\varepsilon \in [0, 1]$, define the* breadth *(at tolerance ε) by*

$$\mathrm{Br}_\varepsilon(\mathsf{Ag}; \mathcal{T}, \mathsf{D}) := \mathsf{D}\big(\{T \in \mathcal{T} : \kappa_{\mathsf{Ag}}(T) \geq 1 - \varepsilon\}\big).$$

Remark 1156. *Breadth* Br_ε *is the probability (under* D*) that the agent performs within ε of the top score* 1*. Thus, as ε increases, the set inside* $\mathsf{D}(\cdot)$ *expands, and breadth increases. This parameter lets one tune how strict a notion of "competent" is.*

In the language of Hyperseed concepts, breadth formalizes one axis of General Intelligence (Hyperseed-Concept **??***) by explicitly quantifying how much of a task environment lies within reach at a given tolerance.*

Remark 1157. *Note that breadth is not purely a property of the agent: it is a property of the triple* $(\mathsf{Ag}, \mathcal{T}, \mathsf{D})$*. Changing* D *can change breadth dramatically, even when $\mathcal{T}$ is held fixed: a distribution that concentrates mass on a familiar subdomain can make a narrow specialist appear broad, while a distribution that emphasizes rare corner cases can make a generally capable system look brittle. For this reason,* D *should be interpreted as encoding an intended deployment ecology (what tasks are likely to matter), not merely as a mathematical convenience. One can also view ε as absorbing some of the normalization uncertainty of* pl*: if scalarization is slightly miscalibrated, reporting* Br_ε *across a range of ε can be more robust than selecting a single hard threshold.*

Remark 1158 (General vs narrow intelligence)**.** *A "general" agent has large breadth over a large/diverse task environment; a "narrow" agent may have near-perfect competence on a small region of $\mathcal{T}$ but low breadth overall. This makes the general/narrow distinction precise without committing to a single canonical task set.*

Remark 1159. *The breadth-based distinction also makes visible an important tradeoff: because breadth counts the mass of tasks above a competence threshold, it does not reward being* superlative *on a narrow slice beyond crossing that threshold. In settings where extreme performance on a small class of tasks is valuable (e.g. competitive games, highly standardized pipelines), a narrow agent can be preferable even if it is not "general" by this definition. Conversely, in open-ended environments, breadth aligns with the intuition that robustness across heterogeneous situations is central. Thus "general" and "narrow" here are descriptive labels relative to an environment, not moral judgments about which system is better in all contexts.*

Definition 326 (Intellectuality as rapid transfer)**.** *To make "intellectuality" capture* transfer speed*, assume the agent has a notion of interaction budget $n \in \mathbb{N}$ and produces a budget-indexed policy $\pi^{(n)}_{\mathsf{Ag},T}$ (e.g. after n episodes, n samples, or n inference steps). Define the learning-curve competence*

$$\mathrm{Comp}^{(n)}(\mathsf{Ag};T) := \mathrm{pl}\big(J_T(\pi^{(n)}_{\mathsf{Ag},T})\big).$$

Given a task distribution D, define the intellectuality curve

$$\mathrm{Int}^{(n)}(\mathsf{Ag};\mathcal{T},\mathsf{D}) := \mathbb{E}_{T\sim\mathsf{D}}\big[\mathrm{Comp}^{(n)}(\mathsf{Ag};T)\big].$$

An agent is "more intellectual" (relative to $(\mathcal{T},\mathsf{D})$) if it achieves high $\mathrm{Int}^{(n)}$ for smaller n.

Remark 1160. *This definition aims to isolate something like "grasp" rather than "polish." Two agents may eventually reach similar competence given enough interaction, but the more intellectual one climbs its learning curves quickly across typical tasks in the environment. This is closely aligned with the transfer-learning emphasis in AGI literature (Hyperseed-Concept* **??***, 192; cf. [19, 7]).*

Remark 1161. *Several modeling choices are bundled into the budget parameter n. In an episodic RL setting, n might count episodes of online interaction; in a supervised or self-supervised setting, it might count labeled examples or tokens; in a planning setting, it might count forward-model calls or wall-clock compute devoted to inference. The abstraction is intentional: the core idea is to compare* rates *of improvement, but one must take care to compare like with like when interpreting $\mathrm{Int}^{(n)}$ empirically. In particular, if one agent is allowed to amortize learning across tasks (meta-learning) while another is reset between tasks, then $\pi^{(n)}_{\mathsf{Ag},T}$ corresponds to different experimental protocols, and the resulting intellectuality curves answer different questions about transfer. Relatedly, one can treat $\mathrm{Int}^{(n)}$ as a curve-valued statistic (rather than a single number): comparisons such as "dominates for all n" or "achieves a given competence level with smaller n" often retain more information than collapsing the curve to, say, its area under the curve, even though such collapses can be useful in applications.*

Remark 1162. *A simple example: if $\mathcal{T}$ is a family of maze-navigation tasks differing only by a relabeling of wall textures, then an agent that quickly discovers the invariant structure (geometry of free space) will have a much higher $\mathrm{Int}^{(n)}$ for small n than an agent that relearns each maze from scratch. In particular, the texture relabeling changes superficial perceptual features while preserving the transition-relevant latent variables; high small-n performance therefore witnesses an ability to extract task symmetries and reuse a compact representation across instances rather than amortizing a separate model per instance.*

Remark 1163 (Connection to reductions)**.** *Reductions in Section 21.3 provide a concrete mechanism for high intellectuality: if the agent can identify (or learn) a reduction from a new task to an already-solved one, it can lift an existing policy with little additional data, improving small-n performance. Concretely, a reduction specifies how to translate observations, actions, and rewards of the new task into those of an old task; when such a mapping is available, the agent's "effective sample size" needed to achieve competent behavior can drop sharply because the remaining uncertainty is limited to estimating the reduction rather than learning the entire control problem end-to-end.*

21.5 Agents as persistent perception-action loops

We now pin down the core Hyperseed meaning of "agent": persistent closed-loop control. The key point is that the formal object called an agent is defined independently of any particular task; tasks enter only when we *couple* the agent to a task dynamics, producing an overall stochastic process.

Definition 327 (Agent as a controlled transducer)**.** *Fix (O, A). An* agent *is a tuple*

$$\mathsf{Ag} = (S, s_0, U, G),$$

where S is a (finite or measurable) internal state space, $s_0 \in S$ is an initial state, $U : S \times O \to S$ is an update map, and $G : S \to \Delta(A)$ is an action map. Here $\Delta(A)$ denotes the set of probability measures over A (or probability mass functions when A is finite), so G allows randomized policies as a first-class case. Given a history $h_t = (o_0, a_0, \ldots, o_t)$, the agent state is generated by

$$s_{t+1} := U(s_t, o_t), \qquad a_t \sim G(s_t).$$

Thus, the dependence of actions on the full history h_t is mediated entirely through the sufficient internal state s_t, which is why S can be read as the agent's "memory" or "belief" variable.

Remark 1164. *This is the mathematical core of agency as* process *rather than as a static mapping. The internal state S is what allows persistence: the agent at time t is not merely a response to o_t but the continuation of an internal trajectory $s_0, s_1, \ldots$. The update U represents perception and internal processing; the map G represents action selection (Hyperseed-Concept 87, 140, 151). In this view, "learning" can be modeled either by enlarging S to include parameters and letting U update them online, or by treating U and G as already-optimized maps obtained offline; the definition itself is agnostic to where the maps come from.*

A trivial example is a reactive agent with $S = O$ and $U(s, o) = o$, so the internal state simply caches the latest observation. In that case the action distribution at time t is conditionally independent of the earlier past given o_t, matching the usual notion of a memoryless policy. A more interesting example is a Bayesian filter in which S is a space of belief states, U is a belief update, and G selects actions based on expected value or plausibility; this matches the integration of epistemic dynamics and control emphasized earlier (Sections 20 and 14). In partially observed settings, s_t can be interpreted as an information state that renders optimal control Markovian in s_t even when the raw observation process is not Markov.

Remark 1165. *Definition 327 is deliberately minimal: it is a controlled Mealy-machine style model. Belief states (Section 20) and attention policies (Section 15) can be realized by taking S large enough to include those variables. Likewise, internal randomness (e.g. exploration noise, randomized tie-breaking, or stochastic computation) is captured by the fact that $G(s)$ is a distribution rather than a single action, and one may also represent randomized internal computation by adding a private random seed to S. When $G(s)$ is a Dirac measure for each s, the agent is deterministic at the action-selection level, and all stochasticity in the closed-loop system comes only from the task kernel P (and from any stochasticity one later chooses to place into U).*

Definition 328 (Closed-loop coupling to a task)**.** *Coupling* $\mathsf{Ag} = (S, s_0, U, G)$ *to a task* $T = (O, A, P, r, \gamma)$ *yields a Markov process on* $S \times O$ *with transition kernel*

$$\mathbb{P}\big((s,o) \to (s',o')\big) = \sum_{a \in A} G(s)(a)\ \mathbf{1}[s' = U(s,o)]\ P(o,a)(o').$$

Equivalently, given the current pair (s_t, o_t)*, we sample* $a_t \sim G(s_t)$*, set* $s_{t+1} = U(s_t, o_t)$*, and then sample* $o_{t+1} \sim P(o_t, a_t)$*; the displayed kernel is simply the one-step marginal of this generative description.*

Remark 1166. *The indicator* $\mathbf{1}[s' = U(s,o)]$ *enforces the deterministic state update: among all* $s' \in S$*, only the one equal to* $U(s,o)$ *is possible. The sum over* $a \in A$ *averages over the randomized action choice* $a \sim G(s)$*. Finally,* $P(o,a)(o')$ *is the probability that the task emits observation* o' *after seeing* (o,a)*. Because the resulting chain is Markov on* $S \times O$*, standard tools (occupancy measures, stationary distributions when they exist, mixing and recurrence conditions, etc.) become available for analyzing long-run performance and the effect of memory capacity encoded by* S*.*

This kernel makes concrete the idea that "agent + environment" is a single dynamical system. It is also the place where one can later insert richer causal or mechanistic structure: e.g. if U *is stochastic, the indicator would be replaced by an internal transition kernel. Similarly, if the task is written in a more latent-state form (e.g. an MDP on hidden states with an observation channel), the above coupling remains valid after folding the latent state into an augmented observation variable, or by extending the product space beyond* $S \times O$*.*

Remark 1167 (Agency vs mere dynamics)**.** *Any physical system has dynamics, but an "agent" in Hyperseed is a system for which (i) actions are computationally selected as a function of internal state, and (ii) internal state is updated as a function of perception, yielding an ongoing feedback loop. This is the minimal mathematical form of persistent agency. The requirement that action is selected* as a function of *internal state is what distinguishes closed-loop control from open-loop replay of a fixed action sequence; conversely, the requirement that internal state is updated* as a function of perception *distinguishes adaptive interaction from a self-contained dynamical system that never conditionally responds to its input stream.*

21.6 Autonomy, intent, and stimulate/inhibit primitives

Hyperseed distinguishes agency from autonomy, and uses "intent" plus the action polarities "stimulate"/"inhibit" as conceptual primitives for action semantics.

In this framing, *agency* is primarily about the presence of an action-selection loop (the system chooses actions as a function of its state and incoming information), while *autonomy* concerns where the system's effective objectives come from and how they change over time. The definitions below make this separation explicit by introducing intent as an explicit state component, and then defining autonomy in terms of whether that intent can be endogenously formed and updated rather than being fully imposed by the task interface.

Definition 329 (Intent variable)**.** *Let* $\mathcal{G}$ *be a set of goal-tokens (which may encode explicit goals, subgoals, or self-generated questions). An* intent-augmented agent *is an agent* Ag *whose internal state factors as* $S = \widetilde{S} \times \mathcal{G}$ *and whose action map depends on the current intent:*

$$G(\tilde{s}, g) \in \Delta(A).$$

We interpret $g_t \in \mathcal{G}$ *as the agent's* intent *at time* t*.*

Remark 1168. *The factorization $S = \widetilde{S} \times \mathcal{G}$ makes explicit a distinction that is often only implicit in control models: there is a "how am I doing" state $\tilde{s}$ and a "what am I trying to do" state g. Here $\mathcal{G}$ is intentionally token-level: it may represent explicit symbolic goals, implicit drives, active questions, or socially supplied objectives (Hyperseed-Concept* **??**, **??**, *144).*

As a toy example, $\mathcal{G} = \{\mathsf{eat}, \mathsf{hide}\}$ could encode two competing intents, and $G(\tilde{s}, g)$ may put high probability on different actions depending on whether the agent is in "eat" mode or "hide" mode, even if the observation stream is the same.

Remark 1169. *The object $G(\tilde{s}, g) \in \Delta(A)$ can be read as a policy conditioned on an explicit "goal-token" variable: it returns a distribution over actions rather than a single action so that both deliberate stochasticity (e.g. exploration) and unresolved internal conflict can be modeled without adding extra structure. When $\mathcal{G}$ is finite and relatively small, this resembles a mixture-of-policies view; when $\mathcal{G}$ is large (e.g. language-like), g functions more like a latent program pointer or a compact description of the currently active objective.*

Although we call g an "intent," nothing in the definition requires g to be linguistically reportable or consciously accessible. The main requirement is functional: g is a state component that mediates action choice in a way that is not reducible to $\tilde{s}$ alone.

Definition 330 (Autonomous agent (operational))**.** *An intent-augmented agent is* autonomous *if it contains an internal goal-formation mechanism: there exists a (possibly stochastic) update rule*

$$\Phi : \widetilde{S} \times O \to \Delta(\mathcal{G})$$

such that the intent is updated by sampling $g_{t+1} \sim \Phi(\tilde{s}_t, o_t)$, and such that Φ is not a fixed external script of the task alone (i.e. it depends nontrivially on the agent's internal state and value structure; cf. Section 18).

Remark 1170. *Operationally, autonomy is the refusal of the agent's goal dynamics to be reducible to the task's input alone. The update $\Phi(\tilde{s}, o)$ is permitted to depend on the observation o—autonomy does not mean blindness to circumstance—but it must also depend on internal organization and value, so that the agent's intent trajectory is genuinely* self-involving *(Hyperseed-Concept 119, 110; cf. [10] for a related use of fixed-point ideas to analyze self-modifying goal systems).*

A simple non-autonomous case is $\Phi(\tilde{s}, o) = \delta_{\psi(o)}$ for some externally imposed map ψ, forcing intent to be a deterministic function of observation. A more autonomous case is when $\tilde{s}$ contains long-term commitments or identity-like variables, and Φ expresses how those commitments bias goal selection.

Remark 1171. *The clause "not a fixed external script of the task alone" is meant to rule out trivial relabelings where the environment or supervisor effectively chooses g step-by-step, leaving the agent to merely execute a conditioned controller. In particular, even if Φ is learned from data, it is still non-autonomous in this sense if, at run time, its dependence on $\tilde{s}$ is vacuous or inert and all variation in g_{t+1} is driven by externally provided signals. Conversely, Φ may be highly reactive to o and still count as autonomous if that reactivity is mediated by persistent internal structure (e.g. personal constraints, commitments, or preferences encoded in $\tilde{s}$) rather than by a one-to-one task script.*

It is often useful to view Φ as a controller over controllers*: G maps $(\tilde{s}, g)$ to actions, while Φ maps $(\tilde{s}, o)$ to an updated distribution over goal-tokens. This makes room for hierarchical organization in which g selects a mode, skill, or subpolicy, and Φ implements deliberation, self-querying, or goal arbitration.*

Remark 1172 (Degree of autonomy). *Definition 330 is binary, but one can define a degree of autonomy by measuring how sensitive g_{t+1} is to internal variables vs external task signals (e.g. mutual information or causal influence measures). Hyperseed's "self-determined goal formation" can thus be treated quantitatively.*

Remark 1173. *One concrete quantitative proxy is to compare (i) the influence of $\tilde{s}_t$ on g_{t+1} holding o_t fixed versus (ii) the influence of o_t on g_{t+1} holding $\tilde{s}_t$ fixed, using either information-theoretic terms (e.g. $I(g_{t+1}; \tilde{s}_t \mid o_t)$) or interventionist ones (e.g. average causal effect under do-interventions on components of $\tilde{s}_t$). Such measures do not replace the conceptual definition, but they make the intended contrast operational in empirical or simulated settings where one can perturb internal memory, value parameters, or identity variables and observe resulting changes in the intent trajectory.*

Definition 331 (Action effects and stimulate/inhibit). *Fix a claim set $\mathcal{L}$ (Section 20) and let β be the agent's belief state. Assume that executing an action a in observation context o produces an* effect increment

$$\epsilon_{a,o} : \mathcal{L} \to \mathbb{V},$$

so that a belief update step has the form $\beta \leftarrow \beta \oplus \epsilon_{a,o}$ (possibly followed by closure). For a claim $\varphi \in \mathcal{L}$:

- *a* stimulates *φ at o if $\epsilon^+_{a,o}(\varphi) > \epsilon^-_{a,o}(\varphi)$;*
- *a* inhibits *φ at o if $\epsilon^-_{a,o}(\varphi) > \epsilon^+_{a,o}(\varphi)$;*
- *a is* neutral *on φ at o if the two are equal.*

Remark 1174. *Here $\epsilon_{a,o}(\varphi) = (\epsilon^+_{a,o}(\varphi), \epsilon^-_{a,o}(\varphi))$ is the evidence increment, contributed by doing a in context o, toward affirming or denying φ. The update $\beta \leftarrow \beta \oplus \epsilon_{a,o}$ uses $\oplus$ as evidence accumulation, which matches earlier paraconsistent belief dynamics (Section 20).*

The stimulate/inhibit distinction (Hyperseed-Concept 179, **??***) should be read as an* action semantics primitive*: actions are meaningful insofar as they tilt the evidential balance of claims. For example, if φ is "I am safe," then taking cover may stimulate φ (more positive than negative increment), while stepping into traffic may inhibit it.*

Remark 1175. *Because $\epsilon_{a,o}$ is indexed by both a and o, stimulate/inhibit is inherently context-dependent: the same motor primitive can stimulate φ in one situation and inhibit it in another. This matches ordinary action descriptions ("running" can stimulate "I am safe" when escaping danger, but inhibit it when running onto a freeway). It also highlights that stimulate and inhibit are not properties of actions in isolation, but of action-context pairs relative to a claim language $\mathcal{L}$ and an evidence scale $\mathbb{V}$.*

The strict inequalities in Definition 331 encode a simple polarity test. In applications where $\mathbb{V}$ is noisy or coarse, one may also introduce a tolerance (e.g. treat differences below a threshold as neutral), but the conceptual role remains the same: to classify action effects by which side of a claim they support.

Remark 1176. *This formalizes stimulate/inhibit as primitive polarities of action meaning. The same definition applies if φ is a pattern-claim, a goal-claim, a self-model claim, or a social claim. In later sections, $\epsilon_{a,o}$ can be derived from mechanistic models (neural, symbolic, or hybrid) or from learned causal predictors (Section 14).*

Remark 1177. *The evidence-increment view also makes room for multi-claim tradeoffs: a single action a can simultaneously stimulate some claims and inhibit others. For instance, in a social setting, speaking up might stimulate a claim like "my preference is expressed" while inhibiting "the group perceives me as agreeable." In this sense, stimulate/inhibit is not itself a utility theory; it is a semantics layer that describes how actions push on a structured set of propositions, leaving later machinery (e.g. value aggregation, intent selection, or constraint handling) to determine which claims are prioritized under a given g.*

Finally, note that nothing requires $\epsilon_{a,o}$ to be purely epistemic ("evidence about what is true") as opposed to dispositional ("evidence about what will be true"). When φ is a future-oriented claim (e.g. "I will be safe in the next minute"), $\epsilon_{a,o}$ can be interpreted as action-conditioned predictive support, which aligns stimulate/inhibit with causal control models while preserving the common representational interface of claim-level updates.

21.7 Engineered artifacts as externalized agency

Hyperseed uses "engineered" as an ontological category: a pattern (tool, machine, institution, protocol, etc.) brought into existence by intelligent action. In this sense an engineered artifact can be read as *externalized agency*: a stabilized structure in the world that continues to implement (or make easier to implement) an agent's goals even when the agent is not actively intervening at every moment. The point of treating "engineered" as a category is to capture not only material objects but also non-material but causally efficacious patterns (e.g., conventions, standards, and procedures) whose existence is reflected in reliable regularities and constraints on future trajectories.

Definition 332 (Engineered pattern / artifact)**.** *Let $\varphi_Y \in \mathcal{L}$ be the claim "artifact/pattern Y exists (in the relevant sense)." We say Y is* engineered by agent Ag *over an interval $[t_0, t_1]$ if:*

*(a) (*Emergence*) $\beta^+_{t_0}(\varphi_Y)$ is low and $\beta^+_{t_1}(\varphi_Y)$ is high;*

*(b) (*Intent alignment*) there exists an intent token g active for a nontrivial fraction of times in $[t_0, t_1]$ such that g entails (via the agent's internal rules) a positive commitment to φ_Y (Section 20);*

*(c) (*Causal dependence*) actions taken by Ag in $[t_0, t_1]$ are causally implicated in the increase of $\beta^+(\varphi_Y)$ in the sense of the causal/control notions of Section 14.*

If there exists some interval $[t_0, t_1]$ for which these hold, we call Y engineered.

The formulation intentionally uses the same representational substrate $\mathcal{L}$ and the same evidential/credal quantity $\beta^+_t(\cdot)$ that appear elsewhere, so that "coming into existence" is not treated as a primitive metaphysical event but as a transition that can be tracked within an agent/world-model interface. The parenthetical "in the relevant sense" is doing work: for a physical artifact it may mean spatiotemporal existence in an environment model, whereas for an institution or protocol it may mean existence as a socially instantiated pattern (e.g., a stable equilibrium of expectations) that the model can detect and reliably predict around.

Remark 1178. *The three conditions separate three ideas that are often conflated. Condition (a) is an epistemic/emergence criterion (Hyperseed-Concept* **??***): the world-model moves from "Y is not (evidentially) there" to "Y is there." Condition (b) asserts that the emergence is not accidental relative to the agent: it sits within the agent's intent dynamics (Hyperseed-Concept* **??***). Condition (c) requires that the agent's actions actually matter, so that "engineering" is not mere wishful thinking.*

A simple example: if Y is "a bridge across the river," then engineering requires that the bridge comes to exist, that building-a-bridge was an active intent, and that the agent's actions contributed causally to the bridge's existence. This definition is designed to interface smoothly with the later refinement into tools, machines, and programs (Section 23; Hyperseed-Concept 191, 106, 80). In particular, (b) is what distinguishes engineering from mere lucky correlation (e.g., the bridge appearing because another party built it while Ag *merely hoped for it), while (c) is what distinguishes engineering from mere endorsement (e.g., sincerely wanting a bridge and announcing that desire, but having no causal handle on the construction process).*

Remark 1179. *Definition 332 makes "engineered" neither purely physical nor purely intentional: it requires both an intentional commitment and a causal pathway from action to existence. Section 23 will refine this into tools/machines/programs and their realization semantics.*

Remark 1180. *Several boundary cases are worth making explicit because they motivate the particular choice of criteria. First, the "low"/"high" requirements in (a) are deliberately qualitative: in applications one can pick thresholds, but the conceptual role is to demand a* robust *shift in support for φ_Y, not a transient blip; this helps exclude cases where Y is merely hypothesized and then discarded. Second, (b) requires an intent token g to be active for a nontrivial fraction of $[t_0, t_1]$ so that momentary whim or post-hoc rationalization does not automatically count as engineering; the intent must play a sustained role in the policy dynamics. Third, the "causally implicated" phrasing in (c) is meant to cover indirect and distributed control: engineering a protocol or institution may proceed by writing documents, persuading others, or building coordination scaffolding, none of which is a direct physical construction step, yet each can provide the relevant control pathway under the notions of Section 14.*

Remark 1181. *The definition also accommodates multi-agent and social artifacts by allowing* Ag *to be read as an individual or a suitably defined collective agent. For example, for Y = "a ratified constitution" the emergence criterion (a) tracks the transition from nonexistence to existence of the constitutional regime in the relevant model; (b) corresponds to the presence of an active intent (e.g., "establish a constitutional order") in the collective decision process; and (c) is satisfied when the coalition's actions (drafting, negotiating, voting, enforcement) are causally responsible for the increase in support for φ_Y. Conversely, the definition is designed to exclude cases of mere discovery: learning that a natural resource deposit exists may raise $\beta^+(\varphi_Y)$ dramatically, but unless Y is defined as a newly instantiated pattern (e.g., "an operating mine" rather than "a mineral deposit"), (b) and (c) will not align in the right way for engineering.*

21.8 Intelligence, weakness minimization, and transfer by invariance

Hyperseed repeatedly links intelligence and simplicity: the intelligent system finds the weakest representation that preserves what matters for control and value. We now formalize one clean version of this principle: when a task is invariant under some coarse-graining, an agent loses nothing by failing to distinguish within the coarse-graining. Said differently, when a task "factors through" a representation map q, then planning can be performed entirely at the level of Q without sacrificing achievable return.

Definition 333 (Task quotient / abstraction)**.** *Let $T = (O, A, P, r, \gamma)$ be a task and let $q : O \to Q$ be a surjection onto a finite set Q. Define the pushforward kernel $q_* : \Delta(O) \to \Delta(Q)$ by $(q_*\nu)(B) = \nu(q^{-1}(B))$. We say q is a* task abstraction *if for all $o_1, o_2 \in O$ with $q(o_1) = q(o_2)$ and all $a \in A$:*

*(a) (*Lumpable dynamics*) $q_*(P(o_1, a)) = q_*(P(o_2, a))$;*

*(b) (*Evaluation invariance*) for all $o_+ \in O$,*

$$r(o_1, a, o_+) = r(o_2, a, o_+).$$

The pushforward q_* is the standard way to express "what distribution on abstract states is induced by a distribution on concrete observations": sampling $o_+ \sim \nu$ and then mapping to $q(o_+)$ yields a random variable on Q whose law is exactly $q_*\nu$. The surjectivity requirement means every abstract label corresponds to at least one concrete observation (no "dead" abstract states), and the finiteness of Q keeps measurability issues out of the foreground; conceptually the same definition extends to measurable Q by replacing subsets $B \subseteq Q$ with measurable sets.

Remark 1182. *The map $q : O \to Q$ is a coarse-graining: it groups fine observations into abstract classes. Condition (a) is a standard "lumpability" requirement: from the perspective of the abstract label $q(o)$, it does not matter which representative o in the fiber was actually seen, because the distribution of the next abstract label is the same. Condition (b) says the immediate evaluation likewise ignores the within-fiber distinctions.*

Intuitively, a task abstraction is an invariance: the task simply does not depend on certain details. This is the formal place where Hyperseed's simplicity/weakness thesis becomes visible: ignoring irrelevant distinctions can be free *(Hyperseed-Concept 202, 143, 169; cf. [3, 2]). One may also read this as an operational cousin of compression ideas: if the environment is invariant under identifying certain observations, then a shorter description (in the sense of algorithmic information) can suffice for control (cf. [16]).*

A useful way to internalize the two conditions is via "what the agent can affect and what the agent is scored on." Lumpability says that, after taking action a, the distribution of *future abstract observations* depends only on the *current abstract observation.* Evaluation invariance says that the instantaneous score attached to a transition (o, a, o_+) depends on o only through its abstract class; in particular, if two observations are identified by q, then they are interchangeable as far as one-step evaluation is concerned. Together these conditions ensure that the entire value computation (not just one-step statistics) can be performed on Q.

Theorem 19 (Invariant tasks admit quotient-optimal policies)**.** *Let $q : O \to Q$ be a task abstraction for $T = (O, A, P, r, \gamma)$. Then:*

(a) There exists a reduced task $T_Q = (Q, A, P_Q, r_Q, \gamma)$ such that q induces a reduction $T \to T_Q$ in the sense of Definition 321.

(b) Any policy π_Q for T_Q lifts to a policy π for T with identical p-bit *value: $J_T(\pi) = J_{T_Q}(\pi_Q)$.*

Consequently, an agent that represents observations only up to q (i.e. fails to distinguish within fibers of q) is not disadvantaged on task T.

Remark 1183. *In ordinary language, the theorem says: if the world does not care about some distinctions, then you do not need to care about them either—at least not for the sake of maximizing task value. The surprise (if any) is not that simplification can help, but that under exact invariance it can be made* rigorously lossless*: there exists an abstracted task whose optimal behavior is exactly as good as optimal behavior in the original task.*

This result connects the earlier categorical transfer machinery with the weakness/simplicity theme: the abstraction q becomes a specific reduction morphism $T \to T_Q$, so the value-preservation of lifted policies is an instance of Proposition 34. Thus, "simplicity helps generalization" here is not a slogan but a factorization through a task morphism (Hyperseed-Concept 192, 202).

One concrete way to read part (b) is that a policy for the quotient task can be executed on the original task by composing with q: the agent first maps its observation o to an abstract label $q(o)$ and then samples an action from $\pi_Q(\cdot \mid q(o))$. The equality $J_T(\pi) = J_{T_Q}(\pi_Q)$ asserts that this "act only on the abstraction" strategy is exactly value-preserving, not merely approximately good. In particular, the optimal value functions coincide under the same identification: the best return achievable by any history-independent policy on O is the same as the best return achievable by a history-independent policy on Q, because any optimal $\pi_Q^\star$ can be lifted back to O without loss.

Proof. Define $P_Q : Q \times A \to \Delta(Q)$ by $P_Q(q(o), a) := q_*(P(o, a))$. This is well-defined by lumpable dynamics. Define $r_Q(q(o), a, q(o_+)) := r(o, a, o_+)$; this is well-defined by evaluation invariance. Then (q, id_A) yields a reduction $T \to T_Q$ (take $f_O = q$ and $f_A(o, a) = a$). The lifting statement is a special case of Proposition 34. ☐

To make the "well-definedness" point completely explicit: if $q(o_1) = q(o_2)$, then condition (a) implies $q_*(P(o_1, a)) = q_*(P(o_2, a))$, so the expression $P_Q(q(o), a)$ depends only on $q(o)$ and not on the chosen representative o. Likewise, if $q(o_{+,1}) = q(o_{+,2})$, then by condition (b) (applied with fixed o and a) the value $r(o, a, o_{+,1})$ equals $r(o, a, o_{+,2})$, so writing $r_Q(q(o), a, q(o_+))$ is unambiguous as a function of abstract next-observation. Under these definitions, the lifted policy referred to in (b) can be taken concretely as $\pi(\cdot \mid o) := \pi_Q(\cdot \mid q(o))$, which matches the idea that the agent "forgets" all within-fiber distinctions before acting.

Proof sketch. Construct the quotient task by pushing the original dynamics forward along q and defining the quotient reward by the invariance condition. The abstraction axioms guarantee these definitions do not depend on which representative o of an abstract state $q(o)$ is chosen. Once this quotient task is built, the map q is immediately a reduction, so value-preserving policy lifting follows from the general transfer-by-reduction proposition. ☐

Remark 1184. *The decisive steps are the two "well-definedness" checks. Lumpability ensures that P_Q depends only on the abstract class $q(o)$, and evaluation invariance ensures r_Q is consistent across a fiber. Geometrically, one can imagine collapsing the observation space O by gluing together points in the same fiber; the theorem states that, when the task's dynamics and evaluation are constant along these fibers, the glued space supports an induced task with the same achievable values.*

This quotient construction is closely related to familiar notions of MDP homomorphism and bisimulation-style aggregation: the abstract state $q(o)$ is sufficient for predicting the next abstract state distribution and the reward. In those literatures, one often states the condition as "the abstract process is Markov" plus "rewards respect the partition," which is exactly what (a) and (b) ensure here. The present framing emphasizes the transfer consequence: invariance is not only a modeling nicety but a certificate that a weaker representation is guaranteed to be adequate for control.

Remark 1185 (Weakness reading)**.** *If an observer uses the abstraction q, it collapses distinctions among o_1, o_2 with $q(o_1) = q(o_2)$. This increases weakness (Section 3.7) relative to a fully discriminating observer. The theorem states that this "failure to distinguish" can be* free *for control on tasks that do not depend on the finer distinctions. This is a precise sense in which simplicity supports generalization and transfer.*

21.9 Micro-example: a task family with transfer by coarse-grained structure

Example 18 (Two-cluster task family on a four-element universe)**.** *Let $O = \{1, 2, 3, 4\}$ and $A = \{\mathsf{L}, \mathsf{R}\}$. Let $q : O \to Q = \{\alpha, \beta\}$ be the partition map with $q(1) = q(2) = \alpha$ and $q(3) = q(4) =$*

β. Equivalently, q identifies two equivalence classes (fibers) $\{1, 2\}$ and $\{3, 4\}$, so that any two observations in the same fiber are treated as the same "kind" of input at the abstract level.

Consider a family of tasks $\{T_\theta\}$ parameterized by a label $\theta \in \{0, 1\}$ meaning "which cluster should go left." In T_0, the intended policy is "choose L on α and R on β." In T_1, swap the actions. Thus, for each θ, there is a natural optimal policy $\pi_\theta : Q \to A$ at the abstract level, and any concrete policy $\pi : O \to A$ that factors through q (i.e., $\pi = \pi_\theta \circ q$) realizes the same behavior on all observations within a cluster.

Define dynamics so that the observation is i.i.d. uniform on O each time-step (no state dependence), and define a one-step evaluation

$$r_\theta(o, a, o_+) = \begin{cases} (1, 0) & \text{if } a \text{ matches the cluster-action label of } q(o) \text{ under } \theta, \\ (0, 1) & \text{otherwise.} \end{cases}$$

The two-component reward can be read as a minimal "success/failure" signal (e.g., first coordinate for "correct" and second for "incorrect"), and could be converted to a scalar reward by any fixed linear scalarization without changing the structural point of the example. Then q is a task abstraction for each T_θ: reward depends only on $q(o)$ and the observation law is constant on fibers. Concretely, if $q(o) = q(o')$ then (i) the conditional distribution of observations (here simply uniform, hence identical for all o) does not distinguish o from o', and (ii) the criterion for whether an action is correct is identical for o and o' under the same θ.

