Remark 3137 (Graph-theoretic intuition beyond one step). *While F is defined using one-step neighborhoods, fixed points often correspond to the persistence of cycles and reciprocal connectivity patterns. In a directed graph, mutual one-step coupling is a local proxy for membership in a bidirectionally constrained subgraph; iterating F can progressively remove nodes that are only "one-way" attached. This perspective is useful when thinking about robustness: entities that remain after repeated application of F are those that cannot be peeled away without breaking mutual predictive support.*

56.3.1 Shared reality across multiple minds

Definition 507 (Shared reality operator). *Let $\{F_i\}_{i \in I}$ be mutual predictive closure operators (one per mind, or per viewpoint). Define the* shared reality operator

$$J(R) := \bigcap_{i \in I} F_i(R).$$

Call any nonempty fixed point $R = J(R)$ a shared reality-system.

Remark 3138. *The operator J takes a candidate set R and retains only what survives every viewpoint's mutual-prediction filter. In this sense J is an algebraic representation of "common ground": the intersection enforces unanimity across the family of minds/viewpoints (Hyperseed-Concept **??**, Hyperseed-Concept **??**). When I indexes multiple agents, this resonates with the idea that stable shared structure is what remains invariant under multiple partial perspectives.*

In practical terms, F_i can vary because different minds have different models, sensors, or thresholds. The shared fixed point notion then becomes a tool for multi-agent or multi-model systems: compute what is robustly real for the group, not merely for an individual. This also connects naturally to work that distinguishes individual vs. collective loci of cognition (e.g. [4] and the collective-location framing in [12]).

Remark 3139 (Interpretation as robustness under viewpoint variation)**.** *Because J is defined by intersection, it is inherently conservative: it retains only those entities that are mutually predictively closed* for all $i \in I$. *Thus, a shared reality-system represents an invariance class under the family of predictive adjacencies induced by the group. If one views each F_i as encoding a different inductive bias or access channel, then J formalizes the idea that shared reality is what persists under such variations—a form of robustness that is social/epistemic rather than purely statistical.*

Remark 3140 (Edge cases: disagreement and the empty intersection)**.** *The insistence on nonempty fixed points is especially relevant in the multi-mind case: if the family $\{F_i\}$ is sufficiently incompatible, J may have only the empty fixed point, reflecting a failure to achieve any nontrivial common ground at the chosen thresholds. This is not a defect of the formalism but a way to represent, within the same algebra, the phenomenon that sufficiently misaligned models (or insufficient communication) can collapse shared reality to a null consensus. In later applications, one can soften unanimity by replacing $\bigcap$ with majority/weighted aggregators, but the present definition isolates the strictest notion of intersubjective agreement.*

Theorem 118 (Existence of minimal/maximal shared reality-systems (lattice theorem))**.** *Assume each F_i is monotone. Then J is monotone, and the set of fixed points of J is a complete lattice under inclusion. In particular, J has a least fixed point* $\mathrm{lfp}(J)$ *and a greatest fixed point* $\mathrm{gfp}(J)$.

Remark 3141 (Why completeness matters)**.** *The complete lattice structure is not merely an abstract convenience: it supports principled selection of canonical shared realities. The least fixed point* $\mathrm{lfp}(J)$ *can be interpreted as the smallest set of entities that is self-sustaining under all viewpoints' mutual predictive closures (a "minimal consensus core"), while the greatest fixed point* $\mathrm{gfp}(J)$ *is the largest such set (a "maximal common world" consistent with the group). These bounding objects allow one to reason about refinement (moving upward from* $\mathrm{lfp}(J)$*) and skepticism (moving downward from* $\mathrm{gfp}(J)$*) while remaining within fixed points.*

Remark 3142 (Standard proof route via Knaster–Tarski)**.** *Given monotonicity of each F_i, monotonicity of J follows because intersections of monotone images preserve inclusion: if $R \subseteq R'$ then $F_i(R) \subseteq F_i(R')$ for all i, hence $\bigcap_i F_i(R) \subseteq \bigcap_i F_i(R')$. The existence of* $\mathrm{lfp}(J)$ *and* $\mathrm{gfp}(J)$ *then follows from the Knaster–Tarski theorem on monotone endomaps of complete lattices (here, $(2^U, \subseteq)$). In particular,*

$$\mathrm{lfp}(J) = \bigcap\{R \subseteq U : J(R) \subseteq R\}, \qquad \mathrm{gfp}(J) = \bigcup\{R \subseteq U : R \subseteq J(R)\},$$

so the extremal shared reality-systems can be characterized respectively as the intersection of all pre-fixed points and the union of all post-fixed points.