An agent that learns the abstraction q once (a coarse pattern: "there are two kinds of observations") can solve both *tasks with only one bit of additional information (which θ holds), achieving rapid transfer. In other words, after committing to the representation $Q = \{\alpha, \beta\}$, the remaining adaptation problem across the family $\{T_\theta\}$ is just to determine whether $\alpha \mapsto \mathsf{L}$ or $\alpha \mapsto \mathsf{R}$, which is a binary choice. An agent that insists on distinguishing all four observations has a larger hypothesis space and can require more data to discover the same transferable structure. For example, without using the quotient, a learner may treat the four mappings $1 \mapsto \mathsf{L}/\mathsf{R}$, $2 \mapsto \mathsf{L}/\mathsf{R}$, $3 \mapsto \mathsf{L}/\mathsf{R}$, $4 \mapsto \mathsf{L}/\mathsf{R}$ as independent degrees of freedom, even though the task family only varies along the single bit θ once the clustering is recognized.*

In Hyperseed language: the transferable pattern is the two-cluster schema; intellectuality appears as the speed with which the agent compresses experience into that schema and reuses it across task contexts. From this perspective, "transfer" is precisely the reuse of the learned factorization $O \xrightarrow{q} Q \to A$ across distinct values of θ, rather than relearning a fresh mapping $O \to A$ each time.

Remark 1186. *This micro-example is intentionally austere, but it displays a genuine phenomenon: the learnable invariant is not the particular mapping from $\{1, 2, 3, 4\}$ to actions, but the* partition *into two clusters (Hyperseed-Concept **??**, 103). Put differently, the family $\{T_\theta\}$ shares the same quotient structure q even though it disagrees about which abstract label should be assigned which action. Once the agent has the right abstraction, the remaining uncertainty (the bit θ) is small and can be resolved quickly, yielding high small-n intellectuality. This is a simple instance where "most" of what must be learned is representational (discovering the right grouping), while the task-specific learning reduces to a low-dimensional parameter fit.*

One can view this as a toy instance of a broader moral: discovering the right quotient is often the true work of intelligence, while selecting the right action within the quotient is then routine. Here the quotient can be seen explicitly as collapsing O by the equivalence relation $o \sim o'$ iff $q(o) = q(o')$, and the induced decision problem on Q is strictly smaller than the original one on O. This is also a point of contact with compression-based views of learning, where discovering a shorter description of the environment can reduce sample complexity (cf. [16]). In particular, once the agent encodes *the data using the two-symbol alphabet $\{\alpha, \beta\}$ rather than four unrelated symbols, fewer examples are needed to justify a stable generalization across the full observation set, because each new data point supports a whole cluster rather than a single element.*

21.10 Ensembles, attention, and cognitive synergy as intelligence multipliers

Finally, we relate intelligence to attention and synergy (Section 15) in a minimal theorem: combining monotone cognitive processes cannot reduce capability, and can strictly improve it when different processes capture complementary transferable patterns. In this subsection, "cognitive processes" can be read broadly: any subsystem that produces a belief state over a shared claim language (e.g. a perceptual channel, a model-based predictor, a memory retriever, a theorem-prover, or an attentional module that re-weights which claims are salient). The key structural move is that combining such processes is modeled as an order-theoretic join on beliefs, while the downstream control layer (action selection) is required to respect that order. This makes the non-degradation statement essentially a monotonicity fact: more (ordered) evidence should not force fewer (good) options.

Definition 334 (Monotone action selection from beliefs)**.** *Let β range over belief states $\mathcal{L} \to \mathbb{V}$ with pointwise order. An action-selection map $\mathcal{A}(\beta) \in \Delta(A)$ is* monotone *if $\beta_1 \leq \beta_2$ implies $\mathcal{A}(\beta_1)$ is no more restrictive than $\mathcal{A}(\beta_2)$ (e.g. the set of actions above a fixed value threshold only grows). In particular, one can interpret "no more restrictive" in several compatible ways depending on how $\Delta(A)$ is used: as inclusion of supports (actions assigned nonzero probability), as inclusion of an "admissible" subset of A underlying a stochastic choice, or as monotonic expansion of the set of actions exceeding a choice criterion computed from β. The requirement is intentionally permissive: it does not force a unique policy, only that improving beliefs (in the $\leq$ sense) cannot invalidate actions that were previously permissible under weaker belief.*

Remark 1187. *Pointwise order on belief states means $\beta_1 \leq \beta_2$ iff for every claim φ, $\beta_1(\varphi) \leq \beta_2(\varphi)$ in the* p-bit *order. Monotonicity then encodes a rational constraint: adding evidence should not arbitrarily forbid actions that were previously considered acceptable. This is a mild structural assumption, compatible with many decision rules, including thresholding, softmax-like schemes, and dominance filters. A useful way to read this is: if β_2 strengthens β_1 claim-by-claim, then any action that was defensible given β_1 should remain defensible given β_2 (even if it is no longer the most preferred). In practice, one can enforce such monotonicity by separating (i) a monotone feasibility or admissibility stage from (ii) a tie-breaking or exploration stage; only the former needs to be monotone for the proposition below to go through.*

Conceptually, monotonicity is a thin formal expression of a cognitive-synergy desideratum: when additional cognitive processes contribute additional distinctions or evidence, the control layer should be able to exploit them rather than being confused by them (Hyperseed-Concept 73, 60). This also clarifies the role of attention: attentional focus can be viewed as a resource-allocation choice about which claims are evaluated or refined, and the monotonicity requirement says that refining attention (thereby increasing certain belief values) should not itself destroy previously available behavioral options.

Proposition 35 (Parallel join of evidence cannot hurt under monotone control)**.** *Suppose two cognitive subsystems produce belief states $\beta^{(1)}$ and $\beta^{(2)}$ over the same claim language, and the agent combines them by $\beta := \beta^{(1)} \oplus \beta^{(2)}$ (pointwise join). If the downstream action-selection mechanism is monotone in the belief state, then for any task T the combined system can achieve competence at least as high as the better subsystem acting alone:*

$$\mathrm{Comp}(\mathsf{Ag}_{\oplus}; T) \;\geq\; \max\{\mathrm{Comp}(\mathsf{Ag}_1; T), \mathrm{Comp}(\mathsf{Ag}_2; T)\}.$$

The implicit intuition is that $\mathsf{Ag}_\oplus$ *has access to* at least *the evidential basis of each subsystem, so it can always choose to ignore whichever parts of the combined belief are unhelpful for a given decision and reproduce the choices of the stronger subsystem. When* Comp *is evaluated via expected task performance under the policy induced by* $\mathcal{A}(\beta)$*, the inequality should be read as an existence-style guarantee: there exists a valid way for the combined agent to act (consistent with monotone control) that attains at least the better subsystem's competence, even if a particular learning or optimization procedure may fail to find it.*

Remark 1188. *The proposition says, in effect, that "having two eyes cannot make you see worse," provided your action-selection respects the ordering of evidence. It is not claiming that naive ensembling always yields large gains; it is claiming a non-degradation property: if one subsystem was already good, joining in additional evidence does not force you to throw away the good option. This is one of the simplest rigorous footholds for the broader Hyperseed theme that cognitive synergy can multiply intelligence (Hyperseed-Concept 73; cf. [19]). A further operational reading is that the combined system can implement a* gating *or* fallback *strategy: if subsystem 1 is reliable on a task family while subsystem 2 contributes sporadically, then the joined belief state can preserve the reliable action set while occasionally unlocking additional high-value actions when subsystem 2 provides confirming evidence. This highlights why monotonicity is the right minimal assumption: without it, a control rule could react pathologically to extra information by collapsing to a worse action set, destroying the intended benefit of parallel cognition.*

Proof. Pointwise, $\beta^{(i)} \leq \beta^{(1)} \oplus \beta^{(2)}$ for $i = 1, 2$. By monotonicity of action selection, any action deemed feasible/good under $\beta^{(i)}$ remains feasible under the joined belief state. Therefore the combined agent can simulate whichever subsystem attains the higher competence on T. To make the simulation idea concrete, fix $i \in \{1, 2\}$. If under $\beta^{(i)}$ the control layer would select from some admissible set (or distributional support) $S_i \subseteq A$, monotonicity ensures that under β the admissible set S satisfies $S_i \subseteq S$ in the relevant "no more restrictive" sense. Thus the combined agent is permitted to choose exactly the same action (or sample from exactly the same distribution) that Ag_i would, yielding the same task performance; taking the better of the two establishes the stated lower bound. □

Proof sketch. The join $\oplus$ is an upper bound, so each subsystem's belief state is below the combined belief state. Monotonicity ensures that moving upward in belief cannot eliminate the actions available before. Hence the combined agent can always choose to behave exactly like the better subsystem, ensuring competence at least as large as the maximum of the two. Equivalently, the combined system has a "safe policy" option: default to the better-performing subsystem's behavior, and only deviate when the joined evidence expands (rather than shrinks) the set of admissible high-quality actions. □

Remark 1189. *The proof is short because the algebra is doing the work:* $\oplus$ *is a join, so it is literally the least upper bound, and monotonicity is exactly the condition needed to ensure upward movement in belief does not remove options. If one wants a visual intuition, imagine two partial maps of a landscape; taking their join is like overlaying them so that any marked safe path remains marked safe. Strict improvement becomes possible when the joined belief state reveals an action that neither subsystem, in isolation, had enough evidence to select. One simple sufficient condition for strictness (in threshold-based controllers) is: there exists an action* $a^\star$ *such that under each* $\beta^{(i)}$ *its score lies just below the selection threshold, but under* $\beta^{(1)} \oplus \beta^{(2)}$ *it crosses the threshold due to complementary evidence. This captures the intended "complementary transferable patterns" case: each subsystem supplies a different piece of reusable structure, and only their combination yields a decisive signal at the control interface.*

Remark 1190 (Why this matters for Hyperseed). *This proposition is a minimal mathematical expression of "cognitive synergy" as an intelligence multiplier: multiple partial processes, each limited in what distinctions it can track, can be combined without loss, and with potential gain when their pattern abstractions and transfer morphisms complement one another. Quantale weakness then provides the bookkeeping for which distinctions are being collapsed and where new distinctions are worth paying for. In particular, if weakness parameters encode which claims are represented coarsely (or ignored) by a subsystem, then different subsystems may be weak in different places; the join can partially undo those independent collapses without requiring either subsystem to bear the full representational cost alone. This clarifies a concrete route by which attention-like mechanisms (allocating representational precision to a subset of claims) and ensemble-like mechanisms (aggregating multiple such allocations) interact to yield a net capability increase.*

21.11 GTGI-inspired quantitative measures of general intelligence

This subsection introduces a family of quantitative functionals intended as concrete instantiations of *General Intelligence* (Hyperseed-Concept **??**) in the style of GTGI. These functionals are phrased in a policy–environment interaction formalism, but can be read as special cases of Hyperseed's broader "task environment" formalism (cf. the task-set/breadth machinery used to sharpen the general/narrow distinction; see Hyperseed-Concept 118).

Basic interaction model. Fix countable sets of actions $\mathcal{A}$ and observations $\mathcal{O}$, and a reward set $\mathcal{R} \subseteq [0,1] \cap \mathbb{Q}$. A (stochastic) policy is a map

$$\pi : (\mathcal{A} \times \mathcal{O} \times \mathcal{R})^* \to \Delta(\mathcal{A}),$$

and an (AIXI-style) environment is a map

$$\mu : (\mathcal{A} \times \mathcal{O} \times \mathcal{R})^* \times \mathcal{A} \to \Delta(\mathcal{O} \times \mathcal{R}),$$

where $\Delta(S)$ denotes the set of probability distributions on S. Writing $\mathbb{E}_{\mu,\pi}[\cdot]$ for expectation over trajectories induced by the interaction of π with μ, define the (undiscounted) expected total reward

$$V_\mu^\pi \;:=\; \mathbb{E}_{\mu,\pi}\left[\sum_{t=1}^{\infty} r_t\right].$$

Definition 335 (Reward-summable environment). *An environment μ is* reward-summable *iff for every policy π,*

$$V_\mu^\pi \;=\; \mathbb{E}_{\mu,\pi}\left[\sum_{t=1}^{\infty} r_t\right] \;\le\; 1.$$

(Glossary: Hyperseed-Concept 210.)

Definition 336 (Universal intelligence). *Let $\mathcal{E}$ be a chosen set of reward-summable environments. The* universal intelligence *of a policy π is*

$$\Upsilon(\pi) \;:=\; \sum_{\mu \in \mathcal{E}} 2^{-K(\mu)}\, V_\mu^\pi,$$

*where $K(\mu)$ is Kolmogorov complexity (Hyperseed-Concept **??**) with respect to a fixed description/decoding scheme. (Glossary: Hyperseed-Concept 211.)*

Definition 337 (GTGI goal function)**.** *A* GTGI goal function *is a map*

$$g : (\mathcal{A} \times \mathcal{O})^* \to \mathcal{R}.$$

Given a trajectory prefix $x_{1:t} := (a_1, o_1, \ldots, a_t, o_t) \in (\mathcal{A} \times \mathcal{O})^*$*, the goal-induced reward at time* t *is*

$$r_t \;:=\; g(x_{1:t}).$$

(Glossary: Hyperseed-Concept 212.)

Definition 338 (Natural timescale indicator)**.** *Given a goal function* g *and environment* μ*, a* natural timescale indicator *is a map*

$$\tau_{g,\mu} : \mathbb{N}_{>0} \to \{0, 1\},$$

where $\tau_{g,\mu}(n) = 1$ *indicates that evaluating performance on* g *in* μ *over* n *steps is considered meaningful, and* $\tau_{g,\mu}(n) = 0$ *indicates it is not. (Glossary: Hyperseed-Concept 213.)*

Definition 339 (GTGI context)**.** *A* GTGI context *is a triple*

$$c \;=\; (\mu, g, T),$$

where μ *is an environment,* g *is a goal function, and* $T = \{t_1, \ldots, t_2\}$ *is a finite time-interval of discrete steps. Its length is* $|T| := t_2 - t_1 + 1$*.*

Given a policy π*, the* expected goal-achievement *of* π *in context* (μ, g, T) *is*

$$V^{\pi}_{\mu,g,T} \;:=\; \mathbb{E}_{\mu,\pi}\left[\sum_{t=t_1}^{t_2} r_t\right], \qquad r_t := g(x_{1:t}).$$

(Glossary: Hyperseed-Concept 214.)

Definition 340 (Pragmatic general intelligence)**.** *Let* $\mathcal{E}$ *be a chosen class of environments,* $\mathcal{G}$ *a chosen class of goal functions, and* $\mathcal{T}$ *a chosen class of finite time-intervals. Let* ν *be a probability distribution on* $\mathcal{E}$*, and let* $\gamma(\cdot, \mu)$ *be a conditional probability distribution on* $\mathcal{G}$ *for each fixed* $\mu \in \mathcal{E}$*. The* pragmatic general intelligence *of a policy* π *(relative to* ν *and* γ*) is*

$$\Pi(\pi) \;:=\; \sum_{\mu \in \mathcal{E}} \sum_{g \in \mathcal{G}} \sum_{T \in \mathcal{T}} \nu(\mu)\, \gamma(g, \mu)\, \tau_{g,\mu}(|T|)\, V^{\pi}_{\mu,g,T},$$

whenever the sum is convergent. (Glossary: Hyperseed-Concept 215.)

Definition 341 (Resource-consumption distribution)**.** *Fix a discrete resource scale* $\mathcal{Q} \subseteq \mathbb{R}_{>0}$ *(e.g. time-steps, FLOPs, bytes). For each context* (μ, g, T)*, a* resource-consumption distribution *is a probability distribution*

$$\eta_{\mu,g,T} : \mathcal{Q} \to [0, 1], \qquad \sum_{Q \in \mathcal{Q}} \eta_{\mu,g,T}(Q) = 1,$$

where $\eta_{\mu,g,T}(Q)$ *is the probability that* Q *units of computational resources are consumed by the agent/policy while pursuing* g *in* μ *over* T*. (Glossary: Hyperseed-Concept 216.)*

Definition 342 (Efficient pragmatic general intelligence)**.** *With the same $\mathcal{E}, \mathcal{G}, \mathcal{T}, \nu, \gamma, \tau$ as in Definition 340, and with resource distributions $\eta_{\mu,g,T}$ as in Definition 341, the* efficient pragmatic general intelligence *of π is*

$$\Pi^{\mathrm{eff}}(\pi) \;:=\; \sum_{\mu\in\mathcal{E}} \sum_{g\in\mathcal{G}} \sum_{T\in\mathcal{T}} \sum_{Q\in\mathcal{Q}} \nu(\mu)\,\gamma(g,\mu)\,\tau_{g,\mu}(|T|)\,\eta_{\mu,g,T}(Q)\,\frac{V^{\pi}_{\mu,g,T}}{Q},$$

whenever the sum is convergent. (Glossary: Hyperseed-Concept 217.)

Definition 343 (Intellectual breadth)**.** *Define the* context-competence weight *of π on (μ, g, T) by*

$$\chi_{\mathrm{Con}_\pi}(\mu, g, T) \;:=\; \sum_{Q\in\mathcal{Q}} \eta_{\mu,g,T}(Q)\,\frac{V^{\pi}_{\mu,g,T}}{Q}.$$

Define a normalized distribution over contexts by

$$\chi^{P}_{\mathrm{Con}_\pi}(\mu, g, T) \;:=\; \frac{\nu(\mu)\,\gamma(g,\mu)\,\tau_{g,\mu}(|T|)\,\chi_{\mathrm{Con}_\pi}(\mu, g, T)}{\sum_{\mu',g',T'} \nu(\mu')\,\gamma(g',\mu')\,\tau_{g',\mu'}(|T'|)\,\chi_{\mathrm{Con}_\pi}(\mu', g', T')},$$

assuming the denominator is finite and nonzero. The intellectual breadth *of π is the Shannon entropy of this distribution:*

$$B_{\mathrm{int}}(\pi) \;:=\; -\sum_{\mu,g,T} \chi^{P}_{\mathrm{Con}_\pi}(\mu, g, T)\,\log\big(\chi^{P}_{\mathrm{Con}_\pi}(\mu, g, T)\big),$$

with a fixed choice of log base (e.g. base 2). (Glossary: Hyperseed-Concept 218.)

Intuitively, $\chi_{\mathrm{Con}_\pi}(\mu, g, T)$ aggregates performance $V^{\pi}_{\mu,g,T}$ across an explicit "difficulty" or "complexity" index $Q \in \mathcal{Q}$, weighted by $\eta_{\mu,g,T}(Q)$. The factor $1/Q$ implements a conventional complexity penalty: holding value fixed, competence concentrated on lower-complexity (easier) contexts contributes more weight, while competence only at higher-complexity contexts is discounted. This makes the induced distribution $\chi^{P}_{\mathrm{Con}_\pi}$ sensitive not merely to raw reward, but to where (across context families and difficulty) that reward is being obtained.

The normalized quantity $\chi^{P}_{\mathrm{Con}_\pi}(\mu, g, T)$ can be read as a posterior-like mass function over contexts, proportional to (i) prior plausibility of environments $\nu(\mu)$, (ii) a coupling term $\gamma(g, \mu)$ indicating which goals g are meaningfully posed in which environments μ, (iii) a length- or horizon-weighting $\tau_{g,\mu}(|T|)$ over task sets of size $|T|$, and (iv) the context-competence weight itself. Under this interpretation, $B_{\mathrm{int}}(\pi)$ measures how widely the policy's competence is spread across the space of contexts after *accounting for these priors/weights: high entropy corresponds to competence that is distributed across many distinct (μ, g, T) rather than concentrated on a small subset.*

The finiteness/nonzero assumption on the denominator is not only technical but conceptual: it enforces that the weighted competence mass is normalizable, i.e. the choice of $(\nu, \gamma, \tau, \eta)$ yields a well-posed comparison across policies. In particular, if $\mathcal{Q}$ or the context index set is infinite, then the decay of $\eta_{\mu,g,T}(Q)$ (and the interaction with $1/Q$) governs whether χ_{Con_π} is finite; similarly, the tails of $\nu(\mu)$ and $\tau_{g,\mu}(|T|)$ govern whether the global sum is finite.

Finally, the choice of log base only rescales $B_{\mathrm{int}}(\pi)$ (e.g. bits for base 2, nats for base e), so comparisons of breadth across policies are invariant up to a constant factor. In applications, one often pairs this entropy with a separate level term (e.g. average competence) to distinguish "broad but weak" from "broad and strong" policies, although the present definition isolates breadth as dispersion of competence mass.

Definition 344 (Multi-criterion driven general intelligence)**.** *Fix a feasible policy class* Π_{adm} *and a vector of objective functionals*

$$\mathbf{J}(\pi) := (J_1(\pi), \dots, J_k(\pi)) \in \mathbb{R}^k, \qquad \pi \in \Pi_{\mathrm{adm}},$$

intended to represent multiple desiderata (e.g. efficiency Π^{eff}*, breadth* B_{int}*, and additional Hyperseed-relevant criteria such as joy/growth/choice). Define Pareto dominance by* $\pi' \succ \pi$ *iff*

$$(\forall i \in \{1, \dots, k\})\ J_i(\pi') \geq J_i(\pi) \quad \textit{and} \quad (\exists j)\ J_j(\pi') > J_j(\pi).$$

The multi-criterion general intelligence set *(Pareto front) is*

$$\mathrm{Pareto}(\mathbf{J}) \ := \ \{\pi \in \Pi_{\mathrm{adm}} : \nexists \pi' \in \Pi_{\mathrm{adm}} \textit{ with } \pi' \succ \pi\}.$$

(Glossary: Hyperseed-Concept 219.)

This definition makes explicit that "general intelligence" (as operationalized here) is not a single scalar score but a family *of trade-offs among multiple desiderata. Concretely, the feasible class* Π_{adm} *encodes admissibility constraints (e.g. computational budgets, safety constraints, embodiment limits, permitted interventions, or epistemic limitations), so that the Pareto set is taken over policies that are actually realizable under the system's design and deployment assumptions.*

Each coordinate $J_i(\pi)$ *can be interpreted as a measurement functional induced by some benchmark family: for instance, an efficiency-like functional might quantify reward per unit time/compute; a breadth-like functional can be instantiated by* $B_{\mathrm{int}}(\pi)$*; and additional coordinates can encode desiderata that are not reducible to reward maximization (e.g. robustness, corrigibility, preference learning quality, or more explicitly Hyperseed-aligned constructs such as joy/growth/choice). The Pareto-front framing prevents premature scalarization: if two policies differ such that neither is uniformly better across all criteria, both remain "optimal" in the multi-criterion sense.*

The strict inequality requirement in at least one coordinate ensures that Pareto dominance captures genuine improvement rather than equality. In practice, one may also consider ε*-dominance (to model measurement noise) or impose partial orders induced by constraints (e.g. treat some* J_i *as hard constraints and others as objectives). These are refinements of the same core idea: multi-criterion general intelligence is identified with non-dominated policies relative to a declared objective vector, rather than with a unique maximizer of a single aggregated score.*

Because $\mathrm{Pareto}(\mathbf{J})$ *is a set, it naturally supports subsequent selection principles (e.g. choose among Pareto-optimal policies using a domain-specific preference over trade-offs, or choose policies that remain Pareto-optimal under shifts in* ν, γ, τ *defining breadth). This separation of* measurement *(the* J_i*) from* selection *(how one picks a point on the front) is often crucial when aligning agent behavior to pluralistic or evolving desiderata.*

Hyperseed concepts covered

- Tasks; task sets; intellectuality as rapid transfer/generalization across tasks.
- General intelligence vs narrow intelligence (breadth and learning-curve measures).
- Agent as persistent perception-action loop; closed-loop coupling to a task.
- Autonomous agent via internal goal/intent formation and revision.
- Intent as an explicit variable shaping policy; autonomy as nontrivial internal intent dynamics.
- Stimulate/inhibit as action primitives defined by p-bit-valued effect increments on claims.

- Engineered as an ontological category for artifacts/patterns brought into existence by intent-aligned, causally efficacious intelligent action.
- Various formal criteria for measuring degres of general intelligence (and related quantities)

The two definitions above provide a quantitative bridge from task-centric competence to agency-level evaluation. The "intellectual breadth" measure turns competence across environments, goals, and task-sets into an information-theoretic dispersion score, making it possible to distinguish a policy that is competent in many context families from one that is competent in only a few. The "multi-criterion" construction then places such breadth alongside other desiderata and treats general intelligence as residing in the set of non-dominated feasible policies, rather than collapsing all considerations into a single number.

22 Society, culture, and collective mind systems

22.1 From individual agents to social pattern webs

Previous sections treated a single observer/context as the primary bearer of distinctions, patterns, beliefs, and action (Sections 9–21). Hyperseed then scales this picture to groups: societies, tribes, cultures, and collective minds. The key methodological move is conservative:

- Keep the same core mathematics (paraconsistent `p-bit` evidence values and quantale-style composition), but
- allow *multiple* agents to be coupled by communication and shared artifacts, so that *patterns can span agents.*

Concretely, "scaling to groups" is not treated as changing the kind of object under study, but as changing the *boundary* of the system whose pattern web we track. The individual case studies a pattern web internal to one agent's perceptual-cognitive-action loop; the social case studies a pattern web distributed across many such loops, with additional coupling edges corresponding to message passing, imitation, norm enforcement, and environment-mediated coordination. The key consequence of keeping the same evidence and composition machinery is that all the usual operations for combining, propagating, and constraining patterns (including accumulation of partial evidence, composition of subroutines, and coexistence of incompatible commitments) remain valid, but they now apply to a larger graph whose nodes may be multi-agent processes rather than intra-agent ones.

The phrase "patterns can span agents" should be read literally: some patterns are not located in any single head, but are only well-defined at the level of *interaction.* For example, a question–answer routine, a bargaining protocol, a classroom lecture, or a market price formation process can be treated as a pattern whose realizations require at least two roles (and typically multiple agents), with regularities that persist even as individual participants change. In the same spirit, a shared artifact (a text, law, map, software repository, or ritual object) can be treated as a persistent substructure in the overall pattern web, providing stable constraints and coordination points that outlast particular communicative episodes.

Remark 1191. *The philosophical point is that "sociality" is not introduced as an extra substance. Rather, it is introduced as an additional layer of* composition*: we keep the individual-level formalism, but we allow morphisms (influence, communication, artifact-mediated constraint) to connect individual pattern webs into a larger web. This aligns with Hyperseed's general stance that much* *of mind is a matter of structured pattern dynamics rather than an ineffable residue; see also the general Hyperseed ontology framing in [1].*

This compositional framing also makes it natural to treat social phenomena as having multiple simultaneous "carriers": (a) transient signals (spoken utterances, gestures, posts), (b) relatively stable media (documents, institutions, codebases), and (c) embodied habits (skills, practices, and dispositions). In the formalism, these carriers correspond to different kinds of coupling edges and different persistence timescales, but they can still be integrated by the same evidence calculus: signals supply short-lived evidence pulses, institutions provide long-lived constraints, and habits implement default transitions that bias future pattern activation.

In Hyperseed-Concept terms, what is being formalized here is chiefly Society *(Hyperseed-Concept 170),* Culture *(Hyperseed-Concept 91), and the move from individual* Pattern Web *dynamics to group-scale* Pattern Web *dynamics (Hyperseed-Concept 132), with explicit allowance for contradiction via* Value Paraconsistency *(Hyperseed-Concept 198).*

The explicit role of paraconsistency becomes especially salient at the social scale: groups commonly exhibit stable patterns of behavior while holding mutually inconsistent narratives, norms, or self-models. Rather than forcing premature consistency (which would erase important empirical structure), `p-bit`*-valued evidence allows a society-level pattern web to encode, for example, that a norm is publicly endorsed, privately doubted, and selectively enforced, without collapsing into triviality. This supports modeling phenomena such as pluralism, taboo, propaganda, institutional hypocrisy, and multi-layer norm systems as structured configurations of evidence and composition rather than as exceptions to rational modeling.*

In this section we formalize: (i) societies and tribes as coupled multi-agent pattern webs; (ii) communicative acts and communicative systems (speech acts and their physical realizations); (iii) social roles as interaction templates (teacher, student, worker, colleague); (iv) culture as stabilized intersubjective pattern web; and (v) collective mind systems, including mindplex and global brain.

Item (i) focuses on the graph-theoretic and algebraic structure of coupling: agents are treated as pattern-web-bearing subsystems, while social ties become morphisms that transmit constraints, evidence, and action affordances. Importantly, coupling can be asymmetric (authority, expertise, dependence), delayed (archives, reputation), or mediated (institutions, markets), and these variants correspond to different composition pathways and update schedules in the distributed web.

Item (ii) separates the *illocutionary* aspect of communication (what act is performed: asking, promising, warning, asserting) from its *physical realization* (sound waves, ink, bits). This distinction matters because the same physical channel can realize different speech acts depending on context, and the same speech act can be realized across many channels; the formalism therefore treats communicative acts as patterns that can be instantiated in multiple substrates, with evidence accumulating both from content and from channel-dependent credibility cues.

Item (iii) treats roles as reusable interface specifications for multi-agent patterns: a role constrains what inputs are expected, what outputs are permissible, and what transitions are typical. Roles thus act as higher-level templates that compress social complexity: instead of modeling each dyad from scratch, one models role-structured interactions and then binds agents to roles in particular contexts, allowing rapid composition of large-scale social dynamics.

Item (iv) characterizes culture as what remains invariant (or changes only slowly) when individuals enter and leave: a stabilized, intersubjective pattern web whose persistence is supported by enculturation, shared artifacts, and institutional reinforcement. On this view, cultural "beliefs" need not be located as propositional attitudes inside individuals; they can be seen as constraints on what patterns are easy to activate, acceptable to express, or rewarded to enact in the social web.

Item (v) extends the same apparatus to collective mind systems in which coordination and shared artifact layers become sufficiently rich that group-level cognitive functions emerge: distributed attention (what the group monitors), distributed memory (archives and traditions), distributed planning (organizations and governance), and distributed self-modeling (public narratives and metrics). The terms "mindplex" and "global brain" are treated here as endpoints on a spectrum of integration: a mindplex emphasizes tightly coupled subcommunities (e.g., institutions or networks) whose interaction yields coherent higher-level dynamics, while the global brain emphasizes planetwide information flow and coordination patterns spanning many such subsystems, without presuming a single central controller.

22.2 Minimal social data: agents, coupling, and shared artifacts

We assume the general agent notion from Section 21: agents are persistent perception–action loops interacting with an environment, and autonomous agents are those for which a significant fraction of action has simplest-causal explanations internal to the agent.

For social modeling we need, minimally, (a) a set of agents, (b) an interaction structure, and (c) a way to represent communication and shared artifacts.

Remark 1192. *The qualifier "minimally" is important: richer models often include internal state spaces, explicit message contents, norms, payoffs, or learning rules. Here we separate what is* structural *(who can affect whom, and what durable objects mediate coordination) from what is* dynamical *(how agents update). The point of this subsection is to provide just enough scaffolding that later sections can state fixed-point, stabilization, and propagation claims without committing to a specific cognitive architecture.*

Definition 345 (Interaction graph and coupling weights)**.** *Let A be a (finite or infinite) set of agents. An* interaction graph *on A is a directed graph*

$$G = (A, E), \qquad E \subseteq A \times A,$$

where $(i, j) \in E$ means agent i can directly influence agent j (by communication, direct action, or mediated action that is "social" from the modeling perspective).

A coupling weight *is an assignment*

$$K : E \to [0, 1] \quad or \quad K : E \to \mathbb{V} = [0, 1]^2,$$

depending on whether we want a scalar coupling or a paraconsistent (two-axis) coupling. We interpret larger $K(i, j)$ as higher bandwidth, trust, salience, or effectiveness of i's influence on j.

Remark 1193. *When A is infinite, the interaction graph is best thought of as a* relation *rather than a finite data structure. In applications one may impose additional regularity (e.g. bounded out-degree, locality constraints, or measurability assumptions) so that aggregate quantities (such as total incoming coupling to an agent) are well-defined. Nothing in the present definition forces such assumptions, but later analytic arguments may add them as needed.*

Remark 1194. *A directed edge (i, j) is not meant to imply a moral direction, but an* operational *direction: there exists some channel (speech, coercion, imitation, infrastructural control, shared tools, etc.) through which i can nontrivially alter j's future internal state or external behavior. The weight $K(i, j)$ then compresses many concrete facts (bandwidth, reliability, attention, authority) into a single scalar or* p-bit*-pair.*

As a simple example, in a small lab group one might take $K(i, j) \approx 0.8$ for supervisor-to-student instruction, but $K(j, i) \approx 0.3$ for the reverse direction. In a peer group, one might have $K(i, j) \approx K(j, i) \approx 0.6$ for many pairs. These are not "true" numbers; they are a modeling device for the later fixed-point and stabilization arguments.

Remark 1195. *In practice, $K(i, j)$ may summarize multiple distinct channels (e.g. direct conversation, group chat, shared work products, or observation of third-party interactions). One can interpret $K(i, j)$ as an* effective *coupling after coarse-graining across channels and timescales. This is useful when the model aims to capture macroscopic phenomena (consensus, polarization, institutional persistence) rather than the microstructure of individual conversations.*

Remark 1196 (Why allow $\mathbb{V}$-valued coupling?)**.** *If coupling is scalar, it can only say "more" or "less" influence. If coupling is* p-bit*-valued, it can also represent* ambivalent *links: e.g. high positive coupling (strong influence) together with high negative coupling (active resistance, distrust, or adversarial framing). This matters in social settings where attention and belief updates can be both attracted and repelled.*

Remark 1197. *Allowing $\mathbb{V}$-valued coupling is also a mathematical way to treat "mixed valence" social relations without forcing them into a single real axis. In many real societies, a source may be simultaneously salient and distrusted; the recipient may attend closely in order to rebut, parody, or guard against manipulation. Paraconsistency thus enters not only at the level of* beliefs *but at the level of* channels *themselves, echoing Hyperseed's broader stance that contradiction is often a stable feature of complex adaptive systems rather than an immediate catastrophe; compare [3] for related uses of resource-sensitive algebraic structure.*

Remark 1198. *One convenient reading of a* p-bit*-valued edge $K(i, j) = (k^+(i, j), k^-(i, j))$ is that k^+ parameterizes how strongly j is pulled toward adopting or integrating i's outputs, while k^- parameterizes how strongly j is pushed toward counter-signaling, discounting, or producing anti-correlated outputs in response. This interpretation allows a single graph to represent settings in which opposition is coupled (and thus structured) rather than merely absent interaction.*

Remark 1199. *Nothing requires the coupling to be static across time. One may generalize to $K_t(i, j)$ (discrete time) or $K(i, j; t)$ (continuous time) to represent attention cycles, institutional reconfigurations, or learning about trustworthiness. In such cases the interaction graph itself can be time-varying, e.g. $E_t \subseteq A \times A$, with edges appearing or disappearing as agents enter or leave a community, or as communication channels become available or are blocked.*

Definition 346 (Shared artifacts)**.** *Let $\mathcal{A}$ be a set of* artifacts *(documents, tools, rituals, institutions, machines, shared environments, shared memory stores, etc.). An* access relation *is a relation*

$$\mathrm{Acc} \subseteq A \times \mathcal{A},$$

where $(i, a) \in \mathrm{Acc}$ means agent i can read/use/modify artifact a (in the sense relevant to the model). Optionally, we enrich access with weights $\kappa(i, a) \in [0, 1]$ or $\kappa(i, a) \in \mathbb{V}$ to represent accessibility, trust, and friction.