Remark 3143 (Computational reading: iteration toward consensus)**.** *When U is finite (or otherwise effectively representable), one can often approximate fixed points by iteration. For example, starting from a large candidate set (such as U itself) and repeatedly applying J yields a descending chain $U \supseteq J(U) \supseteq J^2(U) \supseteq \cdots$ that stabilizes at a post-fixed point and, under common finiteness conditions, reaches* $\mathrm{gfp}(J)$. *Dually, starting from a small seed (when a suitable bottom element is* *chosen, often* $\varnothing$*) and iterating upward can approach* $\mathrm{lfp}(J)$*. This connects the formal lattice result to a concrete procedure: shared reality can be viewed as what remains after repeatedly removing entities that fail some viewpoint's mutual predictive closure.*

Remark 3144. *This theorem says there are canonical extremes of shared reality: a smallest shared reality (the least fixed point) and a largest shared reality (the greatest fixed point). The surprise, if one expects "reality" to be unique, is that the mathematics does not force uniqueness; instead it offers a lattice of stable candidates, ordered by inclusion, within which one can choose according to additional criteria (e.g. minimality, maximality, or pragmatic constraints). In particular, even if every individual viewpoint has a well-defined "closure" behavior, the act of taking a joint closure across multiple viewpoints can admit multiple consistent equilibria. The lattice picture makes this multiplicity orderly: different equilibria are not arbitrary, but sit between canonical bounds and can be compared by refinement (*$R \subseteq R'$*) as a notion of "adding commitments" or "adding jointly endorsed structure."*

The importance is twofold. Conceptually, it makes "shared reality" into an object that can be computed and compared. Technically, it gives us access to the whole fixed-point toolkit on complete lattices. Fixed-point arguments of this kind recur throughout Hyperseed-style analyses of stability (e.g. in goal-system dynamics [10]), and here they support a precise account of intersubjective closure. One can also read the least and greatest fixed points as "minimal common ground consistent with mutual prediction" versus "maximal common ground that remains self-stabilizing under mutual prediction." In applications, these extremes can serve as conservative and liberal baselines, with intermediate fixed points representing different compatible ways of settling ambiguity.

Proof. Each F_i monotone implies $R \subseteq R' \Rightarrow F_i(R) \subseteq F_i(R')$. Intersecting over i preserves inclusion, so J is monotone. Since $(2^U, \subseteq)$ is a complete lattice and J is monotone, the Knaster–Tarski theorem implies that the fixed points of J form a complete lattice and least/greatest fixed points exist. For clarity: completeness of 2^U means that for any family $\{R_\alpha\}_{\alpha \in A} \subseteq 2^U$, both $\bigcap_{\alpha \in A} R_\alpha$ and $\bigcup_{\alpha \in A} R_\alpha$ exist in 2^U and serve as the infimum and supremum under $\subseteq$. Knaster–Tarski then applies directly to the endomap $J : 2^U \to 2^U$, yielding not only existence but also the order structure of the set of fixed points. $\square$

Remark 3145 (Proof sketch and intuition)**.** *The strategy is purely order-theoretic: (i) show* J *is monotone because it is an intersection of monotone maps, then (ii) invoke Knaster–Tarski, which guarantees that any monotone endomap on a complete lattice has a complete lattice of fixed points. Equivalently, there are always stable sets* R *satisfying* $R = J(R)$*, and among them there is a distinguished smallest and largest one with respect to inclusion. This is precisely what makes the fixed-point set itself behave like a "space of candidates" rather than a single solution.*

A useful image is that each mind/viewpoint i *supplies a "filter"* F_i*. Applying* J *applies all filters simultaneously by intersection. Monotonicity ensures filters behave coherently under enlarging hypotheses, and Knaster–Tarski then ensures stable hypotheses exist and can be ordered. In that image, a fixed point* $R = J(R)$ *is a hypothesis set that survives all filters unchanged. The least fixed point can be thought of as what remains after iterating filtering from the bottom (starting at* $\varnothing$*), while the greatest fixed point corresponds to what survives when starting from the top (starting at* U*) and repeatedly enforcing mutual predictability, whenever those iterative characterizations are valid for the operators at hand.*

Remark 3146 (Interpretation)**.** *A shared reality-system is "what all considered minds mutually predict with one another," formalized as a joint fixed point. This is a direct mathematical handle on intersubjective "common ground". More explicitly,* $R = J(R)$ *means that if one assumes* R

as the current candidate for common ground, then each viewpoint's predictive closure does not introduce anything outside R that would still be jointly endorsed after intersecting across minds. Thus R is not merely mutually compatible, but stable under the operation of "take what everyone would infer/predict from the current common ground and keep only what is jointly retained." The existence of extremal fixed points then says there are canonical choices of common ground even when agreement is underdetermined.