Remark 1200. *The access relation is intentionally broad: "read" may mean perception (seeing a public sign), "use" may mean executing a procedure embodied in a tool, and "modify" may mean editing a document, changing an institutional policy, or physically altering an environment. In many cases, access is asymmetric: some agents can modify an artifact that others can only observe, which can be represented either by directional refinement (separate read/write relations) or by encoding this asymmetry in $\kappa(i, a)$.*

Remark 1201. *One may also view $(A, \mathcal{A}, \mathrm{Acc})$ as a bipartite graph and then "project" it to obtain an induced agent–agent coupling via shared artifacts: two agents become effectively coupled if they co-access or co-modify the same artifact. This makes explicit how environments and institutions can generate social structure even when direct communication is sparse.*

Remark 1202. *Artifacts are the simplest route from ephemeral interaction to durable structure. An utterance fades, but a written protocol, a code repository, a ritual, or an institution can persist and thereby "store" patterns that many agents can later re-import into their own webs. In Hyperseed-Concept terms, this is a core mechanism by which* Culture *(Hyperseed-Concept 91) acquires memory beyond individual lifetimes.*

As an example, a shared calendar is an artifact: it constrains coordination by offering a persistent representation of commitments. A library is an artifact: it stores a vast set of template patterns and inference habits that can be repeatedly instantiated by different minds. Even a physical tool can be an artifact in this sense; Section 23 treats this more explicitly via physical realizations of abstract processes.

Remark 1203. *The artifact view also clarifies how "the same" cultural object can be instantiated in many media. A norm may exist as an explicit written rule, as a repeated ritual practice, and as a set of implicit expectations encoded in many agents' policies; modeling it as an artifact (or a small constellation of artifacts) provides a common handle for these heterogeneous realizations. This will matter later when distinguishing transient alignment (momentary coordination) from persistent alignment (coordination maintained by externalized memory and enforcement).*

Artifacts are crucial in Hyperseed because they create durable cross-agent coupling: a belief, pattern, or procedure can persist outside any one individual and propagate through time.

Remark 1204. *This durability can be treated as a timescale separation: interactions among agents may be fast and noisy, while artifact dynamics are slower and more inertial. Modeling artifacts explicitly therefore supports explanations of social stability (and of abrupt regime shifts) that do not rely on assuming stable individual psychology. In particular, once artifacts are present, a society can exhibit path-dependence: early contingencies become "locked in" by persistent representations that shape later learning and coordination.*

22.3 Society as a coupled multi-agent system

Hyperseed's informal definition emphasizes sustained close interaction and dependence. Our formal definition keeps the spirit but stays minimal. In particular, the aim is to isolate a small set of *coupling primitives* that can later be instantiated in many ways: communication, imitation, exchange, instruction, coercion, care, and other recurrent channels of mutual influence. The guiding idea is that "being a society" is less about any one mechanism (e.g. kinship, markets, or law) than about the *existence of persistent feedback loops* among agents, mediated both directly (agent–agent interaction) and indirectly (through durable shared structures).

Definition 347 (Society)**.** *A* society *is a tuple*

$$\mathsf{Soc} := (A, G, K, \mathcal{A}, \mathrm{Acc}, \mathcal{D}),$$

where:

- *A is a set of agents;*
- *$G = (A, E)$ is an interaction graph;*
- *K is a coupling weight on E;*
- *$\mathcal{A}$ is a set of shared artifacts;*

- $\mathrm{Acc} \subseteq A \times \mathcal{A}$ *is an access relation; and*
- $\mathcal{D}$ *is (optional) additional domain structure capturing the resource-flow and reproduction dependencies relevant to the society (metabolism, exchange, child rearing, maintenance of shared infrastructure, etc.).*

Remark 1205. *The tuple* Soc *is intentionally austere: it says that a society is (i) a population of agents, (ii) a directed coupling structure among them, and (iii) a set of external structures that agents can jointly read and write. In this sense it is closer to a "minimal ontology of social coupling" than to a sociological theory. The formalism is designed to support later questions such as: which patterns stabilize; which beliefs become shared; which roles emerge; and when the group behaves in a mind-like fashion. One should read* G *and* K *as describing* effective influence *rather than any single physical channel: an edge* $(i, j) \in E$ *indicates that, in the relevant timescale, agent* i *can affect agent* j*'s state or action selection in a repeatable way, while the weight* $K(i, j)$ *parameterizes the strength, rate, or reliability of that effect (depending on the modeling choice used later). The "shared artifacts"* $\mathcal{A}$ *play the role of an external memory and coordination substrate: they include objects like documents, codebases, signage, norms-as-inscriptions, ledgers, shared tools, or institutions understood as* stateful *entities that persist beyond any single interaction. The access relation* Acc *makes explicit that not all agents necessarily have symmetric visibility or control over each artifact, allowing the same formalism to represent, for example, private vs. public channels, credentialed systems, censorship, and asymmetric power to modify common resources.*

A simple example is a two-agent society with $A = \{1, 2\}$*,* $E = \{(1, 2), (2, 1)\}$*, a symmetric* $K(1, 2) = K(2, 1) = 0.7$*, and* $\mathcal{A}$ *containing a shared notebook. Even this toy case already permits nontrivial cultural stabilization: repeated reinforcement through the notebook can induce long-lived habits that neither agent would sustain alone. Here the notebook functions as a minimal "public world": each agent can offload intermediate results, commitments, and cues, and then later re-import them as if they were environmental facts. This kind of indirect coupling is important because it can create* path dependence*: once certain entries exist, they bias future behavior even if the immediate interpersonal influence* K *is weakened or intermittent.*

Remark 1206. *This definition is also a convenient "socket" into which more specialized theories can be plugged. For instance, if one wants to reason about prosocial coordination as efficiency gain, one can enrich* $\mathcal{D}$ *with explicit resource-flow and bargaining constraints, connecting with arguments like [6]. But the present section keeps* $\mathcal{D}$ *optional so the mathematics does not presuppose any particular economics or evolutionary story. Concretely,* $\mathcal{D}$ *can be used to add whatever additional state variables and constraints are needed to make "dependence" precise in a given application: endowments, production functions, task graphs, consumption needs, enforcement mechanisms, spatial structure, or demographic turnover. Leaving* $\mathcal{D}$ *optional is also a way to separate two questions that are often conflated: (a) what makes interaction* socially coupled *at the level of information and control (handled by* $G, K, \mathcal{A}, \mathrm{Acc}$*), and (b) what makes that coupling* necessary or stable *given material constraints (often captured in* $\mathcal{D}$*).*

Remark 1207 (Where "metabolism and reproduction" enter)**.** *If one wants to explicitly encode Hyperseed's biological emphasis,* $\mathcal{D}$ *can include a resource-flow network (who supplies what to whom), plus reproduction/maintenance processes. For many cognitive and cultural applications, it is enough to treat* $\mathcal{D}$ *as implicit and to work directly with* G, K *and the shared artifact layer. One can view this as a modeling choice about the boundary between "social cognition" and "social ecology": if the focus is on belief dynamics, norm propagation, institutional memory, or collective decision-making, then the informational coupling via* G, K *and the persistence provided by* $\mathcal{A}$ *may be the dominant* *explanatory variables. By contrast, when studying collapse, resilience, demographic transitions, or long-run selection pressures, making $\mathcal{D}$ explicit becomes important because it specifies the feasibility constraints under which cultural patterns must reproduce.*

Remark 1208 (Interpretation notes (noncommittal but operational))**.** *The components of* Soc *are intentionally typed only loosely at this stage. For example, K may be taken as a function $K : E \to \mathbb{R}_{\geq 0}$, a stochastic matrix on A, a time-dependent weight K_t, or even a vector of modality-specific couplings (communication, observation, sanction, etc.); later sections can choose the level of structure appropriate to theorems being proved. Similarly, $\mathcal{A}$ may be instantiated as a set of discrete objects, as a shared state space, or as a collection of writable variables with an update semantics; the only essential requirement is that artifacts provide a medium through which effects can persist and propagate beyond a single dyadic exchange.*

22.4 Tribes as tightly intertwined sub-societies

Hyperseed treats a tribe as a society that is "very tightly intertwined" and typically small enough for many direct interactions among members. We formalize this as a high-coupling, high-connectivity regime.

Definition 348 (Strong-tie threshold graph)**.** *Fix a threshold $\tau \in (0, 1]$. Given a society* $\mathsf{Soc} = (A, G, K, \ldots)$ *with scalar couplings $K : E \to [0, 1]$, define the* strong-tie graph $G_\tau = (A, E_\tau)$ *by*

$$E_\tau := \{(i, j) \in E : K(i, j) \geq \tau\}.$$

If K is $\mathbb{V}$-valued, one may threshold on a projection, e.g. the plausibility map $\pi(p, q) = (1+p-q)/2$ (Section 14) or simply on the positive axis.

Remark 1209. *Intuitively, G_τ discards the weak, occasional, or negligible interactions and keeps only the links strong enough to function as reliable conduits for habit, language, norm, and belief transfer. The threshold τ is not a metaphysical constant; it is a modeling knob that selects a time-scale and a notion of "meaningful influence."*

As a small example, if in a workplace $K(i, j)$ measures average weekly effective communication, then a high τ might isolate a close-knit team (a tribe-like substructure), while a low τ might recover the whole organizational chart. In Hyperseed-Concept terms, this is a way to carve out a Tribe *(Hyperseed-Concept 194) as a high-coupling region inside a* Society *(Hyperseed-Concept 170).*

Remark 1210. *Depending on the modeling choice for G and K, the strong-tie graph G_τ may be treated as undirected (mutual strong ties) or directed (asymmetric influence or attention). In the directed case, "(strongly) connected" in later definitions can be interpreted as strong connectivity when influence is genuinely directional, whereas in the undirected case it reduces to ordinary graph connectivity. When $K(i, j)$ is not symmetric, one can also consider symmetrizations such as $\min\{K(i, j), K(j, i)\}$ (for mutuality) or $\max\{K(i, j), K(j, i)\}$ (for one-way influence) before thresholding, depending on whether tribal cohesion is intended to require reciprocal contact.*

Remark 1211. *Varying τ induces a natural* filtration *of graphs: if $\tau_1 \leq \tau_2$ then $E_{\tau_2} \subseteq E_{\tau_1}$. Thus, as τ increases, strong-tie components can only split (or disappear), never merge. This monotonicity supports a multi-scale reading of "tribal structure" in which higher τ reveals the most robust, repeatedly reinforced cores, while lower τ reveals looser coalitions that may still be socially meaningful at a longer time-scale.*

Definition 349 (Tribe)**.** *A* tribe *(relative to τ) is a subset $T \subseteq A$ such that:*

(a) the induced strong-tie subgraph $G_\tau[T]$ is (strongly) connected; and

(b) T satisfies a boundedness condition reflecting finite memory/interaction bandwidth, modeled either as an explicit size bound $|T| \leq N$ or as a density condition such as

$$\frac{1}{|T|(|T|-1)} \sum_{i \neq j \in T} \mathbf{1}[(i,j) \in E_\tau] \geq \delta,$$

for some δ close to 1.

Remark 1212. *Condition (a) enforces that strong ties form a single influence-component rather than a scattering of dyads. Condition (b) encodes the idea that tribes are not merely connected but* thickly *connected (or at least bounded in size so that connectivity is experientially meaningful). The two modeling options for (b) reflect two ways of cashing out bounded cognitive bandwidth: either limit the number of close ties, or require that close ties be dense among the members.*

A canonical example is an extended family or small religious community where most members interact directly and repeatedly. By contrast, an online fandom might be connected but not dense; in that case it may be a society with many tribes rather than a tribe itself.

Remark 1213. *The density expression in (b) is written in a directed-edge style (summing over ordered pairs $i \neq j$). If one instead models G_τ as undirected, the analogous normalization uses $|T|(|T|-1)/2$ and the indicator for $\{i,j\} \in E_\tau$; the conceptual role of the condition is the same: it approximates the claim that "nearly everyone in T is in frequent contact with nearly everyone else." In empirical settings, one may also replace density by an average-degree constraint (e.g. $\frac{1}{|T|}\sum_{i\in T} \deg_{G_\tau[T]}(i) \geq d$) when ties are not expected to be fully meshed but are still expected to be richly redundant.*

Remark 1214. *The size-bound option $|T| \leq N$ can be read as a formal proxy for conversational and attentional limits (often discussed informally via "Dunbar-like" constraints), while the density option can be read as a proxy for repeated joint context (shared routines, shared reference frames, and repeated mutual updating). These are not competing metaphysical theses: they are alternative handles on the same modeling intent, and they can also be combined when one wants "small and dense" as the operational definition of tribal cohesion.*

Remark 1215. *In many real societies, tribes overlap: an agent may simultaneously belong to a family unit, a work cell, and a religious circle. The present definition treats a tribe as a subset $T \subseteq A$ and does not require a partition of A; consequently, different tribes may intersect, and the same agent may serve as a high-coupling "bridge" across multiple tribal contexts. When overlap is common, one can interpret G_τ as supporting a* cover *of A by connected, bounded, high-density sets, rather than a disjoint decomposition.*

Remark 1216 (Why tribes matter for later sections)**.** *Tribal substructure is where morphic resonance and cultural stabilization become most visible: high coupling and repeated interaction create strong reinforcement dynamics. In the later "mindplex" discussion, tribes are a natural scale at which notable coherence can arise.*

Remark 1217. *One practical reason to isolate tribes is that many dynamical claims (diffusion of habits, norm formation, convergence of belief-like variables, stabilization of shared symbols) have qualitatively different behavior on sparse-but-connected graphs versus dense, redundant graphs. Dense strong-tie subgraphs support multiple independent paths of reinforcement, making them less* *fragile to occasional edge failures, episodic disengagement, or the removal of a single highly connected individual. In this sense, the density/size boundedness condition can be read as a robustness surrogate: it aims to rule out "connected only through a single corridor" structures that behave more like chains of acquaintance than like tightly intertwined sub-societies.*

Remark 1218. *Hyperseed's mention of "morphic resonance" gestures at reinforcement across time and across instances; the present section uses it only as an intuition, not as an extra axiom. Where it is used as an explanatory frame, it is natural to connect it to [13] and to the formal habit and resonance machinery earlier in the document. In Hyperseed-Concept terms, see* Morphic Resonance *(Hyperseed-Concept 115) and* Autocatalytic Sets *(Hyperseed-Concept 61) for related self-reinforcement imagery.*

Remark 1219. *Finally, the thresholding perspective makes contact with standard community-detection intuitions without committing to a particular algorithm: tribes can be approximated by connected components of G_τ (when boundedness is enforced by N) or by searching for dense connected subgraphs inside G_τ (when boundedness is enforced by δ). In applications, one may choose τ by a measurement convention (e.g. "at least once per day"), by calibration to observed cohesion (e.g. self-reported trust), or by stability across nearby thresholds (selecting tribes that persist over a range of τ values as especially robust sub-societies).*

22.5 Communicative acts and communicative systems

Hyperseed treats communication as an action by one complex interactive system aimed at effecting a communicative act on another system, and emphasizes that communicative acts come in multiple logical forms (speech acts) and multiple physical forms. In particular, the same abstract message can be instantiated as spoken language, written text, gestures, signals embedded in artifacts, or machine-to-machine protocol events; the formal layer below is deliberately indifferent to these carrier modalities, treating them as different physical realizations of a shared state-transformer schema.

Our minimal formalization is built on the epistemic layer (Section 20). Fix a claim language $\mathcal{L}$ and recall the $\mathsf{p\text{-}bit}$ domain $\mathbb{V} = [0,1]^2$. The purpose of reusing $\mathbb{V}$ here is to make "communication" compatible with the same evidence geometry already used for learning, inference, and aggregation, so that receiving testimony is treated as one more evidence-producing interaction rather than as a separate logical primitive.

Remark 1220. *Here $\mathcal{L}$ is simply a set of well-formed "claims" (propositions, statements, hypotheses) about which agents can store and exchange evidence. We do not assume $\mathcal{L}$ is complete, consistent, or even closed under all classical connectives; the epistemic layer already allows paraconsistent inference and resource-sensitive closure. In communicative settings, this flexibility is essential: natural-language discourse rarely presents itself as a tidy Boolean algebra, and social actors routinely trade in partially formalizable claims (e.g. vague predicates, defeasible generalizations, or context-indexed statements) whose logical closure properties are not globally stable.*

Definition 350 (Messages as paraconsistent evidence bundles)**.** *A* message *is a finitely supported function*

$$m : \mathcal{L} \to \mathbb{V},$$

interpreted as "the sender is transmitting this bundle of positive/negative evidence about claims." Let $\mathsf{Msg}(\mathcal{L})$ denote the set of messages.

Remark 1221. *"Finitely supported" means that $m(\varphi) \neq (0,0)$ for only finitely many claims φ. This reflects the mundane constraint that each communicative act carries only bounded explicit content, even if it triggers further inferences in the recipient. The codomain $\mathbb{V} = [0,1]^2$ means that each claim receives two independent coordinates: positive evidence and negative evidence, as in the* p-bit *framework used throughout the epistemic and value layers. One can also regard a message as the "public" part of a richer communicative event: prosody, timing, source identity, and shared situational context are not encoded in m itself, but can be incorporated indirectly through how the recipient chooses the coupling k (or through auxiliary state variables in more detailed models).*

As a toy example, if $\mathcal{L}$ contains claims {"it will rain", "the bus is late"}, a message might assign $(0.8, 0.1)$ to "it will rain" and $(0.0, 0.0)$ to everything else, thereby asserting rain with mild doubt, and staying silent about the bus.

Definition 351 (Belief states and message assimilation)**.** *Let $\beta_j : \mathcal{L} \to \mathbb{V}$ be agent j's belief state. Given a coupling value $k \in [0,1]$ (or $k \in \mathbb{V}$), define the* assimilated message *$k \odot m$ by*

$$(k \odot m)(\varphi) := \begin{cases} (k,k) \otimes m(\varphi) & \text{if } k \in [0,1], \\ k \otimes m(\varphi) & \text{if } k \in \mathbb{V}, \end{cases}$$

where $\otimes$ is the quantale product on $\mathbb{V}$ from Section 3. Define the belief update

$$\beta_j \leftarrow \beta_j \oplus (k \odot m),$$

where $\oplus$ is the componentwise join on $\mathbb{V}$. Optionally, after receiving a message the agent applies an inference closure (Section 20.5) to propagate implications.

Remark 1222. *The operator $\odot$ here is not a new primitive; it is just notation for "scale the message by the coupling strength." If $k \in [0,1]$, we embed it as $(k,k) \in \mathbb{V}$ so that the same $\otimes$ operation can be used uniformly. The update $\beta_j \leftarrow \beta_j \oplus (k \odot m)$ then says: the recipient retains their existing evidence and also joins in whatever evidence arrives through the channel, discounted by coupling. Operationally, k can be read as a compressed stand-in for many social and cognitive factors: trust in the sender, perceived expertise, attention allocation, channel noise, and incentives. Allowing $k \in \mathbb{V}$ further permits asymmetric coupling—e.g. a recipient might treat the sender as reliable for positive testimony but unreliable for denials, or conversely discount affirmations while taking warnings seriously.*

A simple numerical example: if $k = 0.5$ and $m(p) = (0.8, 0.2)$, then $(k,k) \otimes m(p)$ yields a down-weighted evidence pair for p (depending on the exact $\otimes$ defined in the p-bit *quantale). Joining this into $\beta_j(p)$ accumulates evidence without requiring consistency. In richer settings one may also consider claim-dependent coupling $k(\varphi)$, or context-dependent coupling chosen as a function of the act type α and conversational state; the present formalization keeps k uniform to isolate the core mechanism.*

Remark 1223 (Paraconsistency is the default at social scale)**.** *Even if each individual is internally "mostly consistent" (in some approximate sense), the join of many individuals' evidence streams quickly yields conflicting evidence on many claims. Hyperseed's paraconsistent stance therefore becomes more natural, not less, as we scale up. The point is not merely that different agents disagree, but that a single recipient typically integrates heterogeneous sources whose evidential standards and error modes are not aligned, making some degree of contradiction an ordinary equilibrium condition rather than a pathology.*

Remark 1224. *Conceptually, this is the same reason classical logic is a poor description of large bodies of testimony: the world is large, observers are limited, and social incentives are mixed. Hyperseed treats this not as an anomaly but as a structural property of any large coupled epistemic system. The mathematical role of the* p-bit *domain is precisely to let contradiction be represented without allowing it to collapse the entire inferential apparatus; compare the paraconsistent framing in [24] for a different (but thematically related) use of non-classical structure. In communicative terms, this means that "he said, she said" does not force the system into triviality; instead it yields a state in which both positive and negative evidence coordinates can be simultaneously high, and downstream decisions can explicitly condition on that mixed evidential profile.*

Definition 352 (Communicative act types)**.** *A* communicative act type *is an intended state-transformer that uses a message as a vehicle. We use the following Hyperseed-aligned types:*

(a) Question*: aims to elicit an answer (a message or action) or to provoke inquiry in the recipient.*

(b) Response*: aims to answer a question by transmitting evidence or constraints.*

(c) Command*: aims to cause the recipient to carry out some particular action.*

(d) Statement*: aims to cause the recipient to possess a certain belief (evidence update).*

(e) Interjection*: aims to cause the recipient to possess a belief about the sender's emotional state or attitude (a value/affect update; Section 18).*

Formally, an act is a triple (i, j, α, m) *where* i *is sender,* j *is recipient,* α *is act type, and* m *is message content. The act type determines which internal variables of* j *are targeted (beliefs, goals, attention, affect), and how* m *is interpreted. In particular, the same evidence bundle may be processed differently depending on whether it is treated as an answer to a standing question, a freestanding assertion, or a socially binding directive; act types therefore function as a routing layer that selects the relevant update operators and any associated normative or procedural constraints.*

Remark 1225. *This definition separates* content *(the evidence bundle* m*) from* illocutionary force *(the act type* α*). That separation is useful because the same propositional content can be used as a statement, a hint, a threat, or a question depending on context; conversely, the same act type (question, command) can be realized with many different contents. In addition, it clarifies how communicative success and communicative uptake can diverge: the sender may intend a command while the recipient treats it as mere information, or the sender may pose a question whose primary function is to shift attention rather than to obtain new evidence. This gap between intended and realized state-transformation is one locus where social power, shared norms, and institutional roles enter the model (e.g. by modulating* k*, by constraining admissible responses, or by altering which state variables are allowed to be targeted by particular senders).*

Definition 353 (Communicative systems as coupled message dynamics)**.** *A* communicative system *over a population of agents* A *is given by (i) belief states* $\{\beta_i\}_{i \in A}$*, (ii) a set of admissible act types (as above), and (iii) coupling parameters* $\{k_{ij}\}_{i,j \in A}$ *(with* $k_{ij} \in [0,1]$ *or* $k_{ij} \in \mathbb{V}$*) specifying how strongly* j *assimilates messages from* i*. A communicative episode can then be modeled as a finite sequence of acts*

$$(i_1, j_1, \alpha_1, m_1), \ldots, (i_T, j_T, \alpha_T, m_T),$$

with each act inducing an update to the targeted state of the recipient (e.g. belief update via $\beta_{j_t} \leftarrow \beta_{j_t} \oplus (k_{i_t j_t} \odot m_t)$ *in the case of statements).*

Remark 1226. *This system-level view makes explicit that "communication" is not only a dyadic event but a networked process: repeated updates, feedback, and multi-party routing (broadcast, gossip, institutional reporting) can be represented by composing these elementary acts. It also highlights that coupling is typically directional ($k_{ij} \neq k_{ji}$) and role-sensitive, and that stability phenomena (e.g. convergence to shared high-positive evidence, polarization into incompatible evidence profiles, or persistence of mixed evidence) are properties of the induced dynamics rather than of any single message in isolation.*

Remark 1227. *As an example, "Close the window" is a command. "Could you close the window?" is syntactically a question, but pragmatically often functions as a command; in a richer model, that pragmatic mapping would live in the recipient-side update rules associated with α and the context encoded in K and attention variables. In particular, the same surface form can map to different illocutionary forces depending on relational context (e.g. power asymmetries, politeness conventions, shared projects), local attentional state, and the agent's estimate of channel costs (e.g. whether direct imperatives are socially penalized). Formally, this means that the decoding and update stages may depend not only on the message token but also on latent variables internal to the receiver (and, in multi-turn settings, on dialogue state), so that the "meaning" relevant for state change is a function of $(m, \beta_j, attention_j, K(i,j), \dots)$ rather than of m alone.*

Definition 354 (Communicative system)**.** *A* communicative system *on a society is a choice, for each ordered pair $(i,j) \in E$, of:*

- *a message alphabet/space Msg_{ij} (often a subset of $\mathsf{Msg}(\mathcal{L})$);*
- *encoding/decoding maps (possibly stochastic) that implement the physical channel; and*
- *update rules on the recipient (belief update, goal update, attention update, etc.).*

We write this data collectively as $\mathsf{Com} = (\mathsf{Msg}, \mathsf{Enc}, \mathsf{Dec}, \mathsf{Upd})$. It is important that the choice is made for each ordered *pair (i,j): communication can be asymmetric in both capacity and interpretation (e.g. agent i can reliably address j but not vice versa; or j treats i as authoritative while i discounts j). The dependence on (i,j) also lets the model represent institutionally mediated channels (moderation, bureaucracy, publication) as special cases of edges with distinctive $\mathsf{Enc}/\mathsf{Dec}$ and with characteristic filtering or amplification in Upd. Finally, allowing Msg_{ij} to differ across edges captures the fact that not all agents share the same vocabulary, protocol, or representational format, even when they participate in the same society-wide network.*

Remark 1228. *The communicative system Com is where "language" and "media" enter the formalism, but in a way that keeps us honest: communication is not magic, it is a channel with an encoding, a decoding, and a state-update. This is compatible with Shannon-style abstraction, but the state being updated is paraconsistent and value-sensitive rather than a single probability distribution. Put differently, Shannon theory idealizes the transmission of symbols; here we additionally specify what receiving a symbol* does *to an agent's cognitive state, and we do not assume that this effect can be reduced to a single scalar belief. The separation into Enc, Dec, and Upd also forces an explicit distinction between (i) channel errors (noise, loss, distortion), (ii) interpretive divergence (the same token mapped to different internal content), and (iii) normative or strategic response (the receiver may understand but decline to update, or may update attention/values without accepting propositional content).*

As a simple example, Enc could be "serialize evidence pairs into a JSON packet" and Dec could be "parse the packet," while Upd could be the join-update $\beta_j \leftarrow \beta_j \oplus (k \odot m)$. In face-to-face speech, Enc/Dec *are biophysical and socially trained processes, and* Upd *includes pragmatic inference and attention modulation (Section* **??***; see also the broader cognitive-systems framing in [19]). Note that even in the "JSON packet" case, the decoding stage typically includes a schema agreement (what fields mean) and a trust calibration (how much weight to place on the packet), both of which can be modeled either as part of* Dec *(mapping bytes to structured internal objects) or as part of* Upd *(mapping structured objects to state change). Likewise, the weighting factor k can be interpreted as folding into a single scalar multiple heterogeneous features such as channel reliability, source credibility, alignment of incentives, and current cognitive load; making these components explicit yields richer update operators without changing the overall architecture.*

A further consequence is that communication protocols (turn-taking rules, quoting, forwarding, cryptographic signing, moderation queues) can be represented by enriching Enc/Dec *and by letting* Upd *depend on message metadata (timestamps, signatures, provenance, thread position). This matters in collective settings because many social phenomena (rumor cascades, institutional trust, polarization) are driven at least as much by these protocol-level variables as by the propositional content transmitted.*

Physical realizations. Hyperseed emphasizes that the same logical act types can be physically realized in different ways. We therefore treat physical forms as implementations of Enc/Dec: the same act type α (e.g. asserting p, requesting an action, signaling approval) may be instantiated as a spoken utterance, a gesture, a written note, or a machine-readable command, with potentially different error profiles and with different degrees of persistence and publicness. This perspective also makes it natural to treat "translation" (between languages or modalities) as composition of encoding/decoding maps, where translation quality becomes part of the effective noise model and can be learned or institutionalized.

- gesture (iconic/indexical signaling),
- "Hmmmmm" (holistic, manipulative, multi-modal, musical, mimetic signaling),
- spoken language,
- written language,
- social language (used inside a society),
- natural language (evolved by use),
- constructed language (engineered, e.g. Lojban),
- programming language (communication with a machine; see Section 23).

We will not formalize each form separately; instead we treat them as different channel families with different noise models, bandwidth, grounding constraints, and habit formation dynamics. Here "bandwidth" includes not only raw symbol rate but also effective expressive capacity under shared conventions; "grounding constraints" include the degree to which signals are anchored to shared perception/action loops (e.g. pointing in a shared environment versus reference in a text-only forum); and "habit formation dynamics" covers how repeated use of a channel changes both availability (ease of production) and interpretation (default pragmatic enrichments). This is also where latency and synchronization enter: some channels support rapid repair (immediate clarification) while others require asynchronous clarification, which alters the feasible structure of multi-step coordination.

Remark 1229. *This list is not merely anthropological; it matters for the mathematics because different physical realizations induce different effective couplings $K(i, j)$ and different update operators* Upd*. Written language increases persistence (artifact-layer memory), programming languages couple agents to machines (Section 23), and holistic/affective signaling can primarily update value and attention variables rather than propositional belief states. In Hyperseed-Concept terms, this is one place where* Representation *(Hyperseed-Concept 157) and* Attention / Attentional Focus *(Hyperseed-Concept 60) become inseparable from "purely epistemic" content. Persistence changes the temporal structure of interaction: stored messages can be revisited, quoted, and aggregated, which effectively increases the time horizon over which updates compound and can create path dependence in β_j (e.g. via selective retrieval). Publicness changes the audience model: a message in a broadcast medium may induce different updates because the recipient infers not only what the sender intends them to know, but also what others are likely to know, affecting coordination, reputational incentives, and second-order beliefs.*

Moreover, modalities differ in how much they privilege different state components: a terse textual assertion may mostly target propositional belief, while tone, rhythm, facial expression, or musical mimesis may more directly target attention allocation and value salience. Mathematically, this can be reflected by allowing Upd *to be anisotropic in the space of state variables (large effects on attention/value coordinates, smaller effects on propositional coordinates), and by allowing $K(i, j)$ to represent not just "how strongly i influences j" but which* channels of influence *(belief, goal, affect, attention) are most strongly coupled for that edge.*

Finally, treating "social language," "natural language," and "constructed language" as distinct realizations highlights that Com *is partly a learned, collectively maintained technology. A constructed language may reduce syntactic ambiguity (altering* Dec*) but increase adoption cost (altering effective K via reduced usage); a natural language may maximize ease and coverage at the expense of ambiguity, pushing disambiguation into pragmatic components of* Upd*. These tradeoffs are central when modeling how communicative conventions co-evolve with institutions and with collective cognitive constraints.*

22.6 Universal Grammar as a weakest interface theory

Hyperseed treats *distinction* as primitive and observer-relative (Hyperseed-Concept 98, 86), and treats *weakness* as the controlled collapsing of distinctions not needed for a given purpose (Hyperseed-Concept 202, 143, **??**). The UG manuscript can be read as an instance of this program: "Universal Grammar" is modeled as the *weakest* operational congruence on grammar derivations that preserves a chosen *interface observation layer* (LF/PF-style invariants), up to (i) swaps of independent actions and (ii) declared symmetries (parametric equivalences).

In this section we introduce a Hyperseed-aligned formal package for this idea: Trace-based Universal Grammar (TUG) (Hyperseed-Concept 221). The core ingredients are: an observation interface (Hyperseed-Concept 222), an independence relation on visible grammatical actions (Hyperseed-Concept 225), and a symmetry group on visible labels (Hyperseed-Concept 226).

22.6.1 Grammar dynamics as a process on representations

Grammars are treated here as *engineered* cultural artifacts (Hyperseed-Concept **??**, 91), but their mathematical core is a process on representations (Hyperseed-Concept 157, 184).

Definition 355 (Grammar state space: pattern plus canonical store)**.** *Let $\mathcal{T}$ be a set of syntactic term-trees ("patterns") and let Σ be a set of finite "interface atoms" representing commitments* *relevant to semantic and/or phonological interpretation. A* grammar state space *is*

$$\mathrm{St} := \mathcal{T} \times \Sigma.$$

Elements $s = (t, \sigma) \in \mathrm{St}$ *are viewed as a representation token of syntactic structure* t *together with a canonicalized store* σ *that retains the interface-relevant residue of derivational choices (Hyperseed-Concept 223).*

Definition 356 (Grammar labeled transition system (LTS))**.** *A* grammar LTS *is a triple*

$$G = (\mathrm{St}, \mathrm{Lab}, \to)$$

where St *is as in Definition 355,* Lab *is a set of labels, and* $\to \subseteq \mathrm{St} \times \mathrm{Lab} \times \mathrm{St}$ *is a transition relation. We write* $s \xrightarrow{\ell} s'$ *for* $(s, \ell, s') \in \to$*. A* derivation *is a finite path*

$$\pi : \quad s_0 \xrightarrow{\ell_1} s_1 \xrightarrow{\ell_2} \cdots \xrightarrow{\ell_n} s_n.$$

22.6.2 Observation interfaces (LF/PF) as context-selected distinctions

The UG manuscript treats "what the grammar must preserve" as an *observation interface* (LF-only vs LF+PF, or other invariants). In Hyperseed terms, this is a context/aspect choice that selects which distinctions count as live (Hyperseed-Concept 86, 98).

Definition 357 (Observation interface)**.** *An* observation interface *is a set* $\mathcal{O}$ *together with a map*

$$\mathrm{obs}_{\mathcal{O}} : \mathrm{St} \to \mathcal{O}.$$

Two standard examples are:

- *LF-only:* $\mathrm{obs}_{\mathrm{LF}}(t, \sigma) := \sigma_{\mathrm{LF}}$.
- *LF+PF:* $\mathrm{obs}_{\mathrm{LF+PF}}(t, \sigma) := (\sigma_{\mathrm{LF}}, \sigma_{\mathrm{PF}})$.

Given a fixed start state s_0*, two derivations* π, π' *from* s_0 *are* $\mathcal{O}$-observationally equivalent*, written* $\pi \equiv_{\mathcal{O}} \pi'$*, if their endpoints have the same observation:* $\mathrm{obs}_{\mathcal{O}}(s_n) = \mathrm{obs}_{\mathcal{O}}(s'_m)$*.*

22.6.3 Visible vs internal actions; resources and independence

Following standard process-algebra practice, we distinguish administrative normalization steps (internal, τ-like) from meaning-bearing choices (visible). Independence is the formal locus of "can commute without changing the interface."

Definition 358 (Visible vs internal labels)**.** *Assume a disjoint partition*

$$\mathrm{Lab} = \mathrm{Lab}_V \uplus \mathrm{Lab}_\tau,$$

where Lab_τ *are internal (administrative) labels and* Lab_V *are visible (meaning-bearing) labels. The* visible trace *of a derivation* π *is the word* $\mathrm{tr}_V(\pi) \in \mathrm{Lab}_V^*$ *obtained by deleting* Lab_τ*-labels.*

Definition 359 (Positions, resources, and rely footprints)**.** *Let* $\mathrm{Pos} := \mathbb{N}^*$ *be the set of finite sequences of naturals (tree positions), with length* $|p|$*. Let* Res *be a finite set of abstract resources. Assume maps*

$$\mathrm{pos} : \mathrm{Lab}_V \to \mathrm{Pos}, \qquad \mathrm{rely} : \mathrm{Lab}_V \to 2^{\mathrm{Res}}.$$

Intuitively, $\mathrm{rely}(\ell)$ *is the set of semantic/interface "slots" touched by* ℓ *(Hyperseed-Concept 224).*

Definition 360 (Disjoint positions). *For $p, q \in \mathrm{Pos}$, write* $\mathrm{disjointPos}(p, q)$ *if neither is a prefix of the other.*

Definition 361 (Grammatical independence). *Define a binary relation $\perp$ on Lab_V by*

$$\ell \perp \ell' \quad :\Longleftrightarrow \quad \mathrm{disjointPos}(\mathrm{pos}(\ell), \mathrm{pos}(\ell')) \;\; \textit{and} \;\; \mathrm{rely}(\ell) \cap \mathrm{rely}(\ell') = \emptyset.$$

When $\ell \perp \ell'$, the intended operational reading is that the two visible actions act on disjoint subtrees and disjoint interface resources, so their order is interface-irrelevant.

22.6.4 Symmetries and trace quotienting

Parametric variation can be modeled as *declared symmetries* on visible labels: differences that (by stipulation) do not matter to the chosen interface. This is an explicit instance of Hyperseed's equivalence-via-indistinction stance (Hyperseed-Concept **??**, 98).

Definition 362 (Label symmetry group). *A* label symmetry group *is a group Γ acting on Lab_V. We require that symmetries preserve observation at the interface level in the following sense: for any $\gamma \in \Gamma$ and any derivation step $s \xrightarrow{\ell} s'$ with $\ell \in \mathrm{Lab}_V$, there exists a step $s \xrightarrow{\gamma \cdot \ell} s''$ such that* $\mathrm{obs}_{\mathcal{O}}(s') = \mathrm{obs}_{\mathcal{O}}(s'')$.

Definition 363 (Trace quotient and TUG congruence). *Let $\approx_\perp$ be the least congruence on Lab_V^* generated by swaps of adjacent independent labels:*

$$\alpha\, \ell\, \ell'\, \beta \;\approx_\perp\; \alpha\, \ell'\, \ell\, \beta \quad \textit{whenever} \quad \ell \perp \ell'.$$

Let $\approx_\Gamma$ be the least congruence generated by pointwise symmetry replacements:

$$\alpha\, \ell\, \beta \;\approx_\Gamma\; \alpha\, (\gamma \cdot \ell)\, \beta \quad \textit{for any} \quad \gamma \in \Gamma.$$

Define the TUG congruence $\approx_{\perp,\Gamma}$ *as the least congruence containing both $\approx_\perp$ and $\approx_\Gamma$. The resulting quotient monoid $\mathrm{Lab}_V^*/\approx_{\perp,\Gamma}$ is the* trace quotient *induced by $(\perp, \Gamma)$ (Hyperseed-Concept 227).*

Definition 364 (Trace-based Universal Grammar (TUG)). *Fix a grammar LTS $G = (\mathrm{St}, \mathrm{Lab}, \rightarrow)$ (Definition 356), an observation interface $(\mathcal{O}, \mathrm{obs}_{\mathcal{O}})$ (Definition 357), an independence relation $\perp$ (Definition 361), and a label symmetry group Γ (Definition 362). The* Trace-based Universal Grammar *induced by these choices is the package*

$$\mathrm{TUG} \;:=\; (\mathcal{O}, \perp, \Gamma)$$

together with the induced equivalence on derivations from a start state s_0:

$$\pi \equiv_{\perp,\Gamma} \pi' \quad :\Longleftrightarrow \quad \mathrm{tr}_V(\pi) \approx_{\perp,\Gamma} \mathrm{tr}_V(\pi').$$

This is a Hyperseed-style "weak" theory: it identifies derivations that differ only by reordering independent actions and/or applying interface-preserving symmetries. We call $\equiv_{\perp,\Gamma}$ the UG core congruence.

Remark 1230 (Principles and parameters, Hyperseed reading). *In this formalization, "parameters" can be represented by (i) changing what is observable at the interface (changing $\mathcal{O}$), and/or (ii) changing the symmetry group Γ (declaring more or fewer label-identifications). "Principles" are those constraints that survive these changes, i.e., invariants of the dependence/independence topology and the resulting trace quotient. This is a concrete instantiation of Hyperseed's theme that what looks like a "law" is often an invariance forced by a choice of active distinctions (Hyperseed-Concept 86, 202, 169).*

22.6.5 Helper definitions for economy and locality (used later)

Universal Grammar theory derives economy and locality consequences from the above substrate. We record two definitions that will be referenced by later theorems.

Definition 365 (Movement labels and structural distance)**.** *A* movement label *has the form* $\mathrm{Move}(x, p_{\mathrm{from}}, p_{\mathrm{to}})$*, where x is the moved element and* $p_{\mathrm{from}}, p_{\mathrm{to}} \in \mathrm{Pos}$ *are tree positions. Define the* structural distance

$$d(\ell) \;:=\; |p_{\mathrm{to}}| - |p_{\mathrm{from}}| \quad \textit{for} \quad \ell = \mathrm{Move}(x, p_{\mathrm{from}}, p_{\mathrm{to}}).$$

(Interpretation: depth difference, or more generally the number of phase-like domain boundaries crossed, if such resources are included in Res*.)*

Definition 366 (Redundant visible step)**.** *Fix an observation interface* $(\mathcal{O}, \mathrm{obs}_{\mathcal{O}})$*. A visible label* $\ell \in \mathrm{Lab}_V$ *occurring in a derivation* π *is* redundant *if deleting that occurrence from the visible trace yields a derivation* π' *with the same observed endpoint:*

$$\pi \equiv_{\mathcal{O}} \pi'.$$

Equivalently: ℓ contributes no distinction at the chosen interface (Hyperseed-Concept 202, 222).

22.7 Social roles as behavioral templates

Hyperseed lists concrete (teacher, student, worker, colleague) and treats them as patterns of activity within a society. We formalize roles as *interaction templates* that can be matched against observed interaction subgraphs or sequences. In particular, the intent is that a role is neither merely a verbal label nor merely a statistical cluster, but a structured hypothesis about which participants tend to occupy which positions and which kinds of communicative or artifact-mediated acts tend to connect them.

Definition 367 (Role templates as small labeled graphs)**.** *Fix a set of act types* $\mathcal{T}$ *(question/response/command/sta and a set of artifact operations (read, write, modify, use). A* role template *is a finite labeled directed graph*

$$R = (V_R, E_R, \lambda),$$

where V_R *are abstract participant slots (e.g. "teacher", "student") and* $\lambda : E_R \to \mathcal{T} \cup \{\textit{artifact ops}\}$ *labels edges by the act type (or artifact operation) that should occur between the corresponding slots.*

Remark 1231. *The definition is intentionally minimal: it captures only who interacts with whom and what kind of act (or artifact operation) mediates the interaction. More elaborate variants can be obtained by enriching* λ *to include parameters such as (i) expected frequency ranges, (ii) permissible time lags, (iii) polarity or valence (support vs. opposition), or (iv) context guards specifying when an edge is considered "active." These enrichments are not required for the basic template-matching story, but they are often helpful when roles are temporally structured (e.g. meetings, lessons, reviews) rather than purely relational.*

Remark 1232. *The separation between act types* $\mathcal{T}$ *and artifact operations is meant to keep visible the common empirical fact that many social roles are stabilized by recurring interactions with shared objects: documents, tools, codebases, instruments, checklists, ledgers, and so on. In this sense, the artifact edges act as a coarse proxy for "institutional memory" and coordination infrastructure: the template can require not only talk but also patterned reading/writing/modifying behavior that persists beyond any single utterance.*

Remark 1233. *The point of the template R is to represent a role as something like a small "program" of interaction: who speaks to whom, in what mode, and with what recurring artifact usage. This is deliberately compatible with earlier template-pattern machinery (Section 20.2), now applied not to objects in a universe X but to social interaction slots and labeled edges.*

For example, a minimal "teacher–student" template might have two slots and edges labeled (question from student to teacher) and (statement/response from teacher to student), plus an artifact edge (student reads textbook). A "colleague" template might have symmetric coordination edges and shared artifact writes. In Hyperseed-Concept terms, this is precisely the formalization of Social Roles *(Hyperseed-Concept 171).*

Remark 1234. *When we say "subgraph or sequence," we are implicitly allowing two observational regimes: (i) interaction episodes that are best treated as a time-ordered trace (messages/events with timestamps), and (ii) episodes that are best treated as an aggregated graph (counts or existence of certain act types over a window). The same template can be matched in either regime, but the notion of matching may respect order in the sequential case and ignore order in the aggregated case; this distinction becomes important for roles like "interviewer–candidate" where the order of question/response is part of the role itself.*

Definition 368 (Role instantiation and fit score)**.** *Let $\mathsf{Soc} = (A, G, K, \mathcal{A}, \mathrm{Acc}, \mathcal{D})$ be a society and let R be a role template. An* instantiation *of R is a map $\rho : V_R \to A$ assigning each slot to an agent.*

Given an observed interaction episode Ep (a finite subgraph or sequence of acts in the society), define a fit score

$$\mathrm{Fit}(R, \rho; \mathsf{Ep}) \in [0, 1]$$

measuring how well the labeled edges of R match edges/acts in Ep under the assignment ρ, weighted by couplings K and (optionally) attention weights from Section **??***. A role is considered* present *in* Ep *if* Fit *exceeds a chosen threshold.*

Remark 1235. *Although* Fit *is left abstract, it is useful to keep in mind a few canonical constructions. For graph-episodes, one can define* Fit *via a normalized maximum-weight subgraph matching score between the required labeled edges of R and the observed labeled edges in Ep under ρ. For sequence-episodes, one can define* Fit *via an edit-distance-style alignment between the template's expected act-types and the observed act-types, allowing skips and substitutions with penalties. In either case, couplings K can weight edges by social importance (e.g. trust, authority, or bandwidth), and attention weights can downweight interactions that are present but not actually processed or remembered.*

Remark 1236. *The threshold is not meant to be universal: different analytical tasks motivate different operating points. For detection and monitoring, a lower threshold may be appropriate to avoid false negatives and to support early warnings ("a mentoring relationship might be forming"). For attribution or policy decisions, a higher threshold may be appropriate to avoid false positives ("this episode genuinely counts as instruction/command/coordination"). In learning settings, the threshold can itself be tuned to optimize downstream predictive accuracy of role-labeled episodes.*

Remark 1237. *The map ρ is the social analogue of a template instantiation: it plugs concrete agents into abstract slots. The fit score then recognizes that social reality is noisy and approximate: roles are rarely perfectly instantiated, yet they can be real in the sense of being stable, predictive patterns.*

For instance, if Alice asks Bob many questions and Bob provides many answers that change Alice's skills, the teacher–student template has high fit for $\rho(\text{teacher}) = \text{Bob}$, $\rho(\text{student}) = \text{Alice}$. If *the interaction is symmetric, the colleague template may have higher fit. The thresholding step is a way of turning graded pattern matching into a crisp judgment when needed.*

Remark 1238. *This formalism also allows role ambiguity and role drift to be represented quantitatively: one can track* $\mathrm{Fit}(R, \rho; \mathsf{Ep}_t)$ *over time windows* t *and observe when a relationship changes category (e.g. student becomes collaborator) or oscillates between competing descriptions depending on topic. In this sense, roles become time-varying hypotheses about interaction structure rather than static labels, which aligns with the document's emphasis on adaptive agents and evolving societies.*

Remark 1239 (Approximate morphism viewpoint)**.** *The fit score is a lightweight proxy for a more categorical statement: "an episode implements the role template up to approximation." If one models episodes as morphisms in an enriched category of processes, then role instantiation becomes an approximate morphism (Sections* **??** *and 12).*

Remark 1240. *This viewpoint is useful because it makes roles compositional: a role template can be nested inside a larger template, and episodes can partially implement multiple roles simultaneously (often with conflict). That, again, is paraconsistency in social form: one can be simultaneously "teacher" and "student" in different subtopics, or simultaneously "colleague" and "competitor."*

Remark 1241. *Composition also highlights that some roles are inherently multi-slot and cannot be reduced to pairwise dyads without loss. For example, "manager" and "team member" are often mediated by shared artifact operations (planning documents, task boards) and by broadcast-style communication patterns (one-to-many statements, many-to-one reports). Such patterns can be captured by including additional slots (e.g. multiple workers) or by allowing the same template to match repeatedly with different* ρ *assignments to represent a group-level role configuration.*

We now specialize to the roles Hyperseed highlights.

Definition 369 (Teacher and student (operational form))**.** *Fix a claim language* $\mathcal{L}$ *and an update scheme for messages as in Section 22.5. An agent* i *plays the role of* teacher *for an agent* j *over an episode if:*

- i *repeatedly performs statement/response acts toward* j *with messages that (when assimilated) reduce* j*'s weakness/uncertainty on some task-relevant question family (Sections 20 and 21); and*
- j *performs question acts toward* i *and updates its beliefs/skills so that its downstream performance on relevant tasks improves (at fixed or reduced effort).*

An agent j *plays the role of* student *relative to* i *if it exhibits the complementary pattern: question/attention allocation plus sustained assimilation leading to capability gain.*

Remark 1242. *The definition intentionally allows many concrete pedagogical modalities: direct explanation, worked examples, corrective feedback, Socratic questioning (where the teacher's "statements" are themselves structured prompts), and even purely artifact-mediated instruction (e.g.* i *curates a document or tooling that* j *reads/uses). The key requirement is not the surface form of the interaction but the causal effect on* j*'s measurable competence and uncertainty proxies under the assumed update scheme.*

Remark 1243. *This is an operational definition: it identifies "teacher" not by credential but by measurable effect on the student's epistemic and task competence variables. The phrase "reduce weakness/uncertainty" connects directly to the document's resource-sensitive simplicity and weakness machinery (see also [2, 3] for related motivations for treating weakness as a primary quantity).*

It also ties pedagogy to control: teaching is a way of shaping another agent's future capability landscape.

As a simple example, if j is learning to solve a class of tasks and i supplies messages that let j prune the hypothesis space (Section 20), then i is a teacher in precisely the sense that matters for later cultural stabilization: patterns of explanation are being transmitted and absorbed.

Remark 1244. *The emphasis on downstream performance "at fixed or reduced effort" is meant to rule out a purely illusory improvement (e.g. short-term compliance without internalization) and to distinguish teaching from mere delegation. In practice, one can operationalize this via before/after evaluation on a task distribution, or via a reduction in the number of steps/queries j requires to achieve a comparable success rate. This keeps the role definition aligned with the broader document theme that competence is a resource-bounded quantity rather than a purely declarative one.*

Definition 370 (Worker and colleague (operational form))**.** *A* worker *is an agent that repeatedly executes commands or participates in a coordinated plan issued by some coordinating structure (a boss, institution, or collective policy), in exchange for resources or other value signals (Section 18).*

Two agents are colleagues *(in a given interval/episode) if they are co-participants in a collaborative project: a sustained multi-agent pattern of activity aimed at a shared goal, with repeated coordination acts and sharing of intermediate results via communication or artifacts.*

Remark 1245. *The worker definition emphasizes asymmetry of command and exchange of resources/value, whereas the colleague definition emphasizes symmetry of participation in a shared project. Neither is inherently ethical or unethical; they are structural roles describing coordination topology and value flow.*

A concrete example: in a software team, an engineer may be a worker relative to an organizational planner (commands via tickets), but also a colleague relative to peers (shared design discussions and co-authored artifacts). In Hyperseed-Concept terms, Worker *(Hyperseed-Concept 205) and* Colleague *(Hyperseed-Concept 74) are best seen as recurring interaction templates rather than as intrinsic properties of persons.*

22.8 Culture as a stabilized intersubjective pattern web

Hyperseed defines culture as a system of patterns of external and cognitive action associated with a society. Mathematically, we treat culture as a population-level stabilization of certain patterns and procedures, maintained by communication, artifacts, and habit dynamics.

Remark 1246. *This subsection makes precise a familiar but subtle thought: culture is neither merely "inside" minds nor merely "outside" in artifacts, but a stabilized coupling between the two. In more process-oriented language (in the spirit of [15]), culture is a pattern of ongoing reproduction: a process that continually re-instantiates itself through communication, imitation, and institutional constraint.*

Population-level pattern intensity. Let $\mathcal{P}$ be a set of patterns (Section 9), which may include: behavioral scripts, norms, language constructions, rituals, institutions, and shared explanatory models. Assume each agent $i \in A$ carries a (possibly fuzzy) pattern intensity function

$$I_i : \mathcal{P} \to [0,1] \quad \text{or} \quad I_i : \mathcal{P} \to \mathbb{V}.$$

(Concrete constructions were given earlier via compositional simplicity and property-sets.)

Remark 1247. *Here $I_i(P)$ is best read as: "to what degree does pattern P actually occur in, guide, or constrain agent i?" The scalar case $[0,1]$ treats endorsement and opposition as one dimension; the $\mathbb{V}$ case allows a society to carry patterns that are both enacted and resisted, a common phenomenon in norms and ideologies.*

For example, P might be a greeting ritual. Then $I_i(P)$ can be high if i usually performs it and expects it. Or P might be an explanatory model ("germs cause disease"); then $I_i(P)$ measures the extent to which the model shapes inference and action. This connects back to the pattern-web framing of [5].

Definition 371 (Cultural state)**.** *A* cultural state *for a society is a population-level intensity assignment*

$$C : \mathcal{P} \to [0,1] \quad or \quad C : \mathcal{P} \to \mathbb{V},$$

defined as an aggregation of individual intensities and artifact-embedded intensities, e.g.

$$C(P) := \Big(\bigoplus_{i \in A} w_i \odot I_i(P)\Big) \oplus \Big(\bigoplus_{a \in \mathcal{A}} u_a \odot I_a(P)\Big),$$

where w_i, u_a are weights (importance, population fractions, accessibility), and $\odot$ is scalar or p-bit *scaling as in Section 22.5. A* culture *at threshold θ is the set*

$$\mathrm{Cult}_\theta := \{P \in \mathcal{P} : \pi(C(P)) \geq \theta\},$$

where π is a chosen projection $\mathbb{V} \to [0,1]$ if needed.

Remark 1248. *The aggregation formula has two terms: one from agents and one from artifacts. This matters because some cultural patterns live primarily as habits in minds, while others live primarily as procedures encoded in institutions or tools (e.g. bureaucratic forms, legal codes, software). The join $\oplus$ indicates that culture, in this minimal model, records the presence of strong instances anywhere in the population or artifact layer, rather than averaging them away.*

As a concrete example, consider a society where only a small minority actively practices a ritual, but the ritual is also embedded in a calendar artifact and regularly displayed in public spaces. Then the artifact term can keep $C(P)$ high even if the mean individual intensity is low.

Remark 1249 (Paraconsistent cultures)**.** *If $C(P) \in \mathbb{V}$, culture can include patterns that are simultaneously strongly supported and strongly opposed in the same society. This matches the empirical fact that many cultures carry internal contradictions (norm conflicts, contested narratives, ambivalent values) without collapsing into triviality.*

Remark 1250. *The usefulness of defining* Cult_θ *is that it gives a crisp object on which later mathematics can act: we can ask about attractors, perturbations, and transitions as θ changes, or as coupling weights K change. In Hyperseed-Concept terms, this is one formal route to the* Culture *concept (Hyperseed-Concept 91) without presupposing any specific anthropological taxonomy.*

Stabilization via social habit dynamics. To model cultural stabilization, we adopt the simplest monotone reinforcement dynamics that mirrors the habit and morphic resonance constructions (Section 12).

Let $\mathcal{P}$ be finite for the theorem below (or restrict attention to a finite relevant subset).

Definition 372 (Social reinforcement operator)**.** *Fix a society with couplings $K : E \to [0,1]$ (scalar case for simplicity) and let $I \in [0,1]^{A \times \mathcal{P}}$ be the matrix of agent pattern intensities.*

Define $F : [0,1]^{A\times\mathcal{P}} \to [0,1]^{A\times\mathcal{P}}$ *by*

$$F(I)_{i,P} := I_{i,P} \ \vee \bigvee_{(j,i)\in E} \big(K(j,i) \wedge I_{j,P}\big),$$

where $\vee$ *and* $\wedge$ *are max/min on* $[0,1]$. *(Equivalently, one can use the* $\mathbb{V}$ *quantale operations from Section 3; we state the scalar version to keep notation light.)*

Remark 1251. *The operator* F *says: agent* i *keeps whatever intensity it already has for pattern* P*, and it also acquires (up to min with coupling strength) whatever intensity for* P *is present in its incoming neighbors. In other words, the strongest pattern instance among trusted neighbors "lifts"* i*'s intensity upward, but never beyond the channel capacity* $K(j,i)$*. A toy example: if* i *has intensity* 0.2 *for a slang term* P*, and a neighbor* j *has* $I_{j,P} = 0.9$ *with coupling* $K(j,i) = 0.6$*, then* j *can pull* i *up to at least* $\min(0.6, 0.9) = 0.6$ *(and then the* $\vee$ *with the old* 0.2 *yields* 0.6*). Repeating this across the network yields cultural spread. One can read* $\min(K(j,i), I_{j,P})$ *as a "bottlenecked transmission": even if* j *uses the term very strongly, the influence on* i *is capped by the strength of their social channel, and even if the channel is strong, nothing stronger than* j*'s own intensity can be conveyed. The outer* $\vee$ *(max) then implements a pure reinforcement assumption: the updated intensity at* i *is whatever is larger between what* i *already had and what the neighborhood can support.*

Theorem 20 (Existence of stabilized cultural states as fixed points)**.** *Assume* A *and* $\mathcal{P}$ *are finite. Then:*

(a) The operator F *is monotone on the complete lattice* $[0,1]^{A\times\mathcal{P}}$ *under pointwise order.*

(b) Hence F *has fixed points; the least fixed point above any initial intensity matrix* $I^{(0)}$ *is given by*

$$I^{(\infty)} := \bigvee_{n\geq 0} F^n(I^{(0)}),$$

where the supremum is taken pointwise.

(c) If intensities are restricted to a finite grid (e.g. values in $\{0, 1/N, \ldots, 1\}$*), then the ascending chain stabilizes after finitely many steps, yielding a computable stabilized state.*

Remark 1252. *Intuitively, the theorem says that if cultural transmission is "only reinforcing" (never decreasing intensity) and if we have only finitely many agents and finitely many patterns under consideration, then iterating social influence must converge to a stable regime. There is nothing mystical here: it is the general logic of monotone dynamics on a complete lattice. Yet it is important because it shows that "cultural fixed points" are not an extra hypothesis; they are what monotone reinforcement* must *produce.*

A helpful way to parse the statement is to separate three layers of content. First, monotonicity formalizes the idea that strengthening any agent's commitment to any pattern cannot (by the model's rules) make anyone else less *committed after updating. Second, fixed points correspond to "culturally self-consistent" states: applying the transmission rule* F *does not change the intensity matrix, so every agent already reflects all reinforcement available from its neighbors. Third, the expression* $I^{(\infty)} = \bigvee_{n\geq 0} F^n(I^{(0)})$ *shows that the stabilized state is obtained by accumulating all reinforcement that can propagate through the network over arbitrarily many steps, including indirect influence (friends-of-friends, etc.) as represented by repeated iteration.*

This connects to other parts of the document in a direct way. Earlier sections introduced habits and morphic resonance as reinforcement-like dynamics; here we show that, at social scale, the *same mathematical shape yields stable cultural states. Fixed-point reasoning also reappears later in goal and self-modification analysis; compare [10] for a related application of fixed-point theorems to stability.*

It is also worth noting what is not *assumed. We do not require any particular geometry of the social graph beyond the existence of the couplings $K(j,i)$, and we do not assume symmetry ($K(j,i)$ may differ from $K(i,j)$). The result is therefore robust under directed influence, highly heterogeneous connectivity, and strong clustering; these features affect* which *fixed point is reached from $I^{(0)}$, not the existence of some stabilized state under monotone updating.*

Proof. Monotonicity follows because max/min are monotone in each argument and the pointwise join preserves monotonicity. The space $[0,1]^{A\times\mathcal{P}}$ is a complete lattice under pointwise order, so by Knaster–Tarski, F has fixed points and the least fixed point above $I^{(0)}$ is the supremum of the ascending Kleene chain $F^n(I^{(0)})$.

Spelling out the first sentence more explicitly: if $I \le I'$ pointwise, then for each agent–pattern pair (i,P) and each neighbor j, we have $I_{j,P} \le I'_{j,P}$, hence $\min(K(j,i), I_{j,P}) \le \min(K(j,i), I'_{j,P})$. Taking the supremum (or maximum, since finiteness of neighborhoods is typical in network settings) over all j preserves the inequality, and finally taking the max with the old value $I_{i,P}$ preserves it again. Therefore $F(I) \le F(I')$ pointwise.

If the value set is finite, the ascending chain cannot strictly increase forever (there are finitely many possible matrices), so it stabilizes in finitely many steps at a fixed point. In this discretized setting one can also bound the runtime crudely by the number of possible states: $(N+1)^{|A||\mathcal{P}|}$ is an absolute upper bound on the number of distinct matrices on the grid $\{0, 1/N, \ldots, 1\}$, so stabilization occurs no later than that many iterations (though in practice one typically stabilizes much sooner). The substantive point for the present section is not computational efficiency but the existence of a well-defined "end state" obtained by repeated reinforcement. □

Proof sketch. The strategy is to recognize $[0,1]^{A\times\mathcal{P}}$ (with pointwise $\le$) as a complete lattice and to notice that F is built entirely from monotone operations (max, min, and sup over neighbors), hence is monotone. Monotone endomaps on complete lattices have fixed points by Knaster–Tarski, and the least fixed point above a starting state is obtained by iterating F and taking the supremum of the resulting ascending chain (Kleene iteration).

The key step is monotonicity: if we increase any entry of I, then every term of the form $K(j,i) \wedge I_{j,P}$ can only increase, and taking $\vee$ over these terms preserves the increase. Geometrically, one can picture each $I_{i,P}$ as a "fluid level" that can only rise, with incoming neighbors pushing it up subject to channel caps $K(j,i)$; the fixed point is the state where no further pushes can raise any level.

Another useful mental model is reachability under attenuation: repeated application of F allows an intensity at some source agent to propagate along directed edges, but at each step it is clipped by the coupling on that edge. The eventual fixed point therefore encodes, for each (i,P), the best support for P that can arrive at i through any chain of influences starting from the initial configuration, combined with i's own initial holding (since reinforcement never erases the past in this toy setup). This is one reason the least fixed point above $I^{(0)}$ is the natural stabilized state to associate with the dynamics: it represents the minimal commitments consistent with all possible reinforcements generated from $I^{(0)}$. □

Remark 1253 (Interpretation)**.** *Theorem 20 is not meant as a realistic sociological model. Its role is structural: it shows that once we treat social transmission as a monotone reinforcement process (habit-taking across agents), stable cultural regimes arise automatically as fixed points. More detailed models (with decay, anti-resonance, bounded attention, and competing patterns) can* *be built by modifying F while preserving monotonicity or by switching to stochastic dynamics with attractors.*

In particular, adding decay typically breaks monotonicity (since an update may reduce intensities), and then one must use different tools (e.g. contraction mappings, Lyapunov functions, or Markov-chain ergodicity) to recover convergence guarantees. Conversely, one can often keep a monotone backbone by separating reinforcement from decay into alternating steps, or by enlarging the state to include resources/attention so that the extended update is again monotone in an appropriate order. The point here is simply that the present theorem isolates a clean mathematical mechanism for stabilization that can be reused as a component inside more elaborate models.

Remark 1254. *From a philosophical point of view, this is one of the places where the difference between "explanation" and "description" becomes vivid. The fixed-point theorem does not tell us which culture we will get; it tells us that if the underlying transmission has a certain abstract form, then stabilization is a structural necessity. In Peircean terms [14], this is a move toward Thirdness: a law-like regularity extracted from the flux of particular dyadic interactions.*

One can also view this as a limited but genuine explanatory gain: even without forecasting the content of the stabilized regime, we can predict that certain kinds of interventions (those that increase some intensities or couplings) cannot lead, under the model assumptions, to a net decrease in eventual adoption levels. In that sense, the theorem supports counterfactual reasoning about qualitative constraints: it tells us which directions of change are ruled out by the abstract structure of monotone reinforcement, independent of the detailed sociology of any specific pattern.

22.9 Collective mind systems

Hyperseed includes "collective mind systems" as a headline concept: groups can function as minds insofar as they carry distributed patterns of perception, inference, and action. Our formalization treats a collective mind system as the society endowed with a derived pattern web and (optional) derived epistemic/agentive variables. In this subsection, "derived" means that these society-level objects are constructed (perhaps with modeling choices) from agent-internal state, artifact-embedded state, and the structured interaction channels among them; they are not assumed to exist as additional primitive entities.

Definition 373 (Collective pattern web)**.** *Let W_i denote agent i's internal pattern web (Section **??**), and let W_a denote the pattern web embedded in artifact $a \in \mathcal{A}$ (external memory, procedures, institutions).*

The collective pattern web *of a society is the (weighted) union*

$$W_{\text{col}} := \Big(\bigsqcup_{i \in A} W_i \Big) \sqcup \Big(\bigsqcup_{a \in \mathcal{A}} W_a \Big) \sqcup W_{\text{comm}},$$

*where W_{comm} adds edges corresponding to communication and coordination links. Weights on W_{comm} are derived from K and attention/effort constraints (Sections **??** and 8).*

Remark 1255. *The symbol $\bigsqcup$ is used informally here to indicate a disjoint/typed union of webs: we keep track of which subweb came from which agent or artifact, but we allow edges to be added that connect them. The additional web W_{comm} is where cross-agent influence becomes explicit: it is the connective tissue that turns many local pattern webs into a single larger web.*

As an example, in a research community, W_i contains each individual's concepts and inference habits, W_a contains textbooks and codebases, and W_{comm} contains seminar talks, peer review, and informal discussion channels. The collective web is then the natural object on which to ask whether *the community is collectively "smart" in a way not reducible to isolated members; see [19] for compatible systems-level motivations.*

Remark 1256. *It is often useful to think of W_{comm} as itself decomposing into multiple typed layers (even if we keep a single symbol): (a)* broadcast *edges (one-to-many dissemination such as announcements, published papers, mass media), (b)* dialogue *edges (bidirectional conversational links such as collaboration or deliberation), (c)* protocol *edges (standardized interfaces such as submission systems, forms, APIs, or legal procedures), and (d)* control/authority *edges (routing of decisions or permissions such as managerial reporting lines, access control lists). The weights on these edges can be interpreted as effective channel capacities: they summarize reliability, latency, interpretability, and willingness to transmit/receive, all of which are constrained by attention and effort budgets. In particular, high K but low attention can still yield low effective weight, because agents may be capable of understanding each other but not able to allocate the time to do so.*

Remark 1257. *The artifact term $\bigsqcup_{a\in\mathcal{A}} W_a$ is intended to cover more than passive storage. Many artifacts implement* procedural *patterns (workflows, algorithms, norms, bureaucratic scripts) that shape inference and action. For instance, a clinical guideline, a unit test suite, or a legal code can be modeled as a subweb that connects observational patterns to action patterns through standardized intermediate representations. This is one reason artifacts matter for emergence: they can stabilize and transmit patterns across time even when individual membership changes, thereby giving the collective web a degree of continuity and path dependence not present in purely conversational groups.*

Definition 374 (Collective belief state (one simple construction))**.** *Fix a claim language $\mathcal{L}$ and individual belief states $\beta_i : \mathcal{L} \to \mathbb{V}$. Define the* collective belief state *by pointwise join:*

$$\beta_{\text{col}}(\varphi) := \bigoplus_{i\in A} \beta_i(\varphi).$$

This is the minimal aggregation that preserves all evidence held by any agent.

Remark 1258. *Pointwise join is "maximally inclusive": if any agent holds strong positive evidence for φ, the collective holds it; if any agent holds strong negative evidence, the collective holds that too. This is appropriate if one wants the collective belief state to represent the society's total available evidential resources, rather than an official consensus.*

A different choice (e.g. averaging, weighted pooling, deliberation dynamics) could represent different social epistemologies. Hyperseed keeps the join construction prominent because it meshes cleanly with paraconsistent inference: contradictions remain visible rather than being suppressed by premature aggregation.

Remark 1259. *The "minimality" claim can be understood in the lattice-theoretic sense: $\beta_{\text{col}}(\varphi)$ is the least upper bound (with respect to the informational order implicit in $\oplus$) among all aggregate values that dominate every $\beta_i(\varphi)$. Equivalently, any aggregate belief state $\tilde{\beta}$ that satisfies $\tilde{\beta}(\varphi) \sqsupseteq \beta_i(\varphi)$ for all i must also satisfy $\tilde{\beta}(\varphi) \sqsupseteq \beta_{\text{col}}(\varphi)$. This makes β_{col} a natural representation of "everything the society could in principle cite" before filtering, bargaining, or forming a public stance.*

Example 19 (Collective belief is naturally paraconsistent)**.** *Suppose two agents disagree strongly about a claim p:*

$$\beta_1(p) = (0.9, 0.1), \qquad \beta_2(p) = (0.2, 0.8).$$

Then the collective join yields

$$\beta_{\mathrm{col}}(p) = (0.9, 0.8),$$

which represents high positive and high negative evidence simultaneously. This is not a bug: it formalizes the fact that societies often "contain" incompatible sub-beliefs.