Theorem 119 (Monotonicity of shared reality in predictive power)**.** *Suppose two families of operators satisfy $F_i(R) \subseteq F_i'(R)$ for all i and all $R \subseteq U$ (i.e., every mind's predictive closure becomes at least as expansive). Let $J = \cap_i F_i$ and $J' = \cap_i F_i'$. Then*

$$\mathrm{gfp}(J) \subseteq \mathrm{gfp}(J') \qquad \textit{and} \qquad \mathrm{lfp}(J) \subseteq \mathrm{lfp}(J').$$

Remark 3147. *This theorem formalizes a sober monotonicity principle: if every mind becomes "more predictively capable" (or less restrictive) in the sense that its closure operator expands, then the extremal shared realities expand as well. In other words, increasing predictive power cannot shrink what is stably shareable. A useful way to read this is comparative statics: when all individual closures are relaxed (pointwise), the joint equilibrium set shifts upward in the lattice order. The conclusion is stated only for the least and greatest fixed points because those are canonical selections, but the same pointwise order $J \leq J'$ also implies inclusion relationships between the full sets of pre/post-fixpoints that underlie intermediate fixed points.*

This connects to the lattice theorem by describing how the lattice of shared realities changes when we perturb the underlying operators. Later, in the robustness subsection, we will perform a similar analysis but at the level of graph weights and thresholded edges. The present result is also a sanity check: if one interprets each F_i as encoding what is predictively reachable or inferable for agent i, then granting agents additional inferential resources should not paradoxically remove stable joint conclusions; it can only keep them or add more, at least at the level of these extremal equilibria.

Proof. Pointwise inclusion $F_i \subseteq F_i'$ implies $J(R) = \cap_i F_i(R) \subseteq \cap_i F_i'(R) = J'(R)$ for all R, i.e., $J \leq J'$ pointwise. For monotone maps on a complete lattice, pointwise order implies monotonicity of least and greatest fixed points: the set of post-fixpoints of J is contained in that of J', yielding $\mathrm{gfp}(J) \subseteq \mathrm{gfp}(J')$, and similarly for least fixed points. Concretely, recall the standard characterizations (Knaster–Tarski):

$$\mathrm{gfp}(J) = \bigcup\{R \subseteq U : R \subseteq J(R)\}, \qquad \mathrm{lfp}(J) = \bigcap\{R \subseteq U : J(R) \subseteq R\}.$$

If $J \leq J'$, then any R satisfying $R \subseteq J(R)$ also satisfies $R \subseteq J'(R)$, so the union defining $\mathrm{gfp}(J)$ is taken over a subset of the family used for $\mathrm{gfp}(J')$, giving the desired inclusion. Dually, any R satisfying $J'(R) \subseteq R$ also satisfies $J(R) \subseteq R$, so the intersection defining $\mathrm{lfp}(J)$ is over a (weakly) larger family, yielding $\mathrm{lfp}(J) \subseteq \mathrm{lfp}(J')$. □

Remark 3148 (Proof sketch and intuition)**.** *The proof compares J and J' pointwise: $J(R) \subseteq J'(R)$ for every R. Fixed points can be characterized as intersections/unions of pre-fixpoints or post-fixpoints; since J is everywhere smaller than J', the collection of post-fixpoints for J is more constrained, hence the greatest fixed point cannot exceed that of J'. The least fixed point comparison is analogous. This is an instance of the general monotonicity of the operators* $\mathrm{lfp}(\cdot)$ *and* $\mathrm{gfp}(\cdot)$ *with respect to the pointwise order on monotone endomaps of a complete lattice.*

An intuition in terms of "constraints": each F_i imposes constraints on what counts as mutually predictive. Replacing F_i by a larger F_i' relaxes constraints, so the stable solutions can only get larger. Said differently, J is the "strict" joint filter and J' is the "lenient" joint filter; a set that *is stable under the strict filter is automatically stable (or at least extendable to stability) under the lenient one, so the maximal stable set under lenience must contain the maximal stable set under strictness. The same reasoning holds at the minimal end: once pre-fixpoint conditions are relaxed, the intersection of all admissible supersets can only move upward.*

56.3.2 A computable graph-theoretic picture (optional but useful)

Definition 508 (Two-sided reachability closure)**.** *Given a directed graph $(U, \to)$, define reachability sets*

$$\mathrm{Reach}^+(R) := \{y : \exists x \in R \text{ with a directed path } x \rightsquigarrow y\}, \quad \mathrm{Reach}^-(R) := \{y : \exists x \in R \text{ with a directed path } y \rightsquigarrow x\}.$$

Define $F^*(R) := \mathrm{Reach}^+(R) \cap \mathrm{Reach}^-(R)$.