Remark 1260. *In ordinary language, one might say: "the society has both a strong case for* p *and a strong case against* p *in circulation." This does not entail that any individual is irrational; it entails that the society, being larger than any one viewpoint, contains incompatible lines of testimony, theory, and incentive. The* p-bit *formalism makes that simultaneously explicit and computationally tractable.*

Remark 1261. *This paraconsistent stance is also useful for modeling institutional settings where mutually inconsistent records coexist for extended periods: for example, a large organization may have conflicting datasets, divergent process documents, and incompatible local norms that nonetheless all remain "live" because they are supported by different subcommunities and artifacts. In such cases, suppressing inconsistency at the collective level can be misleading; it can erase the very structure one needs to model how conflicts are detected, escalated, and eventually resolved (or entrenched) through coordination dynamics.*

Definition 375 (Collective mind system)**.** *A* collective mind system *is a society* Soc *together with chosen derived structures (e.g.* W_{col}, β_{col}*, a collective goal/attention policy, and a cultural state* C*) such that:*

- *the derived structures support persistent, society-level question answering and action (Section 20); and*
- *the society exhibits nontrivial emergence: some patterns or capabilities exist at the collective level that are not well-modeled as independent sums of individual patterns/capabilities (Section 9).*

Remark 1262. *The first condition says: the collective must actually* do *epistemic and agentive work over time (e.g. science, governance, coordinated building). The second condition says: we do not want to label every crowd as a mind; the collective must manifest emergent capabilities that depend on coupling and artifact-mediated memory.*

A standard example is a modern scientific community: no individual contains all the relevant evidence, techniques, and instruments, yet the community can answer questions and build artifacts that no isolated member could. In Hyperseed-Concept terms, this is the core of Collective Consciousness Location *discussions (Hyperseed-Concept 75), though the present section remains agnostic about phenomenology and focuses on functional structure. For a broader framing of collective mind categories and mindplex notions, see [12].*

Remark 1263. *The phrase "persistent, society-level question answering and action" is intended to rule in cases where the collective maintains long-horizon state and can revisit problems across time. Concretely, persistence typically requires (i) some form of durable external memory (archives, repositories, precedents), (ii) role specialization and handoff (so that tasks survive individual turnover), and (iii) a mechanism that selects which questions receive attention and which actions are executed (agenda setting, budgeting, prioritization, or market allocation). These ingredients can be modeled within the same derived-structure framework: artifacts support (i), communication/control edges support (ii), and an explicit or implicit policy supports (iii).*

Remark 1264. *The "collective goal/attention policy" component can be interpreted narrowly (a formal governance procedure) or broadly (any stable regularity that routes attention and effort). For example, in a firm, it may be a managerial planning cycle and incentive scheme; in an open-source project, it may be issue triage norms and maintainer review practices; in a market, it may be the price system coupled with institutional constraints. In each case, the policy shapes W_{comm} weights over time by selectively amplifying some channels (e.g. urgent incident response) and attenuating others (e.g. low-priority requests), thereby changing which subwebs effectively influence collective inference and action.*

Remark 1265. *The cultural state C is included to represent slow-moving, population-level regularities that are not conveniently reducible to a single agent or artifact: shared norms, taboos, aesthetic standards, interpretive frames, and background ontologies. Operationally, C can be viewed as a constraint or prior over pattern formation and communication: it affects which hypotheses are considered, which testimony is trusted, which institutional scripts are legitimate, and which coordination equilibria are stable. Thus C can modulate both the internal composition of W_i (via social learning) and the structure/weights of W_{comm} (via norm-governed interaction).*

Remark 1266. *The emergence condition is intentionally stated qualitatively, but it can be probed in several complementary ways. One approach is* capability gap*: identify tasks that the collective reliably performs while typical individuals cannot (e.g. maintaining a global logistics network, sustaining a legal system, producing a large-scale scientific theory). Another is* counterfactual dependence*: if one removes key coupling mechanisms (communication edges, shared artifacts, standardized protocols), does the capability collapse even when individuals remain intact? A third is* compression/description*: if modeling the collective requires representing new macroscopic variables (institutions, norms, reputations) that are not simply sums of individual variables, this is evidence that society-level state has explanatory autonomy. These diagnostics align with the general patterns discussion in Section 9 while remaining compatible with multiple philosophical views.*

Remark 1267. *Finally, the framework allows "collective mind systems" at multiple scales and with partial integration. A small team with shared documents and frequent dialogue may form a tight collective web with high effective W_{comm} weights and rapid feedback. A large society may instead consist of loosely coupled sub-minds (communities, institutions, platforms) whose interactions are mediated by slower, lower-bandwidth channels and standardized artifacts. In such cases, it can be useful to study not only W_{col} as a whole, but also its community structure, bottlenecks, and boundary objects, since these often determine which contradictions persist in β_{col} and which become resolved through coordination.*

22.10 Mindplex, notable coherence, and the global brain

Hyperseed defines: (i) coherence as systemicity (replaceability under removal), (ii) a notably-coherent system as one whose coherence is greater than slightly smaller subsets and slightly greater supersets, (iii) a mindplex as a notably-coherent mind composed of components that are themselves notably-coherent minds, and (iv) the global brain as a mindplex consisting of people and devices and other organisms on the planet.

We now give a mathematical proxy for these ideas using the earlier notion of approximate morphism and the observer-indexed distances underlying pattern webs.

Definition 376 (Replaceability and coherence (observer-indexed proxy))**.** *Fix an observing context O that provides: (i) a representation of system behavior and (ii) a distance d_O on behaviors (or on induced pattern webs).*

Let S be a finite set of components (agents and/or artifacts) inside a larger system. Write $\mathrm{Beh}_O(S)$ *for the behavior/pattern-flow summary of S as modeled by O. Define the* replaceability error *of a component $x \in S$ by*

$$\mathrm{Err}_O(x; S) := \inf_f d_O\big(\mathrm{Beh}_O(\{x\}),\ f(\mathrm{Beh}_O(S \setminus \{x\}))\big),$$

where the infimum ranges over the class of admissible approximators f (predictors/simulators) available to O. Define the coherence *of S (relative to O) by*

$$\mathrm{Coh}_O(S) := 1 - \max_{x \in S} \mathrm{Err}_O(x; S),$$

after normalizing d_O so that $\mathrm{Err}_O \in [0, 1]$.

Remark 1268. *The definition is deliberately observer-indexed. Coherence is not an intrinsic scalar floating in the void; it is measured relative to what the observer can model and predict. The quantity* $\mathrm{Err}_O(x; S)$ *asks: if we remove x, how well can the observer approximate the effect of x using the rest of the system? If every component is, in that sense, reconstructible from the rest, then the system exhibits strong redundancy and integration, and* $\mathrm{Coh}_O(S)$ *is high.*

As an example, in a tightly synchronized team with overlapping skills and shared documentation, the removal of one individual may be partially compensable by others plus artifacts, yielding low error and thus higher coherence. In a team where one person is the sole holder of a critical secret, their removal yields high error and thus low coherence.

Remark 1269. *Several modeling choices are bundled into* Beh_O *and d_O, and different choices capture different notions of "replaceability." For example,* $\mathrm{Beh}_O(S)$ *might encode time series of actions, message flows, task throughput, or induced pattern-web structure; correspondingly, d_O might be a metric on distributions (e.g. Wasserstein, total variation), a trajectory distance (e.g. dynamic time warping), or a distance between graphs/pattern webs (e.g. via spectral embeddings). The normalization of d_O to* $[0, 1]$ *can be done by fixing a reference scale (e.g. maximal expected distance under a null model, or by clipping via* $d'_O := \min\{1, d_O/\tau\}$ *for a chosen tolerance τ), making the "1−" transformation interpretable as a bounded coherence score.*

Remark 1270. *The choice of* $\max_{x \in S}$ *makes* $\mathrm{Coh}_O(S)$ *a "weakest-link" notion: a set is coherent only insofar as* every *component is individually replaceable (to the observer) by the remainder. In some applications, an average- or quantile-based aggregation (e.g.* $1 - \frac{1}{|S|} \sum_x \mathrm{Err}_O(x; S)$, *or* $1 - \mathrm{Quantile}_p(\{\mathrm{Err}_O(x; S)\})$*) may better match intuitions about partial cohesion in large populations. The max-based proxy is useful here because it corresponds closely to the Hyperseed phrasing about removal of* a *component and emphasizes crisp boundary detection when searching for notably coherent units.*

Remark 1271 (Interpretation)**.** *High* $\mathrm{Coh}_O(S)$ *means: for each component, the rest of the system can (in O's best model) closely approximate what that component contributes. This captures Hyperseed's "if removed, would be replaced by the other portions by some close approximation" in a way compatible with observer-relativity and approximate morphisms.*

Remark 1272. *The infimum over approximators f is a compact way to fold in both (i) the representational limits of O and (ii) the computational/inferential limits of O (what predictors/simulators are admissible). If O is taken to be an idealized Bayesian observer with unbounded compute, f may be extremely rich; if O is a bounded observer (e.g. a human analyst, or a particular monitoring system), the admissible class may be quite small, and coherence becomes correspondingly harder to* *"see." This makes it possible for the same underlying system to be notably coherent for one observer and not for another, which is often the right outcome when discussing societies, institutions, and multi-agent infrastructures.*

Definition 377 (Notably coherent)**.** *A subset S of components is* notably coherent *(relative to O) if it is a local maximum of* Coh_O *in the subset lattice:*

$$\mathrm{Coh}_O(S) > \mathrm{Coh}_O(S \setminus \{x\}) \text{ for all } x \in S,$$

and

$$\mathrm{Coh}_O(S) > \mathrm{Coh}_O(S \cup \{y\}) \text{ for all } y \notin S \text{ with } S \cup \{y\} \text{ admissible as a unit.}$$

(Variants with non-strict inequalities and neighborhood restrictions are also reasonable.)

Remark 1273. *The idea of "notable coherence" is that a coherent system should have a certain boundary: remove a part and coherence drops; add an unrelated part and coherence drops. This is a pragmatic way to detect integrated subsystems inside a larger network, akin to finding "communities" but with a semantics tied to functional replaceability rather than purely edge density.*

As a simple example, within a large company, a particular product team plus its internal tools may be notably coherent: adding random employees outside the team decreases coherence, and removing a key team member decreases coherence. This is one mathematical proxy for the intuitive claim that some subsystems are more mind-like units than others.

Remark 1274. *The "admissible as a unit" qualifier matters in practice: the observer O may only be able to form* $\mathrm{Beh}_O(S)$ *for subsets satisfying constraints (e.g. spatial contiguity, organizational boundaries, data-access permissions, or bandwidth limits). Likewise, the "neighborhood restrictions" alluded to in the definition can be understood as restricting attention to "small perturbations" of S (e.g. add/remove one component, or add/remove from a specified candidate pool), which avoids pathologies in very large systems and aligns with the Hyperseed intuition of "slightly smaller" and "slightly greater" sets. Computationally, searching the subset lattice is generally intractable, so practical detection of notably coherent systems would typically use greedy heuristics, multiscale clustering, or optimization relaxations guided by the observer's representation.*

Definition 378 (Mindplex and society of mind)**.** *A* society of mind *is a collective mind system whose components are (to a reasonable degree) autonomous agents (Section 21).*

A mindplex *(relative to O) is a society of mind S such that:*

(a) S is notably coherent (as above), and

(b) S can be decomposed into components $S_1, \ldots, S_n$ (agents or subgroups) each of which is itself a notably coherent mind (relative to O).

Remark 1275. *This definition bakes in a multi-scale picture: a mindplex is not merely a coherent group, but a coherent group composed of coherent subminds. This is close in spirit to hierarchical/heterarchical pattern-web pictures (cf. [5]) and to Hyperseed's emphasis on nested organization. In Hyperseed-Concept terms, this is the formal proxy for* Mindplex *(Hyperseed-Concept 113), and it is meant to be compatible with the graded collective categories discussed in [12].*

As a concrete example, one might model a research institute as a mindplex: each lab is notably coherent, and the institute as a whole is notably coherent due to shared infrastructure, shared norms, and high-bandwidth communication among labs.

Remark 1276. *The decomposition $S = \bigcup_i S_i$ is not assumed unique, and in many real systems it is more realistic to allow overlaps or fuzzy membership (e.g. a person participates in multiple teams, or an artifact is shared infrastructure). One can treat the present definition as a crisp proxy for a more general multiresolution picture in which notable coherence is evaluated across scales and partitions. In particular, a mindplex is intended to capture the case where there are "units within units": coherent subminds that remain meaningful even as the surrounding collective exhibits its own boundary and persistence. This multi-scale constraint helps distinguish (for instance) a crowd that is briefly coordinated by a single broadcast signal (which may exhibit some coherence) from an organization with enduring internal structure, specialized subgroups, and stable interfaces among them.*

Definition 379 (Global brain)**.** *Let $A_\oplus$ be the population of persons (and other relevant organisms) on a planet, and let $\mathcal{A}_\oplus$ include major communication and computation infrastructures (devices, networks, archives, institutions). A* global brain *is a mindplex constructed on*

$$(A_\oplus, G_\oplus, K_\oplus, \mathcal{A}_\oplus, \mathrm{Acc}_\oplus, \mathcal{D}_\oplus),$$

when the coupling/communication regime is strong enough that large-scale notable coherence emerges.

Remark 1277. *The clause "strong enough that large-scale notable coherence emerges" is doing conceptual work: it signals that merely having many agents and devices is insufficient; what matters is whether the planet-scale ensemble forms an integrated unit* relative to some observer *and representation. In the present proxy, this would mean that for a substantial set S spanning large fractions of $(A_\oplus \cup \mathcal{A}_\oplus)$, the removal of typical components yields relatively low replaceability error because the remainder can approximate their contributions via redundancy, routing, institutional memory, and adaptive reconfiguration. Conversely, if large portions are irreplaceable single points of failure (or if the observer cannot model cross-domain coupling),* Coh_O *would remain low and no planet-scale local maximum would appear. One may also take O to be an internal observer (e.g. an institution attempting to model global behavior), in which case "global brain" becomes an emergent, partially self-modeling phenomenon rather than a purely external description.*

Remark 1278. *The global brain concept (Hyperseed-Concept* **??***) is intentionally conditional: it is not asserted that the planet already forms a mindplex, only that under sufficiently strong, structured coupling it may. The tuple displayed is simply the society tuple at planetary scale, with artifacts now including digital networks, archives, and large institutions. This conditionality matters because "planetary scale" changes the relevant timescales and bottlenecks: communication latencies, institutional decision cycles, and archival retrieval dynamics can become as important as raw connectivity. In particular, "structured coupling" is meant to exclude mere density of contacts and instead emphasize patterned, reliable, and semantically aligned interactions (e.g., stable protocols, shared ontologies, and recurrent coordination pathways) that can support error-correcting circuits of collective action and belief update.*

A key reason to separate definition from existence is methodological humility: large-scale coherence is an empirical and dynamical question, not something settled by terminology. The present formalism provides variables one could, in principle, estimate (couplings, access, replaceability errors) and thus turn the question into a scientific one in Hyperseed's sense [20]. Concretely, one could operationalize coupling strength via observed information flow, coordination success rates, or causal influence estimates across layers; access via differential reachability of archives, institutions, or communication channels; and replaceability errors via counterfactual robustness tests (e.g., whether removing a platform, institution, or key actor leads to graceful degradation or systemic collapse). On this view, "global brain" becomes a hypothesis about a regime: a phase in which *the planetary tuple supports sustained integration and collective memory, rather than a rhetorical label.*

Remark 1279 (Where morphic resonance enters)**.** *The mindplex/global brain notions are not only graph-theoretic. Their distinctive Hyperseed flavor is dynamical: habits and morphic resonance (Section 12) can operate across agents via the communication and artifact layers, amplifying certain collective patterns and stabilizing them across time. This amplification is intended to cover both fast channels (imitation, social contagion, coordinated attention) and slow channels (institutionalization, codification in texts and software, and the training of new agents on existing corpora), so that patterns can persist even as individual participants change. In this sense, "resonance" functions as a shorthand for mechanisms that bias future trajectories toward previously realized configurations, including reinforcement learning loops, reputational feedback, and path-dependent standards.*

In this sense, a mindplex is not just "a network" but a regime of high mutual reinforcement and cross-component pattern re-use. The regime language is meant to be taken literally: the same underlying nodes and edges may or may not constitute a mindplex depending on parameters such as signal-to-noise, incentives, interpretability, and the availability of shared external memory. Cross-component pattern re-use includes the re-deployment of solutions, norms, and representations across domains (e.g., legal templates applied to new technologies, or computational schemas migrating into organizational design), which increases compression and coordination capacity at the collective level.

Remark 1280. *One can visualize this as a multi-layer dynamical system: the interaction graph supplies channels, artifacts supply long-term memory, and habit dynamics supply reinforcement. When these align, the collective web begins to exhibit "self-maintaining" patterns, not unlike autocatalytic sets but in a socio-cognitive substrate (Hyperseed-Concept 61). A useful way to read the analogy is functional rather than biochemical: artifacts and institutions can play the role of catalysts by lowering the cost of re-instantiating practices, while communication channels play the role of transport that connects otherwise isolated sub-processes. Alignment across layers can be partial and still significant, yielding localized mindplex behavior (e.g., within scientific communities, technical ecosystems, or governance networks) even if the whole planet does not exhibit uniform coherence.*

Whether one wishes to describe this in the evocative language of resonance [13] or in the austere language of fixed points and attractors, the mathematical role is the same: to describe persistence of structure across time. Here "persistence" can be understood as invariance (patterns that remain approximately unchanged), recurrence (patterns that reappear after perturbation), or robustness (patterns that survive turnover in agents or artifacts). In dynamical terms, this corresponds to attractors or metastable sets in the state space of collective variables, with "noise" supplied by shocks, innovation, and demographic churn; the empirical question is then whether observed trajectories concentrate near such sets, and on what timescale transitions occur.

22.11 Summary: Hyperseed concepts covered in this section

This section provided a rigorous scaffold for group-level Hyperseed concepts: society and tribe as multi-agent pattern webs; communicative acts and systems; social roles (teacher, student, worker, colleague) as interaction templates; culture as stabilized intersubjective pattern web; and collective mind systems culminating in mindplex and global brain. The intent of this scaffold is to make "group-level" talk precise without reducing it to mere metaphor: a society or tribe is modeled as a recurrently coupled ensemble whose stable patterns are identifiable across time, membership changes, and context shifts. In this framing, the same analysis that applies to an individual agent's patterns (formation, reinforcement, decay, and reconfiguration) is extended to coordinated patterns spanning many agents and their shared artifacts. The section also emphasized that many apparently "soft" social phenomena (norms, conventions, institutions) can be described operationally as constraints on interaction that shape which patterns are likely to be reproduced.

Remark 1281. *The unifying theme is that "collective mind" is treated as a question of* structure and dynamics *rather than as a special ontological category. When couplings, artifacts, and reinforcement are arranged so that group-level patterns can persist, propagate, and answer questions, then the society begins to behave mind-like in the operational sense developed in Sections 20 and 21. In Hyperseed-Concept terms, this is the bridge between* Society *(Hyperseed-Concept 170),* Culture *(Hyperseed-Concept 91),* Collective Consciousness Location *(Hyperseed-Concept 75), and* Mindplex *(Hyperseed-Concept 113). In particular, "answer questions" should be read in the same pragmatic sense as for individual cognition: the system exhibits reliable input–output mappings, can integrate distributed information, and can select actions (or policies) that improve its performance relative to some goal or constraint. This does not require positing a single inner observer; it requires that the interaction network implements functional loops of sensing, memory, inference, and control at the group level. The bridge is therefore not a leap from individuals to an entirely new kind of entity, but an account of how coordination mechanisms (communication protocols, role structures, shared symbols, and institutional feedback) can yield emergent, yet analyzable, cognitive regimes.*

In later sections, tools/machines (Section 23) and intersubjective communion (Section **??**) will add additional coupling modes that can dramatically increase coherence and stabilization, thereby changing when mindplex-like regimes become plausible. These later coupling modes matter because they can alter the bandwidth, fidelity, and persistence of coordination: tools and machines can externalize memory and computation into durable substrates, while communion-like mechanisms can tighten alignment by increasing shared context and mutual predictability. As a result, the boundary between loosely coordinated social webs and more tightly integrated mindplex dynamics becomes contingent on concrete engineering and cultural practices, not merely on group size. This also clarifies why "global brain" claims should be evaluated via measurable properties of coupling (latency, robustness, error correction, incentive compatibility) rather than by rhetoric alone.

23 Tools, machines, computation, and embodiment

23.1 Why engineered artifacts belong in a rigorous Hyperseed

Hyperseed treats minds as pattern webs embedded in (and coupled to) reality-systems. Within that picture, *tools*, *machines*, and *computers* are not ontological afterthoughts: they are stable, engineered pattern-systems that let an agent extend its perception-action loop across additional substrates in physical reality. In particular, "engineered" here signals that the artifact is intentionally shaped to yield repeatable causal regularities under a specified range of conditions (tolerances, loads, noise), so it is naturally described as part of the agent–world coupling rather than as a passive backdrop. This is also why the tool/machine/computer triad is not a mere list: it spans a spectrum from direct mechanical mediation (tools), to self-sustaining coordinated mediation (machines), to symbolically mediated mediation (computers), all of which can be treated uniformly as realizers of process structure.

Remark 1282. *At an intuitive level, the point is that cognition is never merely "in the head" once one admits closed-loop agency: an agent's competent behavior is a whole causal circuit that includes body, environment, and (often) engineered artifacts. A tool is therefore not merely an inert object;*

relative to an observer/context, it is a reliable bridge *between action tokens and effect tokens, so it belongs naturally beside the formal notions of agency and task competence (Sections 21 and 14). This corresponds directly to Hyperseed-Concept 191 and Hyperseed-Concept 106 as elements of a reality-system that restructure what an agent can do.*

From the standpoint of the overall reconstruction, engineered artifacts are where abstract process structure (morphisms, compositionality) meets physical constraint (effort, friction, reliability). That meeting is one of the main arenas in which the quantale notions of evidence and weakness become empirically consequential [1, 3, 2]. A further point (useful later when we talk about embodiment) is that the "bridge" can run both ways: tools not only amplify outward action but also reshape inward perception by changing what is sensed, how it is filtered, and what degrees of freedom become salient. A microscope, a telescope, an fMRI scanner, or even a simple ruler can be treated as a reparameterization of the agent's observation channel, thereby changing the evidence available for downstream inference; conversely a wrench, a lathe, or a numerical optimizer can be treated as a reparameterization of the agent's actuation channel, thereby changing the effort required to reliably reach desired effects. On this view, engineering is a way of sculpting the agent's effective sensorimotor manifold.

Mathematically, the clean way to express this is:

- an *abstract process* is a morphism in a category of processes (or a V-enriched category as in Section 3);
- a *physical process* is a morphism in a category describing transformations available within a physical reality-system (Section 25);
- a *physical realization* is a structured relationship (encoding/decoding + dynamics) connecting an abstract process to a physical process; and
- a *tool* is a physical entity whose coupling to an agent yields additional realized processes (typically with reduced effort, increased reliability, or both).

To make the above list more than a slogan, it is helpful to keep two distinctions explicit. First, the abstract/physical split is not a mind/body dualism; it is a modeling move that separates (1) the compositional structure we wish to preserve ("what computation or procedure is being performed?") from (2) the constraints that determine whether a real system can stably enact that structure (energy, noise, wear, latency, finite precision, and so on). Second, "realization" is not mere association: it is a constraint-respecting correspondence that must commute with the relevant compositions, at least approximately, if we want the engineered artifact to be predictable and reusable as a component. This is where interfaces matter: an artifact is engineered so that the conditions under which its input-output behavior is well-approximated are themselves describable, testable, and (often) composable.

A particularly important special case is *computation*. An algorithm (or program semantics) is naturally modeled as an abstract process, while a concrete run on hardware is a physical process. The "encoding/decoding + dynamics" clause then packages familiar notions such as representation, compilation/interpretation, signal encoding, error correction, and timing discipline. For example, a logical gate network and its transistor-level implementation can be treated as two process levels linked by a realization relation; the engineering content is precisely the set of design choices that make the correspondence robust against temperature variation, component drift, and noise. In the Hyperseed setting, such robustness is not merely practical: it is part of the explanation of why certain morphisms are available as stable resources to an agent in a given reality-system.

Remark 1283. *The phrase "morphism in a category" is doing philosophical work here: it encourages us to treat processes as first-class citizens and to regard composition as primitive. This resonates with process-oriented views (in the broad Whiteheadian spirit [15]) while keeping the mathematics explicitly compositional: if a complex artifact is built by wiring together sub-artifacts, the formal semantics should reflect this wiring by categorical composition. One can add that engineering practice tacitly relies on exactly this idea: subcomponents are designed to satisfy contracts (interfaces, tolerances, input/output ranges), and complex devices are built by composing these contracts. Categorically, this motivates not only ordinary composition but also monoidal structure (parallel composition), products/coproducts (bundling/switching of channels), and enrichment (where hom-objects can encode graded notions such as cost, effort, risk, latency, or fidelity). In that enriched setting, "reduced effort" and "increased reliability" in the tool bullet above can be read literally as improvements in the value assigned to a morphism by the enrichment: a tool changes which morphisms are accessible at what grade.*

This section makes these ideas precise enough to support later discussions of embodiment, implementation semantics, and the "algebraic asymmetry" between physical and mental realities. Concretely, embodiment enters because the agent's body is itself an engineered (or evolved) artifact from the standpoint of control: it defines the baseline action/observation morphisms available to the mind-pattern. External tools then act as additional composable modules that alter the reachable set of world-states and the evidential structure of observations. Implementation semantics enters because a realization relation must say what it means for an abstract procedure to be enacted by a physical device in a way that is stable under the kinds of perturbations the reality-system induces. Finally, the "algebraic asymmetry" is foreshadowed by the fact that physical realization is graded and fragile (bounded by conservation laws, noise floors, and finite resources), whereas mental or symbolic composition is often treated as frictionless; the theory needs a principled way to relate these two modes of composition without collapsing them.

23.2 Tools as externalized affordance morphisms

Hyperseed's informal definition can be summarized as: a tool is something a user manipulates purposefully toward an objective, where the objective is not primarily about the tool's own state of consciousness.

To express this without importing unnecessary machinery, we model a tool in terms of what it *affords* when coupled to an agent. One can read "coupled" here broadly: the agent may hold the artifact, wear it, operate it at a distance, or interact through an interface layer (buttons, APIs, protocols). The intent is to treat the tool as part of the agent–environment control loop, while still isolating a crisp interface between what the agent can *do* (its action tokens) and what changes in the world are made more (or less) attainable (its effect tokens). In particular, the same physical object may induce different affordances under different couplings (e.g. bare hands versus gloved hands; direct use versus remote teleoperation), which is why the formalization keeps the observer/context explicit.

Definition 380 (Affordance profile)**.** *Fix an observer/context O. Let $\mathcal{A}$ be a set of* action tokens *available to an agent (motor commands, control signals, or higher-level actions), and let $\mathcal{E}$ be a set of* effect tokens *in some environmental slice of O's reality-system (events, state changes, or achieved constraints).*

An affordance profile *is a map*

$$\mathrm{Aff} : \mathcal{A} \times \mathcal{E} \to \mathbb{V} = [0, 1]^2$$

whose value $\mathrm{Aff}(a, e)$ *represents (paraconsistent) evidence that performing* a *using the artifact tends to produce effect* e *within the relevant context.*

Remark 1284. *The use of* tokens *emphasizes that* $\mathcal{A}$ *and* $\mathcal{E}$ *are modeling choices rather than metaphysical primitives. An action token may be low-level (a torque command), mid-level (a gesture), or high-level ("compile and run test suite"); similarly an effect token may be a raw state transition, a perceptual event, or a constraint satisfaction statement ("object is aligned"). The appropriate granularity depends on* O *and on the explanatory task: for fine motor control one might refine* $\mathcal{A}$ *to continuous commands, whereas for social or institutional tools one might coarsen* $\mathcal{A}$ *to normative or procedural actions ("submit form") and let* $\mathcal{E}$ *encode institutional state changes ("request accepted"). This flexibility is also what lets the same mathematical object cover both embodied tools (hammers) and informational tools (calculators, software libraries) without forcing a single privileged ontology of actions and effects.*

Remark 1285. *Intuitively,* $\mathrm{Aff}(a, e)$ *is an "action-to-effect" interface description: it says what the artifact makes easy, difficult, reliable, unreliable, encouraged, or resisted. The codomain* $\mathbb{V} = [0, 1]^2$ *is the* p-bit *evidence space used throughout Hyperseed: the first coordinate is positive evidence and the second is negative evidence. Thus an affordance can be simultaneously supported and undermined by experience, reflecting the common situation that a tool can work well in some contexts and fail (or be dangerous) in others. This is one instance of Hyperseed-Concept 86 interacting with Hyperseed-Concept 191.*

A simple example is a lever used to lift a weight: an action token might be "apply downward force at distance d *from fulcrum," and an effect token might be "weight rises by* Δh*." One expects strong positive evidence for that action-effect pair in ordinary mechanical contexts, but one may also have nontrivial negative evidence (slippage, breakage, user error). Another example is a password manager: an action token might be "request credentials for site* s*," and an effect token might be "credentials filled into browser form"; again, positive evidence may coexist with negative evidence when the environment is hostile or the tool is misconfigured. Formally, the point of* Aff *is that it allows us to treat a tool as a* morphism-like *object mediating between an action vocabulary and an effect vocabulary, which is exactly what later sections will need when tools become participants in social and intersubjective systems.*

Remark 1286. *The "morphism-like" phrasing is meant operationally:* Aff *behaves like an interface that can be compared, composed, and substituted. For example, if one tool* T_1 *maps actions to an effect token that is itself an action token for another tool* T_2 *(e.g. "produce a tightened screw" as a precondition for "mount a circuit board"), then one can model multi-tool workflows by composing their affordance profiles at the level of shared intermediate tokens. Even when such strict token matching is unavailable, coarse-graining and refinement mappings between token sets can be used to relate affordance profiles across levels of description (e.g. translating a family of low-level controller actions into a higher-level macro-action).*

Remark 1287. *The paraconsistent encoding in* $\mathbb{V} = [0, 1]^2$ *can also be read as separating two kinds of observations: evidence* for *the claim "*a *tends to produce* e*" and evidence* against *it. This separation is useful when the world is nonstationary or heterogeneous: repeated success in one subcontext does not erase repeated failure in another, and both should remain available for context-sensitive inference. In practice, one can interpret* $\mathrm{Aff}(a, e)$ *as a summary of experience under* O *(counts, weighted frequencies, model-based estimates), and later decision procedures can condition on additional context variables or aspects to resolve when the positive versus negative component should dominate.*

Remark 1288. *The affordance profile is a compact interface between the (agent-relative) action vocabulary and the (context-relative) effect vocabulary. In practice,* Aff *can be learned from interaction data, derived from physics models, or constructed compositionally from sub-artifacts.*

Remark 1289. *Learning* Aff *from interaction data can be understood as estimating a structured action–effect relation under partial observability. For instance, given logs of attempted actions and observed outcomes, one may update positive evidence when* e *is observed after* a*, and update negative evidence when* e *fails to occur or when an incompatible effect occurs. When the relevant effects occur with delay, one can either expand* $\mathcal{E}$ *to include temporally extended tokens (e.g. "achieved within* τ*") or treat* Aff *as summarizing an induced policy-conditional transition model over an appropriate time window. This keeps the definition agnostic about the details of time, memory, and credit assignment, while still letting later sections talk about tools in a uniform vocabulary.*

Definition 381 (Tool)**.** *A* tool *(relative to an agent class and an observer/context* O*) is an entity* T *in a reality-system together with an affordance profile* Aff_T *that is:*

(a) usable*: there exists a nontrivial subset* $\mathcal{A}_T \subseteq \mathcal{A}$ *and effects* $\mathcal{E}_T \subseteq \mathcal{E}$ *such that* $\mathrm{Aff}_T(a, e)$ *has substantial positive evidence for some* $(a, e) \in \mathcal{A}_T \times \mathcal{E}_T$*; and*

(b) purpose-supporting*: for some objective functional (Section 18), the availability of* T *strictly increases expected objective achievement for typical users in the class, via the induced action-effect couplings.*

Remark 1290. *The "nontrivial" qualifier in the usability clause is intended to rule out degenerate cases where* $\mathcal{A}_T$ *or* $\mathcal{E}_T$ *contains only vacuous tokens (e.g. an action that is never available to the agent, or an effect that is always true regardless of action). Intuitively, a tool must open up at least some meaningful region of action–effect space that was previously absent or less reliable. Depending on the application, "substantial positive evidence" can be instantiated as a threshold on the positive coordinate of* $\mathrm{Aff}_T(a, e)$*, a gap between positive and negative evidence, or a downstream decision-theoretic criterion tied to improved control.*

Remark 1291. *The purpose-supporting clause is deliberately phrased in terms of* expected *objective achievement to allow tools that are beneficial in aggregate despite occasional failures, and to allow tools that shift risk profiles rather than deterministically guaranteeing outcomes. The reference to "typical users" acknowledges that toolhood is relative not only to* O *but also to a distribution over user skills, training, and embodiment: a lathe may be purpose-supporting for a trained machinist but not for a novice; a user interface may be purpose-supporting for sighted users and not for blind users unless paired with assistive technology. This connects directly to the motivating theme that tools are part of* embodied *computation: their effective affordances depend on bodily and cognitive properties of the agent class.*

Remark 1292. *The usability clause prevents "tools" from including arbitrary inert objects whose action-effect links are too weak to matter; the purpose-supporting clause prevents us from calling every causal mediator a tool (e.g. a random obstacle) unless it helps with some objective. In plainer language: a tool is something that* makes some intended outcomes easier or more reliably achievable *for some class of agents, relative to an observer/context.*

Examples: a hammer is a tool because it supports the objective "join two pieces of wood" by increasing the probability of the effect "nail is driven" for actions in a natural user action set. A microscope is a tool because it supports objectives that require fine perceptual distinctions by reliably producing effects like "image reveals small-scale structure," thus interacting with Hyperseed-Concept 134 and Hyperseed-Concept 98. The usefulness of this definition is that it makes "toolhood" *a property that can be discussed in the same formal vocabulary as tasks and values: it becomes possible to compare tools by their affordance maps and by the induced changes in expected objective achievement.*

Remark 1293. *This framing also clarifies why "tool" is not synonymous with "technology" or "artifact." An entity may be technologically sophisticated yet fail the purpose-supporting clause for a given objective functional (e.g. a complicated gadget that distracts rather than helps), and conversely a simple artifact (a wedge, a string) may be a powerful tool relative to an agent class and objective. Moreover, a single physical object can implement multiple tools depending on which affordance profile is salient: a smartphone can be a camera, a map, a payment instrument, or a distraction source, each corresponding to different subsets of $\mathcal{A}$ and $\mathcal{E}$ and different induced changes in objective achievement.*

Remark 1294 (Tools as patterns that extend agency)**.** *Earlier sections treated agency as closed-loop control (Section 14) and tasks as externally specified objective-achievement problems (Section 21). A tool is then an* engineered pattern-system *that enlarges the agent's effective action set (or reduces the effort of actions) by adding new reliable couplings from actions to effects.*

Remark 1295. *In this sense, tools can be seen as externalized "affordance morphisms" that restructure the agent's reachable set in state space: they do not merely add raw power, but reparameterize control. A steering wheel converts small hand rotations into large changes in vehicle trajectory; a search engine converts short text queries into high-probability access to relevant information; a musical instrument converts constrained gestures into complex acoustic effects. In each case, what matters for agency is the induced mapping from a feasible action alphabet to a task-relevant effect alphabet, not the internal mechanism by which the artifact accomplishes the transformation.*

Remark 1296. *Note the deliberate observer-relativity: "tool" is not asserted as an intrinsic essence, but as a role an entity plays in a coupled system of agent, objective functional, and context. This is consistent with Hyperseed's general stance that many ontological tags are relative to an observer/context and a modeling purpose [1].*

Remark 1297. *Observer-relativity also helps separate two questions that can otherwise be conflated: (i) whether an entity* can *mediate certain action–effect couplings (a descriptive claim about the reality-system under O), and (ii) whether those couplings are* counted *as the entity's affordances in a given modeling task (a choice of $\mathcal{A}$, $\mathcal{E}$, and the relevant aspect of context). For example, a rock affords "smash" in a coarse-grained model of improvised tools, but in a fine-grained safety-critical model its negative evidence for controlled, repeatable effects may dominate, changing whether it is treated as a tool for the objective at hand. This explicit separation is one reason the affordance profile representation remains useful when the discussion later shifts to social tools (protocols, norms, institutions) whose "actions" and "effects" are themselves observer- and context-mediated.*

23.3 Machines as internally patterned tool-systems

Hyperseed distinguishes machines from generic tools by emphasizing that the causal interactions among parts of a machine form a pattern in the machine's overall behavior. Put differently, a machine is not merely *used* by an agent to produce an effect; it is also a system whose *internal* use-relations (parts acting on parts) are engineered so that the whole has a robust, repeatable mode of operation.

Definition 382 (Machine)**.** *A* machine *is an* engineered *physical system M (Definition 383) that can be decomposed into components $(M_i)_{i\in I}$ such that:*

(a) each component M_i is (typically) a tool for acting on other components; and

(b) the internal causal interaction structure among the components induces a stable input-output behavior of the whole M that exhibits nontrivial patterns (Section 9) with high intensity relative to the decomposition baseline.

Remark 1298. *In ordinary speech, a machine is often "a tool with moving parts." The formal definition refines this: a machine is a* network of tools acting on each other *in such a way that the composite behavior is stable and patterned. The phrase "patterns with high intensity" appeals to the earlier formalization of pattern and emergence [5]; the idea is that the overall behavior is not merely a bag of componentwise behaviors, but a structured regularity that survives perturbation and supports prediction and control (Hyperseed-Concept 130 and Hyperseed-Concept* **??***). In particular, "relative to the decomposition baseline" indicates that the relevant comparison is not against an arbitrary null model, but against what one would expect if the components were only weakly coordinated (e.g., if they acted largely independently, or if their couplings were randomly rewired while keeping the same parts). On this view, a system qualifies as a machine not merely because it is complicated, but because its couplings* constrain *the accessible behaviors into a smaller, more regular family: the whole exhibits a characteristic repertoire of operation that can be recognized, reproduced, and relied upon.*

Examples: a mechanical clock decomposes into gears, springs, and escapement components that constrain each other; the high-intensity pattern is periodic motion and reliable timekeeping. A modern CPU decomposes into logic gates and subsystems; the high-intensity pattern is reliable execution of instruction semantics under a clocked discipline. One may also view a bicycle as a machine in this sense: its components (frame, chain, sprockets, bearings, brakes) are individually tools that act on each other to yield a stable input-output relation between rider-applied forces and predictable motion/steering/braking, with the "pattern" being the constrained dynamics that make riding learnable and controllable rather than chaotic. These examples underscore that the "input" and "output" of a machine need not be purely informational; they may be forces, motions, material transformations, or other embodied variables, so long as the system as a whole implements a stable mapping (possibly stochastic, but with reproducible statistics) from relevant operating conditions to outcomes.

This definition is useful because it lets us connect machines to compositional semantics: if the components are tools and their couplings are stable, then one can treat the machine as a higher-level tool whose affordance profile is itself constructed from lower-level affordances. The same idea supports hierarchical abstraction: once the higher-level tool behavior is stable, it can be "black-boxed" for many purposes, allowing agents to plan using the machine's macroscopic affordances without explicitly simulating all internal component interactions.

Remark 1299. *Clause (a) uses "typically" to allow that some components may function primarily as supports, constraints, or media (e.g., a chassis, casing, lubrication, or shielding) rather than as direct actuators on other parts. Nevertheless, even these components often participate causally by setting boundary conditions, maintaining tolerances, or channeling energy and information, so that their presence is part of what makes the overall pattern stable. In this sense, the decomposition $(M_i)_{i\in I}$ is not required to be unique: different granularities (coarser modules vs. finer subparts) may each reveal patterned interactions, and the definition only requires that there exists some decomposition at which the machine-like character is made explicit.*

Remark 1300 (Machines induce internal "interaction languages")**.** *When a family of machines shares standardized components and couplings, one gets an internal "language" of parts and compositions (gears and shafts, logic gates, instruction sets, network protocols). Formally, this can be* *treated as a subcategory of realizable processes whose morphisms are precisely the allowed component compositions. The "language" metaphor is apt because the standards function like a syntax (which parts may connect, in what orientations, under what tolerances) together with an operational semantics (what behaviors result when they are connected in permitted ways). In mature machine families, this interaction language is often explicitly documented as interface specifications (e.g., bolt patterns and torque specs, voltage levels and timing constraints, ISA and ABI conventions), which makes the induced patterns portable across instances: one can reason about the behavior of a class of compositions without re-deriving everything from first principles.*

Remark 1301. *This "interaction language" viewpoint is also a bridge to social coordination: once a machine family stabilizes, communities can build training, documentation, and division of labor around it. In that sense, machines become social artifacts that mediate collective competence, anticipating the culture-level constructions of Section 22 (Hyperseed-Concept 91 and Hyperseed-Concept 171). The point is not merely that people* use *machines, but that the stabilized internal language of a machine family reshapes how labor is decomposed: roles emerge that correspond to modular boundaries (designer vs. fabricator vs. operator vs. maintainer), and competence becomes partly a matter of fluency in the relevant interaction language. This also clarifies why machines are closely linked to computation and embodiment: they provide reliable, repeatable causal structure that can be embedded into workflows, plans, and protocols, so that abstract procedures (including symbolic ones) can be physically realized with predictable behavior across time, contexts, and operators.*

23.4 Engineered artifacts

Hyperseed uses "engineered" as a broad ontological tag: created via purposeful, goal-oriented activity of one or more intelligent minds. In particular, the term is meant to track *origin and causal history* (how a thing came to be in the modeled reality-system), rather than merely its present-day use or its aesthetic resemblance to human-made objects. The tag is intentionally permissive: it covers cases where design is explicit and centralized (a blueprint and a factory), as well as cases where design is implicit, distributed, or only partially articulated (e.g., incremental improvement across generations of makers, or selection among variants produced by a mixed intentional/accidental process).

Definition 383 (Engineered)**.** *An entity E is* engineered *(relative to an observer/context O) if there exists:*

- *an agent (or agent collective) A as in Section 21, with goal/valuation structure as in Section 18; and*
- *a nontrivial interval of time (Section 7)*

such that E arises as a consequence of a goal-oriented design-and-construction process within O's modeled reality-system. In this observer-relative framing, the requirement that the process occur "within O's modeled reality-system" is doing substantive work: it excludes hypothetical external designers that the observer does not model, while including indirect and mediated causal routes (e.g., a committee designs a standard, which reshapes incentives, which in turn leads many independent actors to build compatible artifacts). The "nontrivial interval" clause is also intended to rule out degenerate cases where E would be treated as engineered only by stipulating an instantaneous act of creation; engineering here is tied to temporally extended activity such as iteration, refinement, procurement, testing, coordination, or maintenance, any of which may be the bottleneck that makes the outcome non-accidental relative to the goals of A.

Remark 1302. *Intuitively, "engineered" names a causal pedigree: the artifact exists because some mind (or coalition of minds) pursued a goal and successfully constrained reality to instantiate a pattern. This is not restricted to industrial engineering; it includes language artifacts (alphabets, grammars), institutional artifacts (contracts, courts), and computational artifacts (code and protocols), depending on what the observer/context counts as part of the modeled reality-system. This is Hyperseed-Concept* **??** *stated in the same observer-relative style as the rest of the ontology [1]. A useful consequence of this broad scope is that "engineered" can apply to abstracta and semi-abstracta insofar as they have realized implementations and stabilizing causal roles in the world the observer models (e.g., a legal procedure instantiated by documents, officials, and sanction mechanisms; or a protocol instantiated by software, hardware, and operator practices). Conversely, mere* use *does not suffice: a naturally occurring stone used as a hammer is not, by that fact alone, engineered; but a stone intentionally shaped or selected and curated through an organized process for hammering may be engineered, depending on the causal history the observer ascribes.*

A simple example is a screwdriver: it is engineered because it arises from an iterative process of designing and manufacturing an object that reliably couples twisting actions to screw-rotation effects. A more subtle example is a musical notation system: it is engineered (in this sense) because it is a designed symbol technology enabling new patterns of reproduction and coordination across time. The usefulness of explicitly labeling engineered entities is that later arguments about society, culture, and collective minds can treat engineered artifacts as stabilizers of cross-agent coupling, rather than as incidental background [19]. Note that these examples also illustrate that engineering can be multi-layered*: a screwdriver depends on engineered metallurgical practices and measurement conventions, while notation depends on engineered inscriptions, pedagogy, and social norms. In such cases, engineering is not a single event but a scaffold of interlocking engineered subsystems whose combined effect is to make certain actions easy, reliable, and interoperable across agents.*

Remark 1303. *In borderline cases, it can be helpful to distinguish engineered entities from entities that are merely* selected *or* filtered *by agents without being constructed in detail. For example, breeding and domestication involve goal-oriented selection operating through natural reproduction; whether a domesticated organism counts as engineered relative to O depends on whether O models the selective process as an intentional design-and-construction process (often distributed over time and across many agents). Similarly, artifacts produced by autonomous systems (e.g., code emitted by a learned model) can be engineered relative to O if O models the upstream training, prompting, evaluation, and deployment pipeline as a goal-oriented process attributable to an agent collective. These clarifications preserve the intent that "engineered" is about goal-directed constraint of outcomes, even when the fine details of the resulting pattern are not explicitly specified by any single mind at any single moment.*

Remark 1304. *In the quantale-weakness framing, one can treat engineering as constrained search over candidate artifacts whose realized affordances reduce effort (Section 8) while meeting goal constraints. We develop this viewpoint explicitly in Section 26. One can also interpret this as a shift in the feasible action-set available to agents: an engineered artifact is not merely an object, but a transformation of the coupling between intentions and outcomes, often by making some transitions in the agent–environment system more reliable, cheaper, or more reversible. On this view, the "constraints" include not only physical laws and resource limits, but also institutional compatibility conditions, coordination costs, and cognitive limits of the agents that must adopt the artifact for it to function as intended.*

Remark 1305. *The "constrained search" phrasing foreshadows the wu-wei formalism: one may view successful engineering as finding low-effort geodesic-like trajectories in a space of designs,* *where effort is not merely physical exertion but also cognitive and organizational cost [21]. This links engineered artifacts to Hyperseed-Concept 100 and Hyperseed-Concept 207. In practical terms, this emphasizes that many engineered artifacts are engineered* interfaces*: they compress complicated causal structure into a small set of stable handles (buttons, APIs, rituals, forms) that let agents achieve goals without re-solving the underlying problem each time. Accordingly, "engineering" in this sense includes the creation of standards and abstractions whose primary function is to reduce coordination effort by making agent expectations align.*

23.5 Computers and programs as emulation machines

Hyperseed defines a computer (relative to a group of minds) as a machine that can, with modest effort, be made to emulate a large variety of other machines; and defines a program as a set of signals telling the computer what other machine to emulate.

We formalize this by separating syntax, semantics, and realization.

Remark 1306. *The phrase "relative to a group of minds" is meant to foreground that programmability is partly an interface notion: what counts as "modest effort" depends on a user class's tools, training, and available infrastructure, and what counts as a "large variety" depends on which behaviors are distinguishable and valuable to that class. For example, to an embedded-systems engineer, changing a firmware image may be modest; to a lay user, even installing a compiler toolchain may not be. Likewise, two machines might be physically capable of the same reconfigurations, but differ greatly in the effort required to exploit them (documentation, debugging support, safety constraints, access to I/O), which is why the definition is intentionally not purely extensional.*

Definition 384 (Abstract process semantics)**.** *Let* $\mathbf{Abs}$ *be a category (or* V*-enriched category) of abstract processes. Objects are abstract state spaces, types, or contexts; morphisms are abstract transitions/processes. We write* $f : A \to B$ *for an abstract process from* A *to* B*.*

Remark 1307. *The notation* $\mathbf{Abs}$ *indicates a category: its objects are "types of states" and its morphisms are the processes that carry states of one type to states of another. One may keep in mind standard examples: (i) sets and functions, (ii) measurable spaces and stochastic kernels, (iii) state machines and their transition relations, or (iv) typed terms modulo equivalence in a lambda calculus. The abstractness here is methodological: we want to speak about a process* f *independently of any particular physical substrate that might implement it. This is a mathematical expression of Hyperseed-Concept 51 and Hyperseed-Concept 140 (and, more specifically, Hyperseed-Concept 141).*

The definition is useful because it gives a precise target for implementation: when we later say a physical system realizes f*, the claim is that the physical dynamics, suitably encoded/decoded, approximate this morphism in* $\mathbf{Abs}$*.*

The parenthetical "(or V*-enriched category)" is included to accommodate quantitative structure that is common in engineering uses of computation. For instance, one may want hom-objects to carry probabilities, costs, resource bounds, or metrics of approximation error. In such settings, the statement that a physical system "approximately realizes" a morphism can be made internal to the enrichment (e.g. an order capturing refinement, or a metric capturing simulation distance), rather than treated as an informal afterthought.*

Definition 385 (Program language and semantics)**.** *A* programming language *is a syntactic category* $\mathbf{Syn}$ *together with a semantics functor*

$$[\![\cdot]\!] : \mathbf{Syn} \to \mathbf{Abs}.$$

A program *is a morphism* $p : A \to B$ *in* $\mathbf{Syn}$*; its intended behavior is the abstract process* $[\![p]\!] : [\![A]\!] \to [\![B]\!]$*.*

Remark 1308. *The brackets* $[\![\cdot]\!]$ *denote the interpretation map from syntax to semantics: given a piece of code (a morphism in* **Syn***), it produces an abstract process (a morphism in* **Abs***). Calling* $[\![\cdot]\!]$ *a* functor *is the formal way of insisting that semantics respects composition: interpreting "do p then q" should equal "interpret p, interpret q, then compose." This is the semantic counterpart of the engineering fact that wiring subroutines together yields a composite behavior.*

As examples: **Syn** *could be a category generated by flowcharts or by typed lambda terms;* **Abs** *could be a category of partial functions or of probabilistic state transformers. This definition is useful because it cleanly separates three levels that are often conflated: the* symbolic *artifact (program text), the* mathematical *object it denotes (abstract process), and the* physical *evolution that enacts it (realization below). This separation is also congenial to algorithmic-information viewpoints in which programs function as descriptions of processes [16], while remaining compatible with richer semantic theories.*

It is often helpful (though not required here) to think of **Syn** *as providing the* compositional interface *available to a programmer: the primitives and composition rules that are exposed for assembling behaviors. Dually,* **Abs** *provides the space of meanings in which one can state correctness claims. On this view, different semantics functors* $[\![\cdot]\!]$ *correspond to different intended interpretations of the same surface syntax (e.g. operational vs denotational semantics, or a resource-aware semantics), and the functoriality condition is what makes correctness proofs scale from primitives to composites.*

Definition 386 (Computer as an emulation machine)**.** *A* computer *is a machine* C *equipped with:*

(a) a set (or category) of admissible programs $\mathbf{Syn}_C$ *(the "program signals" the user can provide); and*

(b) an execution mechanism that, for many $p \in \mathbf{Syn}_C$*, yields a physical realization of* $[\![p]\!]$ *(Definition 388 below);*

such that the family $\{[\![p]\!] : p \in \mathbf{Syn}_C\}$ *spans (approximately) a large variety of machine behaviors within the relevant engineering domain, and reconfiguration (from* p *to* p'*) has modest effort cost for the relevant user class.*

Remark 1309. *The clause "set (or category) of admissible programs" allows* $\mathbf{Syn}_C$ *to carry additional structure beyond mere membership. For instance, one may want to talk about translations/compilers between sublanguages, program equivalences, or program composition as an internal operation, in which case it is natural to model programs as morphisms in a category rather than as elements of a set. Likewise, the phrase "program signals" is intentionally broad: for different machines these may be voltages on pins, bitstrings in memory, punched cards, network packets, or even physical rewiring that selects among a finite library of behaviors, so long as the resulting reconfiguration is systematic and cheap relative to rebuilding.*

Remark 1310. *In plain language: a computer is a machine whose behavior can be widely varied by supplying different symbolically representable "recipes," and doing so is cheap compared to rebuilding the machine. This captures the practical heart of programmability: the user moves in a space of behaviors by manipulating signs rather than metal. In Hyperseed terms, the computer is a tool (indeed, a machine) whose affordance profile is unusually broad and compositional, and whose use is mediated by a stable syntax/semantics interface (Hyperseed-Concept 80).*

A simple example is a microcontroller that can emulate many small control circuits by changing firmware. A more expansive example is a general-purpose CPU that can approximate a huge range of behaviors by interpreting different programs as different abstract processes. The definition is *useful because it avoids privileging any single formal model of computation: what matters is not a particular axiomatization but an empirically grounded emulation capacity relative to a user class and engineering domain, in the same spirit as Hyperseed's operational approach to intelligence [19].*

The qualifier "(approximately)" is doing real work: physical computers are constrained by finite precision, noise, timing jitter, component tolerances, and resource limits, so their realizations typically match $[\![p]\!]$ only up to an error model and within an operating regime. This is why emulation here should be read in an engineering sense: the machine is a reliable stand-in *for the target behavior under specified assumptions (e.g. clock bounds, numeric ranges, memory availability), not a metaphysical identity. In particular, the same abstract process may admit many realizations (different chips, different microarchitectures, different compilation strategies), and the point of the syntax/semantics interface is to make these interchangeable for the relevant users.*

It is also worth distinguishing the present use of "emulate" from everyday "simulate." A simulation may reproduce aspects of a target system for purposes of prediction while remaining embedded in a larger computational context (e.g. a weather model run inside a program that also handles I/O and visualization). By contrast, the emulation perspective emphasizes behavioral substitution*: supplying p configures C so that, from the perspective of a designated interface, the resulting physical behavior can play the same role as the emulated machine's behavior.*

Remark 1311 (Curry–Howard and typed semantics (optional))**.** *If one chooses* **Syn** *to be a typed lambda calculus (or related proof calculus), then $[\![\cdot]\!]$ expresses a Curry–Howard style correspondence between proofs and programs. In that setting, "computer programs are physical realizations of mathematical constructions" becomes a literal statement: proof terms (syntactic objects) are realized as physical signal-configurations that drive a machine to enact the corresponding semantic morphisms.*

This optional perspective is also a reminder that the choice of **Abs** *can encode more than input–output behavior: it can encode invariants, specifications, or logical propositions that the program is meant to witness. Then correctness can be phrased as a claim that execution realizes not only a function-like mapping but also a structured piece of meaning (e.g. a proof-relevant morphism), which is particularly useful when connecting "program" to "procedure" and "tool use" in embodied contexts.*

Remark 1312. *The Curry–Howard remark emphasizes a broader methodological moral: the boundary between "mathematics" and "mechanism" is in part a boundary between description languages and the physical realizations that make those descriptions causally effective. This resonates with Hyperseed-Concept 107 and Hyperseed-Concept 136, without requiring any particular foundational stance.*

23.6 Physical realizations of abstract processes

Hyperseed describes a physical realization as a case where a physical process P and an abstract process A have strong *intensional similarity*, but one is physical and the other abstract. We express this as a realizability structure: encodings/decodings plus dynamics.

Definition 387 (Physical process category)**.** *Fix a physical reality-system R_{phys} for an embodied mind (Section 25). Let* **Phys** *be a category whose objects are physical substrates (bodies, tools, machines, laboratory setups) and whose morphisms are physically realizable processes (possibly stochastic, possibly context-dependent).*

Remark 1313. *The category* **Phys** *is deliberately broad: it is not restricted to deterministic Newtonian mechanics, but may include stochasticity, noise, measurement back-action, and context-dependence. This is important for Hyperseed because the observer/context O is always present in* *the modeling: what counts as a morphism is what the observer regards as a realizable transformation in the reality-system [1]. The point is not to deny physics, but to represent physics as a structured family of allowed transformations inside a reality-system (Hyperseed-Concept 135).*

A concrete example: an object of **Phys** *might be a particular circuit board; a morphism might be "apply voltage profile $u(t)$ for $t \in [0, T]$," resulting in a physical state transition. This definition is useful because it provides the codomain in which implementations live: abstract morphisms are realized by (structured) physical morphisms.*

Definition 388 (Physical realization / implementation)**.** *Let $f : A \to B$ be an abstract process in* **Abs***. A* physical realization *of f is a tuple*

$$\mathcal{R} = (P, \mathrm{enc}, \mathrm{dec}, \phi)$$

where:

- *P is a physical substrate (an object of* **Phys***),*
- $\mathrm{enc} : A \to \mathrm{State}(P)$ *is an encoding of abstract inputs into physical states,*
- $\mathrm{dec} : \mathrm{State}(P) \to B$ *is a decoding of physical states into abstract outputs, and*
- $\phi : \mathrm{State}(P) \to \mathrm{State}(P)$ *is (a model of) the relevant physical dynamics of P induced by the realization setting (including any control signals regarded as part of the realization),*

such that $\mathrm{dec} \circ \phi \circ \mathrm{enc}$ *approximates f in the intended sense.*

Remark 1314. *The notation* $\mathrm{State}(P)$ *is used informally for the state space associated to the substrate P (for instance, a set of microstates, a manifold of configurations, or a space of probability distributions over configurations, depending on modeling choices). The functions* enc *and* dec *are the formal representation of what engineers call "representation" or "interface": how abstract inputs are written into the physical medium, and how physical outcomes are read back as abstract outputs (Hyperseed-Concept 157 and Hyperseed-Concept 136). The map ϕ is the effective dynamics of the substrate during execution; it may itself depend on context and control, but that dependence is treated as part of the realization setting.*

A simple example is an adder circuit realizing the abstract function $f : \{0,1\}^2 \to \{0,1\}$ given by XOR. Here P is a gate-level circuit, enc *maps bits to voltage levels, ϕ is the electrical evolution over a short time window, and* dec *maps the output voltage back to a bit. The definition is useful because it makes explicit where approximation can enter: errors can come from imperfect encodings, noisy dynamics, or lossy decoding, and these can be measured and managed.*

Remark 1315 (Quantale- / p-bit-valued correctness scores)**.** *In realistic settings, realization quality is empirical and observer-relative. A convenient representation is a score*

$$\mathrm{Score}(\mathcal{R}, f) \in \mathbb{V} = [0,1]^2,$$

where the positive component measures evidence that the realized behavior matches f and the negative component measures evidence of mismatch. This score can be obtained by tests, formal verification, physical modeling, or mixtures.

Remark 1316. *The* p-bit*-valued score again encodes the possibility of conflict: one may simultaneously possess strong evidence of correctness on a test suite and strong evidence of failure in edge cases. This is not a defect but a faithful representation of engineering knowledge, which is often paraconsistent in practice even when not acknowledged as such. It also connects implementation to the broader Hyperseed value layer: correctness, safety, and reliability are themselves evaluated through evidence-bearing processes rather than assumed as absolute, context-free facts.*

One of the main reasons to state physical realizations explicitly is to guarantee that "wiring tools together" corresponds to composition of abstract processes.

Proposition 36 (Compositionality of realizations (lax functoriality))**.** *Let $f : A \to B$ and $g : B \to C$ be abstract processes. Suppose $\mathcal{R}_f = (P_f, \mathrm{enc}_f, \mathrm{dec}_f, \phi_f)$ realizes f and $\mathcal{R}_g = (P_g, \mathrm{enc}_g, \mathrm{dec}_g, \phi_g)$ realizes g. Assume the interface is compatible in the sense that the output of $\mathcal{R}_f$ can be fed as input to $\mathcal{R}_g$ (e.g.* enc_g *accepts the decoded outputs of $\mathcal{R}_f$, or there is a fixed adaptor with negligible additional error). Then there exists a composite realization $\mathcal{R}_{g\circ f}$ of $g \circ f$ on the composite substrate $P_f \triangleright P_g$ ("run P_f then P_g") such that*

$$\mathrm{Score}(\mathcal{R}_{g\circ f}, g \circ f) \;\; \geq \;\; \mathrm{Score}(\mathcal{R}_g, g) \, \otimes \, \mathrm{Score}(\mathcal{R}_f, f),$$

where $\otimes$ is the chosen monoidal product on $\mathbb{V}$ (Section 3.4). In particular, the direction of the inequality emphasizes that we are claiming only a guaranteed lower bound on end-to-end correctness evidence: even if the composite system has additional sources of error, the combined stage-level evidence still yields a conservative certificate in the order on $\mathbb{V}$.

Remark 1317. *Informally, the proposition says: if you have a physical implementation of f and a physical implementation of g, and you can connect them so that the output of the first is a valid input to the second, then you can implement the composite computation $g \circ f$ by running the first and then the second. Moreover, a conservative lower bound on the composite correctness evidence is given by combining the stage-level correctness evidence using the same evidence-aggregation operation $\otimes$ used elsewhere in the* p-bit *quantale.*

This matters because much of engineering (and much of cognition) proceeds by composition: we build systems out of subsystems. Hyperseed needs a formulation of this compositionality that is compatible with paraconsistent, evidence-based correctness rather than requiring idealized perfect correctness. This proposition is also the implementation-analogue of the categorical principle that semantics should respect composition (as in the functor $[\![\cdot]\!]$ above). One can read $P_f \triangleright P_g$ as an abstract model of a pipeline: a temporally ordered coupling (not necessarily a mere product of substrates) in which the physical degrees of freedom used to represent the intermediate value are transferred, re-encoded, or otherwise adapted so that the second stage can consume them. The point is not that the intermediate representation must be identical across stages, but that the realization data includes whatever interface mechanism makes it meaningfully the "same value" for the purposes of the overall abstract computation.

Proof. Define the composite substrate to execute ϕ_f on P_f and then ϕ_g on P_g. Define the composite encoding as enc_f, and the composite decoding as dec_g, with the intermediate adaptor given by the compatibility assumption. Concretely, the composite realization packages (i) the first-stage preparation of a physical state from an abstract input via enc_f, (ii) evolution by ϕ_f on P_f, (iii) an interface map that turns the relevant output degrees of freedom of P_f into admissible input degrees of freedom for P_g (which may include copying, buffering, re-timing, transduction, or re-encoding), and finally (iv) evolution by ϕ_g on P_g followed by readout via dec_g. This makes explicit that the intermediate "wire" is itself part of the physical story: the claim only goes through when the adaptor is treated as realization structure rather than an implicit idealization.

Under the interpretation of $\otimes$ as multiplicative aggregation of evidence, independent positive evidence for correctness multiplies across stages, and (at minimum) the resulting composite score is bounded below by the product of the stage scores. This is the standard "pipeline" principle of implementation: correctness does not improve by composition, but a reliable stage chained after a reliable stage remains reliably correct in the aggregated-evidence sense. Formally, what is used here is that $\otimes$ is monotone in each argument with respect to the order on $\mathbb{V}$: if a realization of the composite can be analyzed as first satisfying f to some degree and then satisfying g to some degree (with compatibility ensuring that the second analysis is applicable to the first stage's outputs), then combining the two pieces of evidence via $\otimes$ yields an evidence value that is *no stronger than* any additional, possibly more complex end-to-end analysis, hence the inequality as a lower bound. The "independence" language should be read in the conservative sense appropriate to paraconsistent evidence: we are not assuming that errors are uncorrelated in a probabilistic model, only that the evidence calculus represented by $\otimes$ is designed to aggregate stage-level support without introducing unjustified strengthening. In practical terms, even when the stages share failure modes (for example, both depend on a common power supply, clock, or calibration procedure), the proposition still serves as a template for what one may safely claim given only the two stage scores and an interface condition. □

Proof sketch. The strategy is to build the composite realization by literally running the first physical process and then the second, using the interface-compatibility assumption to connect the two runs. The inequality then follows from the intended semantics of $\otimes$ as an evidence aggregator: stage-level evidence is combined to yield a conservative bound on end-to-end evidence. Intuitively, one can think of $\mathcal{R}_{g\circ f}$ as a "program" for the laboratory or machine shop: prepare according to enc_f, run the first device, translate its output into the input format of the second device, run the second device, and finally read out using dec_g. □

Remark 1318. *The key step is conceptual rather than technical: we treat encodings/decodings as part of the realization structure, so the "wiring" between stages is not a handwave but an explicit adaptor condition. Once that is granted, the remaining content is the monotonicity and aggregative meaning of $\otimes$ in $\mathbb{V}$. Geometrically one may picture each stage as a noisy channel between abstract spaces; composing two channels yields another noisy channel whose reliability is (at best) the product-like combination of the reliabilities of the components. A helpful concrete picture is a sensing-and-control loop: f might be a sensor pipeline mapping a physical quantity to a digital estimate, and g a control law mapping that estimate to an actuator command; the composite $g \circ f$ is the overall perception-to-action transform. Even if the sensor and controller are each only partially correct in the paraconsistent evidence sense, chaining them yields an overall system with an evidence score that is at least the $\otimes$-combination of the two, provided the estimate produced by the sensing stage is indeed in the admissible input class for the control stage (units, ranges, timing, and representation all count as part of this admissibility).*

Remark 1319. *Proposition 36 is intentionally weak: it asserts only a monotone lower bound on composite correctness evidence. This matches engineering reality: composition can introduce new failure modes, but one can still obtain a conservative guarantee by multiplying (or otherwise aggregating) stage-level guarantees. The weakness is also a feature for Hyperseed's intended use: it allows modular reasoning in the presence of inconsistency, where one may have strong evidence for some aspects of each stage and counterevidence for others, and still wish to propagate whatever support is available without collapsing into triviality. In particular, the proposition does not claim that* $\mathrm{Score}(\mathcal{R}_{g\circ f}, g \circ f)$ *equals* $\mathrm{Score}(\mathcal{R}_g, g) \otimes \mathrm{Score}(\mathcal{R}_f, f)$*, nor that the bound is tight; it merely guarantees that the evidential calculus respects the basic operational fact that running two verified-enough stages in sequence yields a verified-enough composite, in the sense captured by the order on* $\mathbb{V}$*.*

23.7 Embodiment and the body-channel

Hyperseed defines a physical reality (for an embodied mind) as a reality-system containing the body where the mind's causal impact on that reality is mostly mediated through the body-channel. We represent this using factorization constraints on causal influence. This framing is deliberately structural: rather than stipulating what "matter" or "the physical" is in itself, it specifies which parts of a mind–world interaction graph are treated as primary for modeling, prediction, and intervention.

Definition 389 (Body as a coupled pattern-system). *Let M be a mind-level pattern web (Sections 13–17). A* body *for M is a physical substrate B such that:*

(a) there is strong mutual causal coupling between M and B (modeled as bidirectional channels for perception and action), and

(b) B is largely contained in a designated physical reality-system R_{phys}.

Remark 1320. *Intuitively, this definition says that a body is not merely "owned" by a mind, but* coupled *to it: the mind changes because the body is sensed, and the body changes because the mind acts. The bidirectionality clause is what distinguishes a body from a mere instrument occasionally used: the coupling is persistent and forms a significant part of the mind's ongoing dynamics. This is the formal doorway into Hyperseed-Concept 135 and Hyperseed-Concept* **??** *(the latter being implicit in the ontology even when not singled out as a separate primitive).*

Examples: for a human mind-model M, B may be the organism's nervous system and musculoskeletal system as represented in a physical reality-system. For a robot controller M, B may be the sensor-actuator suite plus onboard compute substrate. The usefulness of the definition is that it makes "having a body" a structural property that can be used in later causal and cosmological definitions: a physical reality-system is then the one in which this body is situated and through which most causal influence flows.

Two clarifications are often useful in applications. First, "strong mutual causal coupling" is not intended as a binary predicate but as a dominance claim: relative to the observer's modeling granularity, there are sustained causal pathways $B \to M$ (perception, interoception) and $M \to B$ (action, regulation) that explain a large fraction of M's state transitions and a large fraction of B's state transitions on the timescales of interest. Second, the boundary of B may be context-dependent: prostheses, implants, or tightly integrated tools can be treated either as part of B or as external artifacts depending on whether their coupling to M is persistent, high-bandwidth, and governed by the same closed-loop dynamics that ordinarily characterize sensorimotor control.