Remark 3149. *This definition replaces one-step prediction neighborhoods with arbitrary-length reachability. The notation $x \rightsquigarrow y$ denotes the existence of a directed path from x to y (possibly of length 0 or positive length, depending on convention; here it suffices that it is a preorder). Then* $\mathrm{Reach}^+(R)$ *is everything downstream of R, while* $\mathrm{Reach}^-(R)$ *is everything upstream of R, and $F^*(R)$ keeps what lies in both the upstream and downstream cones. Note that* Reach^+ *and* Reach^- *are themselves monotone in R (adding starting vertices can only add reachable vertices), so F^* is monotone as an intersection of monotone maps; therefore the earlier fixed-point existence results apply directly to F^* as well.*

Computationally, this is valuable because reachability is a standard graph primitive, and fixed points of F^* can be related to strongly connected structure. Conceptually, moving from F to F^* corresponds to allowing multi-step mutual predictability, which is often closer to the way reasoning systems actually propagate implications. In particular, membership $y \in F^*(R)$ means that y is both reachable from some element of R and can reach back to some element of R, so y lies in the same "mutual influence zone" as R up to directed paths. When R is a singleton $\{x\}$, $F^*(\{x\})$ collects exactly those vertices that are mutually reachable with x, i.e. the strongly connected component of x (under the convention that reachability includes the length-0 path). More generally, $F^*(R)$ aggregates the union of strongly connected components that intersect R, together with any vertices that sit in directed cycles connecting into and out of R; fixed points $R = F^*(R)$ therefore correspond to sets that are closed under this two-sided reachability notion.

Theorem 120 (Fixed points of F^* are "path-convex" (interval-closed))**.** *Let $\preceq$ be the reachability preorder on U (so $a \preceq b$ iff $a \rightsquigarrow b$). Then for any $R \subseteq U$,*

$$F^*(R) = \{z \in U : \exists a, b \in R \text{ with } a \preceq z \preceq b\}.$$

Hence R is a fixed point of F^* iff R is order-convex with respect to $\preceq$: whenever $a, b \in R$ and $a \preceq z \preceq b$, then $z \in R$.

Equivalently: $F^*(R)$ consists of all nodes that lie on a directed "two-sided" reachability chain starting in R and ending in R. When $\preceq$ happens to be antisymmetric (so it is a partial order), this is the familiar notion of order-convexity; when $\preceq$ is merely a preorder, the same condition should be understood up to mutual reachability (i.e. within and between $\preceq$-equivalence classes).

Remark 3150. *The theorem says that the closure $F^*(R)$ is exactly the set of points that lie on some directed "interval" between two points of R (with respect to the reachability preorder). Thus, F^* is an interval hull operator, and its fixed points are precisely the interval-closed (order-convex) subsets.*

This is important because it translates a fixed-point definition of reality into a geometric one: a reality-system is not an arbitrary set of nodes, but an "unbroken region" in the reachability order. In explanatory terms, it gives a crisp style of justification: to explain why z belongs to the closure of R, exhibit $a, b \in R$ such that a can reach z and z can reach b.

It is also useful to keep in mind the directed-graph picture. If U is the vertex set of a directed graph and $\rightsquigarrow$ denotes existence of a directed path, then $a \preceq b$ means "there is a path from a to b." In that setting, $z \in F^*(R)$ precisely when z lies on a directed path that starts somewhere in R and can be continued to end somewhere in R (not necessarily on the same path segment, but with the same intermediate vertex z witnessing both reachability conditions).

Finally, the preorder perspective clarifies what "interval" means when cycles are present. If $a \preceq b$ and $b \preceq a$, then a and b are mutually reachable and are indistinguishable by $\preceq$; the corresponding equivalence classes (strongly connected components in the graph interpretation) behave like the "points" of an induced partial order. The order-convex sets in the theorem can then be read as unions of equivalence classes that are convex in this induced partial order.

Proof. $z \in \mathrm{Reach}^+(R)$ iff $\exists a \in R$ with $a \preceq z$. Also $z \in \mathrm{Reach}^-(R)$ iff $\exists b \in R$ with $z \preceq b$. Thus $z \in F^*(R)$ iff both conditions hold, i.e. iff $\exists a, b \in R$ with $a \preceq z \preceq b$. The characterization of fixed points is immediate.