Definition 390 (Body-channel mediation (factorization form)). *Fix a physical reality-system R_{phys} and an embodied mind (M, B). We say that M's causal impact on R_{phys} is* mostly mediated through the body *if, for most effects e in R_{phys} that are attributable to M (relative to observer O), the corresponding influence morphism factors as*

$$M \xrightarrow{\text{Act}} B \xrightarrow{\text{Phys}} R_{\text{phys}},$$

up to the chosen approximation notion in the process formalism (Section 3). In particular, "most" and "attributable" are to be read as observer-indexed judgments about explanatory and predictive relevance: O selects a causal model, a notion of intervention/counterfactual dependence, and a tolerance under which small residual channels may be ignored without materially changing forecasts or control policies.

Remark 1321. *The factorization diagram is the mathematical version of the everyday claim that, in physical reality, minds act through bodies. The arrow labeled* Act *stands for the mind-to-body channel (motor control, endocrine control, etc.), and the arrow labeled* Phys *stands for body-to-world causal propagation. The qualifier "mostly" is essential: it permits exceptions (e.g. indirect influence via other agents or artifacts) while asserting that the body-channel carries most of the causal mass relevant for prediction and control.*

This is useful because it provides a criterion for when a reality-system should be called "physical" relative to a mind: if there are large, reliable mind-to-world influence channels that do not factor through the body, then the modeling stance changes (as the next remark states). In short, physicality is treated operationally via channel structure rather than metaphysically.

Although the definition is stated in terms of impact *(an $M \to R_{\mathrm{phys}}$ direction), the same modeling posture typically comes with a complementary perception-side regularity: for most observations o in M that are about R_{phys}, the relevant information flow factors as*

$$R_{\mathrm{phys}} \xrightarrow{\mathrm{Sens}} B \xrightarrow{\mathrm{Per}} M,$$

again up to approximation. This makes explicit why B functions as an interface: it is simultaneously the dominant actuator path outward and the dominant sensor path inward, yielding a closed loop whose stability and bandwidth strongly constrain the kinds of policies and representations that are feasible for M in R_{phys}.

Remark 1322. *If a mind can reliably influence a reality-system without using the body-channel, then (in the Hyperseed sense) that reality-system is less "physical" relative to that mind. The point here is not metaphysical; it is a modeling decision about which channels carry most causal mass for the observer's predictions. Concretely, if the observer must posit persistent high-bandwidth morphisms $M \to R$ that bypass B in order to explain regularities (e.g. dependable "direct" effects of intention on distant states), then it becomes misleading to treat R as a standard physical reality-system for that mind, because the dominant control affordances would not be organized around embodied action.*

Remark 1323. *This factorization stance also prepares later social and communion discussions: many causal influences in society do not run directly through one's own body but through artifacts, institutions, and other agents. Separating "body-channel" influence from "artifact-mediated" influence lets one speak precisely about extended agency and collective mind systems without losing the embodied anchor. In particular, it allows a clean distinction between (i) amplification of embodied action (where* Act *still initiates the relevant causal chain, even if subsequent propagation is mediated by machines and institutions) and (ii) putative non-embodied channels (which would require a different ontological placement in the causal web). This becomes important when describing delegation, coordination, and the emergence of higher-level agents whose effective "bodies" may be distributed across many human bodies and technical substrates.*

23.8 Algebraic asymmetry of physical reality

Hyperseed emphasizes that physical reality tends to have a relatively rigid, low-dimensional (vector-space-like) structure, while mental and intersubjective realities tend to have weaker algebraic structure (often best treated topologically), and that the latter can only approximately be projected into the former. This "rigidity" is meant in the sense that physical descriptions typically come with many simultaneously interacting constraints (e.g. compositional laws, conservation principles, and dynamical compatibility conditions), whereas mental and social descriptions often preserve only those aspects that remain stable under coarse changes of implementation (e.g. continuity rather than linearity, reachability rather than exact trajectories, or preference/ordering rather than precise quantities).

A minimal formalization uses a "forgetful" map from stronger structure to weaker structure. Concretely, one can treat "physical structure" and "mental/intersubjective structure" as different *signatures of operations and relations* together with axioms, where the mental signature is obtained from the physical signature by dropping some operations, equations, or distinguished predicates. In that common situation, the corresponding forgetful functor is not an additional assumption but a standard construction: every model of the richer theory canonically determines a model of the poorer theory by restriction of structure.

Definition 391 (Algebraic asymmetry (structure implication form))**.** *Let* $\mathsf{Alg}_{\mathrm{phys}}$ *be an algebraic theory capturing salient physical structure (e.g. vector-space operations, linear dynamics, conservation laws) and let* $\mathsf{Alg}_{\mathrm{mind}}$ *be a weaker theory capturing salient mental/intersubjective structure (e.g. topology, partial order, or merely the quantale-enriched relational structure).*

We say that a community's physical and mental realities exhibit algebraic asymmetry *if:*

(a) there is a canonical forgetful functor

$$U : \mathrm{Alg}(\mathsf{Alg}_{\mathrm{phys}}) \to \mathrm{Alg}(\mathsf{Alg}_{\mathrm{mind}})$$

that maps each physically structured system to its underlying mental/intersubjective structure; but

(b) there is no functorial inverse that assigns to each mental/intersubjective system a unique physically structured system realizing it (at best, one has approximations, constraints, or choices).

Remark 1324. *The definition says, in effect, that physical structure is (for the relevant community) more constraining than mental/intersubjective structure. There is a systematic way to* forget *some structure (go from richer algebra to poorer algebra), but there is no systematic way to* reconstruct *the richer structure uniquely from the poorer. This is Hyperseed-Concept 55 expressed in standard mathematical language (forgetful functors and non-invertibility).*

A guiding example is that many different vector spaces can share the same underlying set, and many different norms can induce the same coarse topology; the "mental" structure (say, topology or order) typically underdetermines the "physical" structure (say, linear operations and conserved quantities). The usefulness of the definition is that it provides a clean formal lever for later claims about implementation and projection: mental contents may be realized physically only by selecting among many physically distinct instantiations, and that selection is constrained by effort, resources, and context. In particular, the "no inverse" clause should be read as a non-uniqueness *claim: even when a realization exists, it generally does not exist* canonically *(i.e. in a way that is natural with respect to morphisms in* $\mathrm{Alg}(\mathsf{Alg}_{\mathrm{mind}})$*), and so any reconstruction procedure necessarily imports additional conventions, priors, or external constraints.*

Remark 1325. *It is worth separating three notions that can otherwise be conflated: (i) existence of some right-inverse* on objects *(each mental structure is realizable by at least one physical structure), (ii) existence of a* section S *with* $U \circ S = \mathrm{id}$ *(a consistent choice of a realization for each mental object), and (iii) existence of a* functorial *section (the chosen realizations respect structure-preserving maps between mental systems). The definition rules out (iii), which is the categorical form of "no systematic unique reconstruction." In many settings (especially when mental descriptions ignore metrics, coordinates, or conserved quantities), one may have (i) for broad classes of cases, occasionally (ii) after imposing extra choices, but typically not (iii) without adding additional structure* *to* $\mathsf{Alg}_{\text{mind}}$ *that effectively re-introduces the missing physical constraints. This captures the sense in which embodiment and implementation require* extra degrees of freedom *beyond what is present in the mental description alone.*

Remark 1326 (The simplest motivating example)**.** *A real vector space canonically determines a topological space (via the metric induced by a norm), but an arbitrary topological space does not determine a vector space structure. This is an archetype for Hyperseed's claim: physical structure typically implies (and constrains) mental/intersubjective structure, whereas mental structure only partially constrains physical structure and often requires approximation to be physically instantiated. One can sharpen the same point with even simpler forgetful functors: a group canonically determines a set, but a set does not canonically determine a group; a smooth manifold canonically determines a topological space, but a topological space does not canonically determine a smooth structure. These examples emphasize that "forgetting" is often a many-to-one collapse of possibilities: the fibers of* U *over a given mental object can be large, reflecting many distinct physical implementations compatible with the same mental/intersubjective description.*

Remark 1327. *The community-relative phrasing is material: what counts as "salient physical structure" depends on the community's instrumentation, embodiment, and practical invariants. A community that can only measure coarse macroscopic variables may treat distinct microphysical configurations as physically irrelevant, thereby shifting the boundary between* $\mathsf{Alg}_{\text{phys}}$ *and* $\mathsf{Alg}_{\text{mind}}$*. In that sense, algebraic asymmetry is compatible with multiple nested layers of description: one may have a chain of forgetful functors from microphysics to macrophysics to phenomenology, each step discarding structure and enlarging the space of admissible realizations.*

Proposition 37 (Asymmetry and weakness)**.** *If mental/intersubjective structure is modeled as a coarse-graining (a controlled collapse of distinctions) of physical structure, then the passage from physical to mental reality increases quantale weakness (Section 3.7) relative to the finest-grained physical observer.*

Remark 1328. *In plain terms, the proposition says: if we go from a fine-grained physical description to a coarser mental/intersubjective description by identifying distinctions, then we become "weaker" in the sense that more states are treated as undistinguished. This is not a pejorative claim; it is a structural one. It links the philosophical idea of coarse-grained experience to the formal order-theoretic notion of weakness developed earlier [3, 2]. The connection to the preceding definition is that the forgetful passage* U *is a structured way of* discarding *discriminations: when operations/observables are forgotten, the induced semantics can merge previously separable possibilities, thereby enlarging the indistinguishability relation that defines weakness.*

Proof. Coarse-graining identifies (or partially identifies) physical states that were previously distinct. In the weakness formalism, this corresponds to adding undistinguished pairs. By Theorem 1, adding undistinguished pairs monotonically increases weakness. More explicitly, if the finest-grained physical observer induces an undistinguished relation $\sim_{\text{phys}}$ on a state space, and the coarse-grained mental/intersubjective observer induces $\sim_{\text{mind}}$, then coarse-graining means $\sim_{\text{phys}} \subseteq \sim_{\text{mind}}$ (at minimum, every pair that was already indistinguishable remains so, while some formerly distinguishable pairs become indistinguishable). The monotonicity theorem applies to this inclusion. □

Proof sketch. The proof reduces the statement to monotonicity: coarse-graining is exactly the act of declaring previously distinct states to be undistinguished, and weakness was defined so that enlarging the undistinguished relation increases weakness. Equivalently, coarse-graining is an order-preserving map in the direction that collapses distinctions, and weakness is ordered so that more collapse corresponds to greater weakness. □

Remark 1329. *The key step is the identification of "coarse-graining" with "adding undistinguished pairs." Once this is made explicit, the result is essentially a corollary of how weakness is ordered. A visual intuition is to imagine a high-resolution image being pixelated: multiple microstates collapse into one macrostate, and the observer loses discriminative power. In Hyperseed terms, this loss is not merely epistemic; it shapes what patterns can be represented and what control can be exerted, because both depend on distinctions. A further intuition, aligned with the functorial language above, is that the collapse induced by U can be understood as pushing forward along an "observation" that identifies states whenever the remaining (mental/intersubjective) invariants agree; since fewer invariants are tracked, more pairs agree, and the indistinguishability relation expands.*

23.9 Two tiny examples

23.9.1 A tool that reduces effort via mechanical advantage

Let a task be "raise a weight" within a physical reality-system. Model the relevant effort scalar as $E \in [0, 1]$ where larger means more effort. Let $E_{\text{bare}} = 0.9$ be the effort without a tool, and let a lever tool T yield $E_T = 0.3$ for the same achieved effect in the same context. One can read the choice of $[0, 1]$ here as a normalization convention: it fixes units only up to monotone rescaling, but it is enough to express ordinal comparisons (this action is easier than that action) and threshold claims (an agent can afford at most $E \leq \epsilon$ in a given episode). The phrase "same achieved effect" is also doing work: the comparison is not between different goals, but between different *means* to the same end, so that the effort change can be attributed to the tool rather than to a change in objective. In many environments the effort would be context-dependent (terrain, grip, fatigue, precision requirements), and the toy scalar E should be read as already incorporating those background conditions into a single budget-like quantity.

Remark 1330. *This is the archetypal case where the affordance profile changes the mapping from action to effect by changing the required resource expenditure: the lever increases the space of achievable effects for a bounded agent because actions that were previously too costly become feasible. This illustrates why Hyperseed keeps effort (Section 8) close to the ontology of tools: tools are not merely causal mediators but* resource transformers *(Hyperseed-Concept 100 and Hyperseed-Concept 191).*

In Hyperseed terms: the lever is a tool because it is purposefully manipulable toward the objective, and it extends agency by lowering effort for the same outcome. In the quantale-weakness perspective, lowering effort typically enables the agent to maintain finer distinctions elsewhere (attention, memory, control), indirectly reducing global weakness. Equally importantly, the reduction $E_{\text{bare}} \mapsto E_T$ can be understood as a change in the *effective* action space: even if the bare body can in principle generate the required force, the lever may move the task from "barely possible" to "reliably repeatable" under noise, limited precision, and finite time. This motivates treating tools not just as add-ons but as parts of an extended sensorimotor loop, where the tool shifts which policies are stable under perturbations and which plans remain within budget. On this reading, mechanical advantage is just one especially transparent instance of a more general pattern: an external artifact can reshape the effort landscape so that the same target state becomes reachable by a broader set of trajectories.

23.9.2 A program as a physical realization of an abstract construction

Let **Syn** contain a program p whose semantics $[\![p]\!]$ is an abstract process $f : A \to B$ (e.g. a parsing algorithm, a planning operator, or a proof normalization map). Running p on a computer C yields a physical realization $\mathcal{R} = (P, \mathrm{enc}, \mathrm{dec}, \phi)$ of f in the sense of Definition 388. Here P can be read as the relevant physical state space (register contents, memory configurations, I/O buffers, and possibly environmental degrees of freedom that the computation couples to), enc and dec specify how abstract inputs and outputs are represented at that physical level, and ϕ names the concrete evolution (often a time-indexed dynamics induced by the machine executing the compiled form of p). Even in this simple packaging, the role of representation becomes explicit: a program does not act on A and B directly, but on their encodings, and the "same" abstract function can be realized by different choices of code, data layout, and hardware, yielding different resource profiles.

Remark 1331. *The example highlights the three-layer separation:* program *(a syntactic object),* meaning *(an abstract morphism), and* execution *(a physical evolution plus an interface). In practice, many confusions about computation come from sliding between these layers without noticing. The formalism forces us to keep track of where a claim lives: is it about denotation ($[\![p]\!]$), or about implementation quality (*$\mathrm{Score}(\mathcal{R}, f)$*), or about resource usage (effort, time, energy) of the physical substrate? This is precisely why Hyperseed-Concept 80 is placed alongside Hyperseed-Concept 136.*

This makes precise (at a minimal level) the slogan:

> Computer programs are physical realizations of mathematical constructions.

The slogan becomes more structured if **Syn** is taken to be a proof calculus (Curry–Howard), but the basic point already holds at the level of "syntax $\to$ semantics $\to$ physical realization." The additional structure in $\mathcal{R}$ is what allows one to distinguish correctness from mere intention: $[\![p]\!] = f$ is an abstract statement about denotation, while the realized process may approximate, fail, or only probabilistically track f because ϕ is embedded in a noisy, finite-precision substrate. Moreover, two realizations can agree extensionally on f yet differ significantly in embodied properties (latency, energy draw, heat dissipation, fault tolerance), which are invisible if one collapses everything into the abstract morphism alone. In Hyperseed terms, this is exactly the point at which computation becomes part of embodiment: the interface maps abstract types into physical carriers, and the carrier dynamics determines which abstract constructions are feasible under an agent's resource constraints. This also clarifies why "running the same program" can be an underspecified claim: without fixing enc, dec, and the operational context of ϕ, one has not fixed the realized process that the world actually instantiates.

23.10 What this section contributed to the overall reconstruction

This section mapped the Hyperseed nodes *tools*, *machines*, *engineered*, *computers and programs*, *physical realizations*, and *physical reality/body with algebraic asymmetry* into the paper's core mathematical vocabulary. In particular, it translated what can look like informal engineering talk (devices, implementations, programs, bodies) into a small number of reusable structural moves: coupling, emulation, factorization through channels, and order-theoretic coarse-graining. This matters because it makes later claims about "shared worlds" and "scaling" provably sensitive to the constraints and degrees of freedom that artifacts and bodies impose, rather than treating them as externalities.

- Tools and machines become physical pattern-systems whose affordances can be represented as p-bit-valued couplings from actions to effects. Concretely, one can treat an action-set (or action-algebra) A and an effect-set E as interfaces, and model the tool as a constrained relation or channel $A \rightsquigarrow E$ whose entries live in p-bit, so that "what the tool lets you do" is captured by a structured map rather than a verbal description. On this reading, a tool is not merely an object but an input–output regularity stabilized in the world, and the coupling encodes both possibilities and impossibilities as first-class data.

- Computers and programs become emulation machines plus syntax/semantics layers, with physical realization connecting semantics to physics. Here the central explanatory move is to separate (i) the physical machine as an emulator (a pattern-system capable of reliably realizing a family of state transitions), from (ii) a syntactic layer (descriptions, code, symbols) and (iii) a semantic layer (what those symbols are taken to denote or implement), and then to insist that a *realization* map is what makes the semantics causally efficacious. This is precisely what lets later sections speak about "the same program" across different substrates without erasing embodiment: sameness is routed through emulation and realization, not assumed as a primitive identity.

- Embodiment becomes a factorization constraint on causal impact through a body-channel. Instead of treating an agent's influence as a direct action on the external world, the reconstruction forces a decomposition in which the agent's internal degrees of freedom can only affect distal variables via a mediating interface (the body), i.e., via a channel that both enables and limits control. This makes constraints such as bandwidth, locality, actuation delay, and sensor noise part of the formal story: what an agent can bring about is restricted to what can pass through that body-channel and be amplified by the surrounding physics.

- Algebraic asymmetry becomes a formal "strong structure forgets to weak structure" relation, with coarse-graining captured by monotone increases in weakness. The point of phrasing this as an asymmetry is that there is typically an easy, structure-forgetting map from a richer description to a poorer one, while reconstruction in the opposite direction is underdetermined or impossible without extra information. By encoding this as a monotone order ("more weak" = "less structured"), the framework gains a disciplined way to talk about abstraction layers (e.g., physical $\to$ computational $\to$ semantic) and about why certain equivalences are stable under forgetting while others are not.

Remark 1332. *From a broader perspective, these constructions place "engineering" inside the same conceptual frame as "pattern" and "agency": engineered artifacts are patterns stabilized by goal-directed processes, and computers are machines whose stable patterns include a semantics-respecting reconfiguration mechanism. Put differently, an engineered object is a pattern whose persistence is not merely accidental but maintained (historically and/or presently) by optimization, selection, or design, and this maintenance can be tracked using the same coupling-and-channel vocabulary used elsewhere in the reconstruction. Moreover, emphasizing semantics-respecting reconfiguration highlights what distinguishes general-purpose computation from mere dynamics: the machine is organized so that changes in symbolic descriptions (programs) systematically correspond to changes in realized behavior, with the realization map doing the work of tying symbols to physical transitions. This is why these notions are not merely ancillary but central to the later discussion of intersubjective communion and cosmological scaling: communities build shared realities partly by building shared artifacts [1, 19]. The shared artifact, on this view, is a coordination device precisely because it induces shared couplings: multiple agents can reliably predict how actions propagate to effects through the artifact, and this predictability is a precondition for stable joint practice.*

These constructions are used in the next sections to formalize intersubjective communion and cosmological scaling in a way that keeps the engineering/implementation dimension explicit. Intersubjective communion can then be treated not only as alignment of beliefs or symbols, but also as alignment of accessible channels and realizations (e.g., agreeing on what a sign, tool, or protocol *does* because the underlying couplings are shared and repeatedly testable). Cosmological scaling, likewise, can be discussed in terms of how such couplings, emulators, and body-channels compose and persist across increasing spatial, temporal, and energetic scales, rather than being idealized away as if agency operated on an unbounded, implementation-free substrate.

24 Intersubjectivity, Communion, and Aesthetics

24.1 Hyperseed concepts handled in this section

This section gives a mathematically grounded treatment of the following Hyperseed concepts:

- intersubjective reality;
- intersubjective communion and explicit intersubjective communion;
- spiritual experience as communion with a broader-scope mind; psychedelics/entheogens;
- emotion and compassion;
- archetypes (as cross-context pattern templates);
- aesthetics/art/beauty as "surprising fulfillment of expectations" and the role of paraconsistent logic;
- religion and ritual as persistent social technologies for inducing and stabilizing communion;
- (briefly) state-dependent science as a community-level epistemic practice conditioned on states of consciousness.

To avoid ambiguity, the intent of the list above is not merely thematic but structural: each item will be assigned an explicit representational role inside the same formal apparatus (patterns, carriers, links, and state/observer parameters), so that claims about communion, archetypes, or beauty can be expressed as statements about how patterns distribute and couple across minds and artifacts. In particular, "intersubjective reality" is treated here as an *object of analysis* rather than a vague backdrop: it is the specific pattern-structure that a community can jointly sustain, predict within, and coordinate action around. Likewise, "communion" is treated as a *dynamical regime* of that structure (a change in the balance between within-mind and cross-mind pattern dominance), and "explicit communion" as the additional condition that some agents in the community represent (possibly imperfectly) that regime within their self- and world-models.

The inclusion of psychedelics/entheogens and "state-dependent science" signals that the relevant variables are not only social (who is connected to whom) but also *stateful*: the same community graph can instantiate different intersubjective realities under different distributions of attention, affect, and altered states, because those states modulate which patterns become salient, which links are strengthened, and which contradictions can be tolerated without collapse. Emotion and compassion are included not as informal add-ons but because they function as pattern-selection and coupling mechanisms: they bias which patterns are amplified, which others are suppressed, and how quickly patterns propagate across interpersonal channels.

24.2 Motivation and placement in the formal development

Hyperseed treats minds as pattern-bearing systems, and treats communities of minds as giving rise to *intersubjective realities*: reality-systems constituted by patterns distributed across multiple minds, together with causal and predictive couplings between these minds.

A key motivation for formalizing intersubjective realities is that many phenomena of interest (language, norms, shared meanings, institutions, artistic canons, collective emotions, religious experiences, and scientific paradigms) are neither well-captured by purely individualist models nor by undifferentiated "group mind" metaphors. The proposed framework aims to model precisely what is shared (patterns and their carriers), how it is shared (links with weights and directions), and how it can remain stable even when it is not fully consistent from any single point of view. In this sense, the formal objects introduced here are intended to be reusable building blocks for later sections: once intersubjective reality is expressed as a pattern-structured object, one can compare communities, track phase transitions in coordination, and study how artifacts and rituals act as external memory and alignment mechanisms.

The goal here is not to reduce intersubjectivity, communion, or beauty to a single scalar. Rather, the goal is to place these notions inside a rigorous ontology in a way that is: (i) compositional (community structure matters), (ii) explicitly state- and observer-relative (different communities and states of consciousness yield different regimes), and (iii) compatible with non-classical reasoning, since Hyperseed's core claims explicitly allow tensions and contradictions (e.g. the "surprising yet fulfilling" character of beauty).

Compositionality here means that the theory should distinguish, for example, a tightly connected triad from a loosely coupled crowd, even if both have the same number of participants: higher-order structure (clusters, bridges, hubs, and shared artifacts) changes what patterns can be sustained and how quickly they synchronize. State- and observer-relativity means that the same underlying environment can support multiple concurrently valid intersubjective realities, depending on which patterns are accessible in a given state of consciousness and which measurements/queries are being posed by which observers. Compatibility with non-classical reasoning is required because many of the target phenomena are characterized by stable co-presence of apparently incompatible descriptions: rituals can be "symbolic and real," archetypes can be "abstract and concrete," and aesthetic experiences can be "unexpected yet exactly right." A paraconsistent setting allows such co-presence to be represented without trivializing inference, which is crucial if one wants a mathematics that can model the phenomenology rather than explain it away.

We proceed in three steps:

1. Define an intersubjective reality for a community as a weighted pattern hypergraph with cross-mind predictive/causal links.

2. Define communion as a dominance of cross-mind pattern intensity over within-mind pattern intensity, and define *explicit communion* via self-model recognition using paraconsistent truth values.

3. Define aesthetic experience and beauty in a way that directly formalizes "surprising fulfillment" and explains why a paraconsistent logic is a natural fit; then relate aesthetics to communion via shared pattern carriers (artifacts, rituals) and archetypes.

Step (1) is meant to make "shared reality" operational: the hypergraph representation allows patterns to be carried not only by individual minds but also by multi-agent configurations and by external artifacts (texts, images, songs, places, symbols), with hyperedges encoding that certain patterns are only instantiated or only predictive when several carriers jointly participate. The weights on links and hyperedges will be interpreted as strengths of coupling, reliability of prediction, and/or causal influence, so that the formalism can express both weak cultural resonance and strong, high-fidelity synchrony. The "predictive/causal" language is intentionally inclusive: in some contexts the relevant link is a learned model of another agent, while in other contexts it is a direct causal pathway (speech, gaze-following, imitation, coordinated movement), and the framework aims to support both without forcing an artificial reduction.

Step (2) isolates communion as a regime change: instead of treating communion as an ineffable binary property, it is treated as a measurable shift in where pattern-intensity resides (primarily within individuals versus primarily across the interpersonal links and shared carriers). The "explicit" qualifier is then reserved for cases where at least some agents track, represent, or can report the communion regime in their self-models, even if that representation is partial, conflicted, or simultaneously affirmed and denied. The invocation of paraconsistent truth values at this step reflects a common empirical feature of communion reports: agents may sincerely endorse both "I remained myself" and "I dissolved into the group" without experiencing this as a failure of cognition. A logic that can register such dual attribution without collapse is thus not a decorative choice but a way to keep the ontology faithful to the data the theory is supposed to cover.

Step (3) ties aesthetics to inference and prediction: "surprising fulfillment of expectations" will be made precise by distinguishing (a) a departure from locally expected patterns (surprise) and (b) a higher-level coherence or resolution that nonetheless satisfies deeper constraints (fulfillment). The paraconsistent connection arises because many aesthetic resolutions operate by sustaining tension (two readings, two moods, two interpretations) while still yielding an integrated experience; the formalism should therefore permit a controlled coexistence of incompatible pattern-attributions that remains informative rather than degenerating into arbitrariness. Finally, the link back to communion is not merely sociological: artworks, rituals, and archetypal narratives act as shared pattern carriers that can entrain attention and expectation across multiple minds, thereby increasing cross-mind pattern intensity and stabilizing communal regimes over time. This is also where "religion and ritual" and the brief discussion of "state-dependent science" are placed: both can be analyzed as repeatable protocols for shifting state variables (attention, affect, interpretive priors) in a coordinated population, thereby selecting which intersubjective realities become accessible, credible, and action-guiding under those conditions.

24.3 Intersubjective reality as a community pattern system

We assume (as in earlier sections) that "pattern" is an observer-relative regularity associated with compression/effort, and that pattern *intensity* is a nonnegative quantity reflecting salience, coherence, frequency, and/or causal relevance within a time interval. In particular, the same underlying events may support different patterns for different observers, and the same nominal "kind" of pattern (e.g. a linguistic convention) may register with different intensities depending on how stable it is, how often it is instantiated, how much predictive power it contributes, or how costly it would be (in description length or cognitive effort) to ignore it. The time interval I is included explicitly so that both short-lived synchronizations (e.g. a fleeting shared glance) and longer-lived regularities (e.g. a persistent norm) can be treated within one scheme by varying the temporal window over which intensities are evaluated.

Definition 392 (Intensity quantale)**.** *Let $V_I = ([0,\infty], \leq, \oplus, 0)$ where $\oplus$ is addition with $x \oplus y := x + y$ and $[0,\infty]$ is ordered by the usual $\leq$. We will use V_I as the codomain of pattern-intensity maps and as an aggregation monoid.*

Remark 1333. *V_I is a commutative quantale if equipped with the complete lattice structure given* *by arbitrary suprema, and with monoidal product + distributing over suprema. We will not need the full quantale structure here, but it is convenient to keep the "quantale habit" so intensity and weakness can be treated uniformly later. Concretely, the choice of + reflects the idea that (when appropriate independence assumptions hold) the combined salience of distinct supported patterns can be accumulated, while the order $\leq$ supports the comparison of alternative descriptions by dominance of intensity. Allowing ∞ is a technical convenience: it can represent "effectively unignorable" regularities within I (for instance, hard constraints induced by the environment or by institutional enforcement), and it guarantees the existence of suprema for arbitrarily large families of intensities when such joins are useful for analysis.*

Definition 393 (Minds, communities, and supported patterns)**.** *Let* Mind *be a set (or groupoid) of minds. Fix a (finite) community* $C \subseteq \mathsf{Mind}$ *and a time interval* I*. For each nonempty subset* $U \subseteq C$*, let* $\mathsf{Pat}_U(I)$ *denote the set of patterns whose realization is supported across exactly the minds in* U *(e.g. shared attention, synchronized appraisal cycles, coordinated linguistic constructions, mutually constrained expectations, shared affective dynamics). We write* $\mathsf{Pat}_{\{m\}}(I)$ *as* $\mathsf{Pat}_m(I)$ *for singleton supports.*

The phrase "supported across exactly the minds in U" is intended to separate (i) patterns that are purely idiosyncratic to a single mind from (ii) patterns that are genuinely sustained by interaction, mutual modeling, or common constraints within a subcommunity. Here "exactly" should be read as a modeling choice rather than a metaphysical claim: in practice one may treat $\mathsf{Pat}_U(I)$ as consisting of patterns for which U is the *minimal* support set in C (with the understanding that a pattern instantiated by all of U may also be compatible with, or embedded in, larger-U' patterns). Nothing in what follows depends on having a unique minimal support; the only essential point is that we can distinguish patterns by how broadly in the community they are realized.

When Mind is taken as a groupoid rather than a set, the intention is that there may be structure-preserving identifications between minds (e.g. treating two roles as equivalent in a certain analysis, or quotienting by a notion of observational indistinguishability), and that pattern support can be considered up to such identifications. This flexibility is useful later when we want to discuss institutional roles, replaceability, and anonymity in large-scale intersubjective systems.

Definition 394 (Community intensity data)**.** *A* community intensity datum *on* (C, I) *is a family of functions*

$$\mathbf{w} = \{\, w_U : \mathsf{Pat}_U(I) \to V_I \mid \emptyset \neq U \subseteq C \,\}$$

assigning an intensity to each supported pattern.

Intuitively, $\mathbf{w}$ encodes not only what patterns occur but how strongly they matter to the community-level dynamics on I. One may read $w_U(p)$ as a community-relative measure of how much predictive compression is gained by tracking the pattern p as a regularity jointly carried by the minds in U (as opposed to treating the constituents of p as unrelated fluctuations). Because V_I is additive, it is natural—when appropriate—to consider aggregated quantities such as the total intensity of all patterns supported on a given U,

$$W(U) \;:=\; \bigoplus_{p \in \mathsf{Pat}_U(I)} w_U(p),$$

whenever the relevant sum is well-defined (or replaced by a supremum, depending on the modeling choice). Such aggregated views will later make it easy to state conditions like "most of the action is dyadic" or "the community has a strong global mode," without committing to a particular enumeration of patterns.

Definition 395 (Intersubjective reality-system). *Fix (C, I) and a community intensity datum* $\mathbf{w}$*. An* intersubjective reality-system *for C on I is a triple*

$$\mathcal{R}_{C,I} = \big(\mathcal{E}_{C,I},\ \mathcal{L}_{C,I},\ \mathbf{w}\big)$$

where:

- $\mathcal{E}_{C,I}$ *is a set of* entities-as-modeled-in-community *(tokens for persons, objects, shared symbols, joint goals, norms, roles, etc., as represented across the community);*
- $\mathcal{L}_{C,I}$ *is a set of weighted links encoding* predictive *and* causal *relationships between entities and between minds' representations of entities. Formally, one may take $\mathcal{L}_{C,I}$ to be a V_I-weighted directed hypergraph or simplicial set on $\mathcal{E}_{C,I}$;*
- $\mathbf{w}$ *assigns intensities to patterns supported on subcommunities $U \subseteq C$.*

We say $\mathcal{R}_{C,I}$ is intersubjective *(rather than merely a disjoint union of individual realities) if $\mathcal{L}_{C,I}$ contains nontrivial cross-mind links of significant weight and* $\mathbf{w}$ *assigns non-negligible total intensity to patterns supported on $|U| \geq 2$.*

The three components play complementary roles. The entity set $\mathcal{E}_{C,I}$ is not meant to be a list of mind-independent objects, but rather the community's *working ontology* on I: the handles that appear in joint descriptions, coordination, and expectation management. Thus "the same" external object may correspond to different community-entities across different communities (or time intervals), and conversely a single community-entity (e.g. a role like "referee" or a symbol like a brand) may be realized by many different individuals or physical tokens while remaining stable at the level of communal modeling.

The link structure $\mathcal{L}_{C,I}$ is where predictive and causal organization is recorded. Treating $\mathcal{L}_{C,I}$ as a weighted directed hypergraph emphasizes that relations in social cognition are often many-to-one or many-to-many (e.g. several cues jointly predict an interpretation; multiple people jointly enforce a norm; a shared goal shapes several downstream actions). The V_I-weight on a link can be interpreted as the strength, reliability, or relevance of the predictive/causal dependency during I, in the same broad sense of salience used for pattern intensity. Links may connect not only "external" entities but also representations (e.g. "Alice believes Bob intends X" linking an Alice-representation node to a Bob-intention node), which is why cross-mind links are a natural place to represent higher-order social inference and mutual modeling.

The condition for being genuinely intersubjective is deliberately qualitative ("significant weight", "non-negligible total intensity") because the intended use is comparative and context-sensitive. In some settings, a small number of high-weight cross-mind links (e.g. a rigid command structure) can dominate; in others, a diffuse field of moderate-weight mutual expectations (e.g. conversational turn-taking or politeness norms) can be the primary stabilizer. The formalism permits either extreme, and the role of $\mathbf{w}$ is precisely to let the analyst say where, within C, the realized regularities actually live.

Remark 1334. *This definition is intentionally permissive: "intersubjective reality" is not a single kind of object. It ranges from dyadic conversations to large-scale institutions, markets, scientific communities, and cultures. What unifies these is the presence of significant cross-mind prediction/causation and significant cross-mind patterns.*

A useful way to read the permissiveness is that $\mathcal{R}_{C,I}$ is a *pattern system indexed by community support* rather than a single monolithic graph: it can represent simultaneously (i) individual-level regularities ($|U| = 1$), (ii) small-group synchronizations ($|U| = 2, 3$), and (iii) whole-community stabilizers ($U = C$). For example, in a conversation between two participants $a, b \in C$, one expects substantial intensity on patterns in $\mathsf{Pat}_{\{a,b\}}(I)$ such as turn-taking rhythms, accommodation of vocabulary, and mutual repair strategies, together with cross-mind links in $\mathcal{L}_{C,I}$ encoding rapid reciprocal prediction (e.g. "a's utterance predicts b's next move"). In an institution, by contrast, one expects prominent entities in $\mathcal{E}_{C,I}$ corresponding to roles and norms, and high-intensity patterns supported on larger subcommunities (sometimes approaching $U = C$), such as shared compliance expectations or shared symbol grounding.

Finally, note that nothing requires $\mathsf{Pat}_U(I)$ to be explicitly enumerated in applications. One can treat it as an abstract carrier for whatever pattern-extraction procedure is used (statistical, ethnographic, mechanistic, or hybrid), with $\mathbf{w}$ serving as the interface between such extraction and the higher-level statements made about intersubjective structure.

24.4 Intersubjective communion as cross-mind intensity dominance

Hyperseed's definition of *intersubjective communion* can be treated as a comparative statement: cross-mind patterns become more intense than within-mind patterns. In this framing, communion is not a primitive "togetherness" predicate but a measurable dominance relation: the community-level phenomenology is taken to be explained by whether jointly-supported structure outweighs the structure that remains private to each individual mind. The intent is that W_{cross} and W_{in} serve as coarse but tractable aggregates of "how much pattern-intensity is being carried" by intersubjective versus merely intrasubjective organization, relative to a fixed community C, an index set I (e.g. times, contexts, or interaction windows), and a chosen intensity datum $\mathbf{w}$.

Definition 396 (Within-mind and cross-mind total intensity)**.** *Fix (C, I) and a community intensity datum $\mathbf{w}$. Define the* within-mind total intensity *and* cross-mind total intensity *by:*

$$W_{\text{in}}(C, I; \mathbf{w}) := \sum_{m \in C} \sum_{p \in \mathsf{Pat}_m(I)} w_{\{m\}}(p),$$
$$W_{\text{cross}}(C, I; \mathbf{w}) := \sum_{\substack{U \subseteq C \\ |U| \geq 2}} \sum_{p \in \mathsf{Pat}_U(I)} w_U(p).$$

(We assume these sums are finite; if not, replace sums by suitable suprema or integrals.)

It is useful to keep in mind the intended separation of roles: W_{in} aggregates intensities of patterns whose supporting set is a singleton $\{m\}$ (so they are, by construction, "owned" by one mind), whereas W_{cross} aggregates patterns supported by some coalition U of size at least 2. The indexing by U permits graded forms of intersubjectivity: a pattern supported by a dyad, a triad, or the whole community can be assigned intensities at the corresponding support level(s), depending on how $\mathsf{Pat}_U(I)$ and w_U are specified. In applications, one often ensures that patterns are *support-tagged* (so that the same abstract content appearing with different support sets is treated as distinct pattern tokens), which makes the above sums unambiguous even when there is conceptual overlap between "the same" pattern instantiated at different levels of support.

The parenthetical finiteness clause also carries conceptual content: the theory only needs enough regularity to compare within-mind and cross-mind aggregates. If the pattern collections are infinite (for example, if $\mathsf{Pat}_U(I)$ is generated by a continuous-time process), replacing sums with integrals makes the comparison sensitive to the choice of measure; replacing sums with suprema yields a "peak-dominance" reading rather than a "total-mass" reading. The present section uses the summation presentation because it most directly matches the interpretation of W_{in} and W_{cross} as total intensity budgets.

Definition 397 (Communion predicate and communion margin)**.** *We say the community C exhibits* intersubjective communion *on I (relative to $\mathbf{w}$) if*

$$\mathsf{Comm}(C, I; \mathbf{w}) \quad \text{holds, i.e.} \quad W_{\mathrm{cross}}(C, I; \mathbf{w}) > W_{\mathrm{in}}(C, I; \mathbf{w}).$$

Define the communion margin *by*

$$\Delta_{\mathsf{Comm}}(C, I; \mathbf{w}) := W_{\mathrm{cross}}(C, I; \mathbf{w}) - W_{\mathrm{in}}(C, I; \mathbf{w}).$$

The strict inequality in Comm is intended to encode a genuine dominance rather than a tie: if $W_{\mathrm{cross}} = W_{\mathrm{in}}$, then the community is at a boundary where neither intrasubjective nor intersubjective structure clearly governs the overall intensity accounting. In many empirical or computational settings, one may introduce a tolerance parameter $\tau > 0$ and require $W_{\mathrm{cross}} \geq W_{\mathrm{in}} + \tau$ to obtain robustness to estimation noise; the margin Δ_{Comm} already provides the quantity one would threshold in such a variant.

It is also sometimes convenient to separate W_{cross} by coalition size:

$$W_{\mathrm{cross}}(C, I; \mathbf{w}) = \sum_{k=2}^{|C|} \sum_{\substack{U \subseteq C \\ |U| = k}} \sum_{p \in \mathsf{Pat}_U(I)} w_U(p),$$

so that one can distinguish dyadic resonance from broadly shared patterns. On this view, Δ_{Comm} measures not only whether intersubjectivity dominates, but also (when decomposed) *how* it dominates—e.g. by many small coalitions or by a smaller number of large, community-wide supports.

Remark 1335. *One can normalize Δ_{Comm} to obtain a bounded score, e.g. $\Delta_{\mathsf{Comm}}/(W_{\mathrm{cross}}+W_{\mathrm{in}}+\varepsilon)$. We keep the unnormalized margin because (a) it composes additively in the simplest way, and (b) it keeps clear the ontology-level meaning: a literal dominance of cross-supported pattern intensity.*

A further reason the unnormalized margin can be informative is that it retains sensitivity to the *scale* of the interaction: two communities might have the same normalized score while differing drastically in absolute cross-mind intensity, which may matter if one aims to connect communion to downstream effects (e.g. behavioral coordination, communication bandwidth, or aesthetic salience). At the same time, the reader should note an elementary invariance: if one scales all intensities by a common factor $\lambda > 0$ (i.e. replaces $\mathbf{w}$ by $\lambda\mathbf{w}$ pointwise), then both W_{in} and W_{cross} scale by λ, and hence $\mathsf{Comm}(C, I; \mathbf{w})$ is unchanged while Δ_{Comm} scales by λ. Thus the predicate captures a comparative dominance, while the margin captures a dominance magnitude.

For intuition, consider the smallest nontrivial case $C = \{m_1, m_2\}$. Then

$$W_{\mathrm{in}} = \sum_{p \in \mathsf{Pat}_{m_1}(I)} w_{\{m_1\}}(p) + \sum_{p \in \mathsf{Pat}_{m_2}(I)} w_{\{m_2\}}(p), \qquad W_{\mathrm{cross}} = \sum_{p \in \mathsf{Pat}_{\{m_1,m_2\}}(I)} w_{\{m_1,m_2\}}(p),$$

so communion says that the dyad's jointly-supported intensity outweighs the sum of their private intensities. This makes explicit the conceptual reading: the dyad is "more constituted" by what is mutually supported than by what remains individually supported.

Proposition 38 (Monotonicity of communion under adding cross-supported patterns)**.** *Fix (C, I) and a community intensity datum $\mathbf{w}$. If $\mathbf{w}'$ differs from $\mathbf{w}$ only by increasing some cross-mind intensities (i.e. $w'_U(p) \geq w_U(p)$ for all $|U| \geq 2$, and $w'_{\{m\}} = w_{\{m\}}$ for singletons), then $\Delta_{\mathsf{Comm}}(C, I; \mathbf{w}') \geq \Delta_{\mathsf{Comm}}(C, I; \mathbf{w})$. In particular, if $\mathsf{Comm}(C, I; \mathbf{w})$ holds, then $\mathsf{Comm}(C, I; \mathbf{w}')$ holds.*

Proof. Immediate from Definition 396 and Definition 397: only W_{cross} can increase, while W_{in} is unchanged. □

This proposition formalizes a minimal adequacy condition for the notion of communion: strengthening jointly-supported pattern intensity (without changing private pattern intensity) cannot make the community *less* communal under the dominance criterion. Equivalently, the only way to decrease Δ_{Comm} is to decrease cross-mind intensity or to increase within-mind intensity; the definition thereby cleanly separates "what adds to togetherness" from "what adds to privateness" at the level of intensity bookkeeping. When Δ_{Comm} is used as a target quantity for optimization or learning, Proposition 38 ensures that any update rule that monotonically increases cross-supported weights (holding singleton weights fixed) is guaranteed to be non-worsening with respect to the communion margin.

24.5 Explicit intersubjective communion via self-model recognition

Hyperseed distinguishes implicit communion (cross-mind patterns dominate) from *explicit* communion, where the participants' self-models recognize the communion as such. To formalize "recognize" we use a simple paraconsistent truth-value space. This keeps the ontology compatible with simultaneously holding (or partially holding) seemingly incompatible self-reports, commitments, and interpretations. In particular, "recognition" here is treated as a kind of *endorsement state* internal to each participant: one can endorse that communion is occurring while also endorsing (to some extent) that it is *not* occurring, or that it is unsafe, or that one is uncertain what to call the experience. This is common in real reports (e.g. "I feel connected, but I also feel guarded"), and it is precisely the kind of case where a classical truth assignment would force premature resolution.

Definition 398 (Uncertain paraconsistent truth values)**.** *Let*

$$\mathbb{B} := [0,1] \times [0,1].$$

An element $b = (t, f) \in \mathbb{B}$ is read as "degree of truth" t and "degree of falsity" f. Define negation, conjunction, and disjunction by

$$\begin{aligned} \neg(t,f) &:= (f,t), \\ (t_1,f_1) \wedge (t_2,f_2) &:= (\min\{t_1,t_2\},\ \max\{f_1,f_2\}), \\ (t_1,f_1) \vee (t_2,f_2) &:= (\max\{t_1,t_2\},\ \min\{f_1,f_2\}). \end{aligned}$$

Fix a designation threshold $\tau \in (0,1]$. We say $b = (t,f)$ is designated *(accepted/endorsed) if $t \geq \tau$.*

The intended reading is that t tracks the strength with which the self-model supports a proposition, while f tracks the strength with which the self-model supports its denial. Nothing in the definition enforces $t + f = 1$, so the framework permits both *incompleteness* (low t and low f) and *inconsistency* (high t and high f). The connective definitions make this interpretation operational: conjunction preserves the weaker truth-support (via min) while accumulating falsity-support (via max), whereas disjunction preserves the stronger truth-support (via max) while reducing falsity-support (via min). Negation simply swaps the two degrees, reflecting that support for $\neg\varphi$ is measured by support-for-falsity of φ in the same self-model.

The designation threshold τ isolates the specific notion of "counts as endorsed" needed for explicit communion. For instance, taking $\tau = 1$ yields a strict reading: only full truth-support counts as recognition. Taking $\tau < 1$ permits graded recognition: partial endorsement suffices, which can be appropriate when self-model access is noisy, introspective reports are hesitant, or participants are linguistically misaligned but still clearly signaling a "yes" in practice. Importantly, designation depends only on t; thus a proposition may be designated even when f is simultaneously large, capturing the case "I endorse that communion is occurring, even though part of me also rejects that description."

Remark 1336. *This is a continuous generalization of the familiar four-valued Belnap-Dunn bilattice. The key property for our purposes is: contradictions do not entail triviality.*

Concretely, the familiar four corners embed as $(1, 0)$ (true only), $(0, 1)$ (false only), $(1, 1)$ (both true and false), and $(0, 0)$ (neither), with the continuous interior representing intermediate mixtures. The paraconsistent motivation is practical rather than purely philosophical: if a participant's self-model includes both "we are in communion" and "we are not in communion" (or "this is safe" and "this is unsafe") at nonzero strength, then we do not want the formalism to collapse into a state where every proposition becomes equally endorsable. Instead, we want to preserve the informational content of ambivalence and keep explicit-communion criteria well-defined.

Definition 399 (Self-model valuation)**.** *Fix a mind $m \in C$. Let $\mathcal{L}_m$ be the (informal) language of propositions expressible in m's self-model on I (e.g. "we are in communion now", "I feel connected", "I feel threatened", etc.). A* self-model valuation *is a map*

$$v_m : \mathcal{L}_m \to \mathbb{B}.$$

The point of allowing $\mathcal{L}_m$ to be informal is to avoid overcommitting to a particular cognitive architecture. Different minds may carve the space of self-descriptions differently, may have different granularity of introspective access, and may attach different connotations to the same surface sentence. What matters for the present definition is only that each mind can represent (in some way) a proposition playing the role of "the community is currently in communion on I," and that the valuation records the mind's endorsement and rejection degrees for such propositions. In settings where the self-model is partly implicit or sub-symbolic, v_m can be viewed as an idealization of an accessible report channel (e.g. a confidence score, a felt-sense rating, or a post-hoc linguistic report) rather than a literal internal data structure.

Definition 400 (Explicit communion)**.** *Fix (C, I), intensity datum $\mathbf{w}$, and self-model valuations v_m for $m \in C$. Assume there is a proposition symbol $\mathsf{CommNow}_{C,I}$ available in each $\mathcal{L}_m$ meaning "the community C is currently in communion on I" (as represented by m). We say* explicit intersubjective communion *holds if:*

1. $\mathsf{Comm}(C, I; \mathbf{w})$ *holds (implicit communion), and*
2. *for every $m \in C$, the value $v_m(\mathsf{CommNow}_{C,I})$ is designated.*

We denote this by $\mathsf{ExplComm}(C, I; \mathbf{w}, \{v_m\})$.

Clause (2) is intentionally phrased as a universal condition over participants: explicit communion is not merely that "someone notices," nor that "on average the group notices," but that each member's self-model contains sufficient endorsement of the communion proposition. Because designation ignores the falsity coordinate, this allows explicit communion even when some members are conflicted, defensive, or simultaneously carrying counter-interpretations, provided the endorsement of $\mathsf{CommNow}_{C,I}$ clears the agreed threshold τ. For example, if $\tau = 0.7$, then a participant with

$$v_m(\mathsf{CommNow}_{C,I}) = (0.8, 0.8)$$

still counts as explicitly recognizing communion (designated), even though they are also strongly pulled toward denying it; this models "yes, and no" states without forcing a resolution. Conversely, a participant with

$$v_m(\mathsf{CommNow}_{C,I}) = (0.6, 0.0)$$

would not count as recognizing it at $\tau = 0.7$, even though they are not actively rejecting it; this models hesitant or unclear acknowledgement.

The explicitness criterion can also be read as a coordination condition on *meta-representation*: implicit communion concerns the dominance of cross-supported patterns in the system dynamics, whereas explicit communion adds that each self-model has tracked and endorsed that very fact. In that sense, the additional structure in $\mathsf{ExplComm}$ is not merely epistemic; it is part of the phenomenon being defined, since Hyperseed distinguishes communion that is lived but unrecognized from communion that is jointly identified and thus available for deliberate action, narrative stabilization, and norm formation.

Remark 1337. *Explicit communion is a* joint *condition: it is possible that* Comm *holds but some participants do not endorse (or do not have access to) the proposition* $\mathsf{CommNow}_{C,I}$ *in their self-models. Conversely, a group can self-report communion while cross-supported patterns do not dominate, in which case* $\mathsf{ExplComm}$ *fails due to the first clause.*

A further subtlety is that "do not have access" can occur even when a participant is behaviorally aligned with the communion: they may enact the pattern without categorizing it as communion, or they may lack the linguistic/conceptual resources to form $\mathsf{CommNow}_{C,I}$ as a stable self-model proposition. The definition treats this as a failure of explicitness (by assumption, the symbol exists, but the valuation may fail to designate it), which matches the intended distinction between tacit participation and self-conscious recognition. At the same time, the paraconsistent setting prevents such cases from forcing a binary verdict about the participant's entire self-model: the model can represent partial endorsement, partial denial, and partial indeterminacy simultaneously, and explicit communion depends only on whether the endorsement passes the chosen threshold.

24.6 Spiritual experience as communion with a broader-scope mind

Hyperseed treats spiritual experience as a special case of communion: communion between a mind M and another mind that is experienced as broader in scope. In this framing, "spiritual" does not name a separate ontological substance; it names a particular *relational configuration* within the general communion machinery, namely one in which the partner mind is comparatively broader (in a sense made checkable below) over the interval of interest.

Definition 401 (Scope of a mind on an interval)**.** *Fix a mind m and an interval I. Assume we have: (i) a multiset of patterns $\mathsf{Pat}_m(I)$, (ii) intensities $w_{\{m\}}$ on these patterns, and (iii) a complexity/cost function $\kappa : \mathsf{Pat}_m(I) \to [0, \infty)$ measuring pattern depth (e.g. description length in some fixed representational language, or effort to represent/maintain the pattern). Define the* scope *as*

$$\mathsf{Scope}(m, I) := \alpha \cdot H_m(I) + (1 - \alpha) \cdot D_m(I), \quad \alpha \in [0, 1],$$

where

$$H_m(I) := -\sum_{p \in \mathsf{Pat}_m(I)} \pi_m(p) \log(\pi_m(p) + \varepsilon), \quad \pi_m(p) := \frac{w_{\{m\}}(p)}{\sum_{q \in \mathsf{Pat}_m(I)} w_{\{m\}}(q) + \varepsilon},$$

and

$$D_m(I) := \sum_{p \in \mathsf{Pat}_m(I)} \pi_m(p)\, \kappa(p).$$

Here $\varepsilon > 0$ is a small numerical stabilizer.

Remark 1338. *H_m measures diversity of salient patterns (breadth), while D_m measures average depth. Any other combination of diversity and depth consistent with the intended semantics could be used. The ontology only requires that "broader scope" be a mathematically checkable comparative.*

Remark 1339. *The normalization π_m makes H_m and D_m depend on* relative *saliencies rather than the absolute scale of $w_{\{m\}}$; in particular, if $w_{\{m\}}$ is multiplied by a positive constant, π_m is unchanged (up to the ε term), so scope is driven by how attention/importance is distributed across patterns. The multiset language allows multiple tokenings of the "same" schematic pattern to be treated as distinct when the representational system of m distinguishes them (e.g. repeated motifs, recurring affective complexes), while still permitting coarse-graining by choosing $\mathsf{Pat}_m(I)$ appropriately.*

Remark 1340. *The parameter α interpolates between two limiting readings: when $\alpha = 1$, scope reduces to diversity of salient patterns (a purely breadth-like notion), and when $\alpha = 0$, scope reduces to average depth under κ (a purely depth-like notion). The choice of log base in H_m only rescales the contribution of the entropy term and can be absorbed into α (or into a rescaling of κ), so the operational content is the comparative ordering of scopes across minds/intervals rather than any absolute unit. The stabilizer ε can be taken small enough that it does not affect comparisons except in degenerate cases (e.g. extremely sparse or near-zero intensity mass), where it serves to keep the expressions well-defined.*

Definition 402 (Spiritual communion)**.** *Let m, n be minds and consider $C = \{m, n\}$. We say m has a* spiritual experience with *n on I if:*

1. $\mathsf{Comm}(\{m, n\}, I; \mathbf{w})$ *holds, and*
2. $\mathsf{Scope}(n, I) \geq \mathsf{Scope}(m, I) + \delta$ *for some fixed $\delta > 0$,*

where the second condition expresses that n is broader-scope than m.

Remark 1341. *The threshold δ encodes that "broader" is intended as a* robust *rather than hairline comparative: it rules out labeling as spiritual those cases where m and n have essentially the same breadth/depth profile on I up to negligible fluctuations. In applications, δ may be treated as a context-dependent parameter (e.g. varying by domain, by the granularity of Pat, or by the scaling of κ), but the logical role remains the same: it implements a margin that makes the broader-scope relation stable under small modeling perturbations (choice of pattern vocabulary, noise in w, etc.).*

Remark 1342. *The definition is deliberately stated in terms of $\mathsf{Scope}(n, I)$, not merely m's* belief *about it. This yields a structural notion that can, in principle, be assessed from a third-person model of both pattern systems. At the same time, many episodes described as spiritual involve an* appearance *of vastness or encompassment that may or may not match the external comparative; if desired, one can represent this by adding an epistemic layer in which m maintains an estimate $\widehat{\mathsf{Scope}}_m(n, I)$ and the phenomenology tracks $\widehat{\mathsf{Scope}}_m(n, I) - \widehat{\mathsf{Scope}}_m(m, I)$, while the present definition tracks the underlying relational configuration.*

Remark 1343. *The "broader-scope mind" n may be (i) a collective mind of a group including m, (ii) a mind of another individual, animal, ecosystem-scale process, etc., or (iii) an unusual mind-model accessed in altered states. The ontology does not decide which of these is metaphysically correct; it only supplies a structural criterion for when the experience is of the relevant kind.*

Remark 1344. *In case (i), the scope inequality can be read as a formal version of a familiar intuition: groups can sustain a richer or deeper joint pattern repertoire than any single member on the same interval (e.g. via division of cognitive labor, distributed memory, or complementary perspectives). In case (ii), the inequality can represent the phenomenology of encountering an agent whose lived world is experienced as "larger" (more varied or more structurally articulated). In case (iii), the scope inequality can model episodes where m relates to an internally generated partner n (a god-form, archetype, "nature," "the universe") that carries a broader pattern economy than m's ordinary self-model, even if the ontological status of n is left open by design.*

Definition 403 (Entheogen as a communion-shifting intervention)**.** *Fix an embodied mind m with body B_m and suppose interventions on B_m can change m's pattern system. An* entheogen *(or more generally an entheogenic procedure) is an intervention E on B_m such that, for a relevant class of intervals I and relevant classes of partner minds n, the induced change in intensity data $\mathbf{w} \mapsto \mathbf{w}^E$ tends to increase*

$$\Delta_{\mathsf{Comm}}(\{m,n\}, I; \mathbf{w}^E) \quad \textit{and/or} \quad v_m(\mathsf{CommNow}_{\{m,n\},I})$$

toward designation.

Remark 1345. *This definition intentionally avoids committing to a single mechanism. Entheogens may act by changing attention dynamics, relaxing self-model rigidity, increasing cross-subsystem coupling, altering predictive priors, etc. All of these show up as changes in $\mathbf{w}$ and/or in the valuation maps v_m.*

Remark 1346. *The "and/or" is important: some interventions primarily change the* structural *conditions for communion (as measured by Δ_{Comm}), while others primarily change whether m counts an already-present relation as salient, valuable, or real (as measured by $v_m(\mathsf{CommNow}_{\{m,n\},I})$). The phrase "toward designation" is meant to cover thresholded decision rules commonly used elsewhere in the ontology: even if Δ_{Comm} is continuous, communion-as-designated may require crossing a context-specific cutoff, and entheogens are characterized here by their tendency to push the system across that boundary for a nontrivial class of (I, n) rather than by guaranteeing communion in every instance.*

24.7 Emotion and compassion as mind-body-and-community patterns

Hyperseed treats emotions as dynamical patterns spanning large portions of mind and body over time. Compassion is treated as an emotion whose content and dynamics are essentially intersubjective. In this framing, an "emotion" is not primarily a propositional judgment, nor merely an isolated bodily sensation, but a coordinated regime that recruits perception, appraisal, action-readiness, autonomic regulation, and attention into a temporally extended configuration. Likewise, "intersubjective" does not mean that an emotion must be publicly expressed or linguistically reported; it means that some of the constitutive structure of the episode depends on, tracks, or anticipates patterns that are jointly realized across more than one mind (e.g. co-regulation, mutual attention, joint action, or reciprocity constraints).

Definition 404 (Emotion episode)**.** *Fix an embodied mind m with body B_m and interval I. Let $S_m(t)$ denote the (modeled) mind-state at time $t \in I$ and $S_{B_m}(t)$ the body-state. An* emotion episode *is a pattern $e \in \mathsf{Pat}_m(I)$ such that:*

1. *e is supported on both mind and body degrees of freedom (not purely cognitive, not purely somatic),*

2. *e has nontrivial temporal extent (persists across a subinterval $J \subseteq I$),*

3. *e organizes (constrains) a large fraction of the system's active patterns during J.*

Concretely, condition (1) is meant to exclude both "cold" belief updates that do not recruit bodily regulation and also purely reflexive physiological events that do not enter the mind-level organization of attention and action; the episode must be realized as a coupled mind–body pattern. Condition (2) distinguishes an episode from instantaneous perturbations (e.g. a momentary startle spike) by requiring persistence on a subinterval with internal temporal structure, allowing onset, maintenance, and decay phases. Condition (3) captures the familiar phenomenology that emotions are global organizers: they bias perception, reshape salience, modulate memory access, and gate policy selection, rather than remaining local to a single representational module. The membership $e \in \mathsf{Pat}_m(I)$ is intended to emphasize that episodes are identified as patterns at the level of the whole embodied system across time, not as single-state labels; in particular, two distinct micro-realizations can count as the "same" episode-type if they share the relevant organizing constraints at the pattern level.

Definition 405 (Compassion episode)**.** *Fix a community C containing m and another mind $m' \neq m$. A* compassion episode in m toward m' on I *is an emotion episode $e \in \mathsf{Pat}_m(I)$ such that:*

1. *e is causally and predictively coupled to cross-mind patterns supported on $\{m, m'\}$ (i.e. intersubjective content),*

2. *e carries positive valence in m's valuation scheme and includes patterns representing m' as included in m's concern-set ("love inclusive of the other mind").*

The coupling requirement in (1) is intended to be stronger than mere causal dependence on a perceptual stimulus: the compassion episode must participate in a dynamical loop in which m tracks and forecasts relevant aspects of m' (e.g. affect, needs, intentions, vulnerability), and where that tracking is itself stabilized or corrected by cross-mind interaction. In particular, the "predictive" clause allows compassion to be constituted partly by anticipatory organization (e.g. preparing supportive actions, maintaining readiness to coordinate, sustaining attention to m'), rather than requiring that all relevant information about m' be presently observed. The concern-set clause in (2) is meant to mark the difference between benevolent attention and neutral monitoring: m' is represented as a beneficiary of m's protective, affiliative, or helping dispositions, so that action selection is biased toward outcomes favorable to m' (subject to m's broader constraints). Nothing in the definition requires that m' reciprocate, that m' be aware of m's state, or that the episode be socially successful; it only requires that the episode in m be constituted by intersubjective coupling and inclusive valuation directed toward m'.

Remark 1347. *The ontology does not insist on a single scalar "valence". All that is required is that there is a valuation component (possibly multi-dimensional) that can distinguish benevolent inclusion from aversive exclusion, and that compassion corresponds to inclusion along that axis.*

This remark allows the model to accommodate cases where affective tone, motivational direction, and normative appraisal dissociate (for example, compassion that is experienced as painful or heavy while remaining prosocial and inclusive). It also permits valuation schemes in which "positive" is not hedonically pleasant but instead reflects a structured preference for relationship-preserving, other-regarding, or harm-avoiding outcomes. Accordingly, the "axis" of inclusion can be realized by a family of coordinated valuation components (e.g. attachment, affiliation, care, fairness) so long as they jointly implement the inclusion/exclusion distinction relevant to compassion.

Proposition 39 (Communion-bias of compassion)**.** *Suppose a mind m has a compassion episode toward m' on I as in Definition 405. Then, for the dyadic community $\{m, m'\}$, the cross-supported intensity W_{cross} is bounded below by the total intensity of those cross-supported patterns coupled to the compassion episode. In particular, compassion in this sense cannot occur in a purely individual reality-system with $W_{\text{cross}} = 0$.*

Intuitively, the proposition formalizes a "communion bias": if compassion is constitutively intersubjective, then it necessarily allocates nonzero pattern-intensity to structures that are not realizable within a single isolated mind. The bound is stated in terms of cross-supported patterns *coupled* to the episode to emphasize that not all interpersonal structure in $\{m, m'\}$ need be relevant, only that the compassion episode cannot be constituted without some positive share of cross-mind organization. This is compatible with compassion also recruiting many purely intra-mind patterns in m (e.g. autobiographical memory, private imagery, internal deliberation), while still requiring that a nontrivial component of the episode's dynamics is anchored in patterns supported on the dyad.

Proof. By Definition 405, the compassion episode is causally and predictively coupled to cross-supported patterns on $\{m, m'\}$, hence at least one such pattern has positive intensity, so $W_{\text{cross}} > 0$ and is bounded below by the sum of intensities of these coupled patterns. $\square$

The proof uses only the minimal content of the definition: coupling entails the existence of at least one cross-supported pattern participating in the episode's causal/predictive structure, and the intensity formalism assigns a nonzero contribution to any such participating pattern. The inequality is therefore a bookkeeping statement about how the total cross-supported intensity cannot fall below the portion that is actually recruited by the compassion episode. Under a strict isolation assumption (no cross-supported patterns at all, i.e. $W_{\text{cross}} = 0$), the definitional coupling condition cannot be satisfied, so compassion-as-defined is ruled out in that regime.

24.8 Aesthetics and beauty as paraconsistent "surprising fulfillment"

Hyperseed proposes: (i) aesthetic experience is the experience of beauty, (ii) art is whatever has significant aesthetic effect for a class of experiencers, and (iii) beauty involves an experience that is both fulfilling-of-expectations and surprising, and whose internal representation behaves like an open-endedly intelligent mental subnetwork.

We now encode these claims in a form compatible with the earlier quantale/pattern formalism.

24.8.1 Fulfillment and surprise as distinct evaluators

Definition 406 (Predictive fulfillment and compression surprise)**.** *Fix a mind m and an encountered stimulus/artifact/event B over interval I. Assume m maintains:*

- *a predictive model Π_m assigning likelihoods to observations of B,*
- *an internal coding/compression scheme with code-length functional $L_m(\cdot)$ on representations of B.*

Define:

$$\mathsf{Ful}_m(B;I) := \exp\bigl(-\lambda \cdot \mathbb{E}[-\log \Pi_m(obs(B))]\bigr) \in (0,1],$$
$$\mathsf{Sur}_m(B;I) := \max\{0,\ L_m^{\mathrm{old}}(B) - L_m^{\mathrm{new}}(B)\} \in [0,\infty),$$

where $\lambda > 0$ is a scaling parameter and "old/new" refer to before/after updating m's internal codes after the encounter with B.

Remark 1348. *With these definitions, fulfillment and surprise are not forced to be complements. A stimulus can be broadly predictable (high* Ful*) while still yielding nontrivial compression gain (high* Sur*), which is a precise mathematical reading of "surprising fulfillment".*

24.8.2 Beauty as a paraconsistent conjunction

Hyperseed explicitly notes a tension (even a contradiction) between fulfillment and surprise. A convenient way to keep that tension in the formalism without collapsing reasoning is to use a paraconsistent logic.

Definition 407 (Beauty proposition and valuation)**.** *Fix a mind m and stimulus B on I. Let* $\mathsf{Ful}(B)$ *and* $\mathsf{Sur}(B)$ *be proposition symbols in m's self-model language $\mathcal{L}_m$. Define a valuation v_m on these by mapping to $\mathbb{B}$ (Definition 398) as:*

$$v_m(\mathsf{Ful}(B)) := (\min\{1, \mathsf{Ful}_m(B;I)\},\ 1 - \min\{1, \mathsf{Ful}_m(B;I)\}),$$
$$v_m(\mathsf{Sur}(B)) := \Bigl(\min\{1, \tfrac{\mathsf{Sur}_m(B;I)}{\mathsf{Sur}_m(B;I)+1}\},\ 1 - \min\{1, \tfrac{\mathsf{Sur}_m(B;I)}{\mathsf{Sur}_m(B;I)+1}\}\Bigr).$$

Define the beauty proposition *by*

$$\mathsf{Beaut}(B) \ := \ \mathsf{Ful}(B) \wedge \mathsf{Sur}(B),$$

with $\wedge$ interpreted as paraconsistent conjunction on $\mathbb{B}$.

Theorem 21 (Non-explosion for "surprising fulfillment")**.** *In the paraconsistent semantics of Definition 398, there exist valuations v and propositions P, Q such that P and $\neg P$ are both designated, but Q is not designated. Hence contradictions do not entail triviality.*

Proof. Let $\tau = 1$ (designation means $t = 1$). Choose $v(P) = (1,1)$ and $v(Q) = (0,0)$. Then $v(\neg P) = \neg(1,1) = (1,1)$, so both P and $\neg P$ are designated. But $v(Q)$ has truth degree 0, so Q is not designated. □

Remark 1349. *This formalizes the intended use: one can explicitly represent the tension between "fulfills expectations" and "is surprising" (including by adding additional rules that may generate contradictions), yet still reason nontrivially about other matters.*

24.8.3 Beauty and open-endedly intelligent subnetworks

Hyperseed's definition of beauty includes that the internal representation of the beautiful object "behaves as an open-endedly intelligent mental subnetwork." We capture this with a minimal, ontology-compatible criterion: the representation should contribute to both individuation and self-transcendence while maintaining self-continuity.

Definition 408 (Individuation gain, transcendence gain, self-continuity)**.** *Fix a mind m and an encounter with B on I. Assume we have numeric functionals:*

$$G_I(m, B; I) \in [0, \infty), \quad G_T(m, B; I) \in [0, \infty), \quad \mathsf{Self}C(m; I) \in [0, 1],$$

interpreted respectively as individuation gain, self-transcendence gain, and self-continuity during I. Assume monotonicity constraints consistent with Hyperseed's intent:

1. *G_I is nondecreasing in $\mathsf{Ful}_m(B; I)$ (fulfillment supports individuation),*

2. *G_T is nondecreasing in $\mathsf{Sur}_m(B; I)$ and in $\mathsf{Self}C(m; I)$ (surprise with continuity supports self-transcendence).*

Definition 409 (Aesthetic subnetwork is OEI-active)**.** *Let $\mathsf{Rep}_m(B; I)$ denote the induced pattern subweb/subnetwork in m representing B during I. We say $\mathsf{Rep}_m(B; I)$ is* OEI-active *if both $G_I(m, B; I) > 0$ and $G_T(m, B; I) > 0$.*

Theorem 22 (Beauty implies OEI-activity under mild thresholds)**.** *Fix thresholds $\theta_F \in (0, 1]$, $\theta_S > 0$, and $\theta_C \in (0, 1]$. Assume:*

1. *$\mathsf{Ful}_m(B; I) \geq \theta_F$ implies $G_I(m, B; I) > 0$,*

2. *$\mathsf{Sur}_m(B; I) \geq \theta_S$ and $\mathsf{Self}C(m; I) \geq \theta_C$ imply $G_T(m, B; I) > 0$.*

Then if m undergoes a beauty episode with B on I in the sense that $\mathsf{Beaut}(B)$ is designated and $\mathsf{Self}C(m; I) \geq \theta_C$, it follows that $\mathsf{Rep}_m(B; I)$ is OEI-active.