In particular, the forward direction uses only that $F^*(R)$ is defined as an intersection: membership in $F^*(R)$ means simultaneously satisfying a forward-reachability witness $a \in R$ and a backward-reachability witness $b \in R$. Conversely, if witnesses $a, b \in R$ exist with $a \preceq z \preceq b$, then z lies in both reachability sets, hence in their intersection.

As a small boundary check: if $R = \varnothing$ then $F^*(R) = \varnothing$ by the displayed characterization, and if $R = \{a\}$ then $F^*(R) = \{z \in U : a \preceq z \preceq a\}$, i.e. the $\preceq$-equivalence class of a (all nodes mutually reachable with a). This illustrates how F^* treats cyclic structure as "collapsed" into equivalence classes even before any further convexity across classes is considered. □

Remark 3151 (Proof sketch and intuition)**.** *The proof is a direct logical unpacking: membership in the intersection* $\mathrm{Reach}^+(R) \cap \mathrm{Reach}^-(R)$ *is exactly the conjunction of "reachable from R" and "can reach R", which is equivalent to lying between some $a \in R$ and some $b \in R$ in the preorder $\preceq$.*

One can picture $\preceq$ as defining a directed landscape. The set $F^*(R)$ is the region that is simultaneously downstream of R and upstream of R. Fixed points are regions that contain every node that lies between any two of their nodes, hence they are "path-convex."

A complementary way to say this is that $F^*(R)$ supplies all "bridge" nodes needed to make R closed under interpolation along reachability: whenever R contains endpoints of a reachability interval, the entire interval must also be present. This is exactly the directed analogue of taking the convex hull in Euclidean geometry, except that "straight lines" are replaced by preorder intervals.

This intuition also makes clear why the operator is well-suited to multi-step mutual predictability: a node counts as stabilized by R only if it is both supported by (reachable from) some element of R and can, in turn, support (reach) some element of R. The two-sidedness is what forces an "interval" rather than merely a forward closure.

Remark 3152 (Use)**.** *This provides a clean structural reading: if reality is defined via multi-step mutual predictability, then reality-systems are exactly the "interval-closed" subsets of the predictive reachability order. This supports explanation: to justify why z is in reality-system R, it suffices to exhibit $a, b \in R$ with $a \rightsquigarrow z \rightsquigarrow b$.*

Moreover, the theorem identifies $F^*(R)$ as the smallest reality-system (fixed point) that contains R, in the following sense: if S is any fixed point with $R \subseteq S$, then the interval condition forces $F^*(R) \subseteq S$. This "least closed superset" reading is exactly what makes F^* behave like a closure *operator relative to the interval-closed sets, and it is the property that underwrites robust inference: once R is accepted, any intermediate node on a two-sided reachability chain between accepted nodes is also forced to be accepted.*

When applying the criterion in practice, it is often helpful to choose a as a node in R that most directly generates z (a minimal witness for $a \preceq z$) and choose b as a node in R that z most directly generates (a minimal witness for $z \preceq b$). This makes the justification not just existence-based but also explanatorily economical: it displays z as an interpolant that transmits influence from a to b.

56.4 Robustness theorems

56.4.1 Robustness of approximate morphism degrees

Theorem 121 (Degree monotonicity under graph perturbations)**.** *Let $f : X \to Y$. Suppose G, G' are V-graphs on X and H, H' are V-graphs on Y with $G' \leq G$ and $H \leq H'$ pointwise. Then*

$$\deg(f; G', H') \geq \deg(f; G, H).$$

Remark 3153. *This is a robustness statement about correspondence quality. It says: if we make the internal graph* less demanding *(by reducing edge weights: $G' \leq G$) and/or make the external graph* more supportive *(by increasing edge weights: $H \leq H'$), then the measured degree of preservation cannot get worse; indeed, it can only improve.*

In a reasoning system, $G' \leq G$ often arises when we prune weak internal edges or lower our internal claims; $H \leq H'$ arises when additional external evidence strengthens the world model. The theorem therefore formalizes a safe engineering expectation: conservative internalization and improved external evidence should not break previously established correspondences. This is a quantitative stability property of Mind–World Correspondence (Hyperseed-Concept 112) under refinement and noise.

Concretely, the pointwise inequalities mean that for every ordered pair (x, x') one has $G'(x, x') \leq G(x, x')$, and for every ordered pair (y, y') one has $H(y, y') \leq H'(y, y')$. Thus the comparison is uniform across the entire relational structure, not merely on average. If $V = [0, 1]$ with the usual order, the situation is especially intuitive: lowering G relaxes the demanded internal similarity/entailment strengths, while raising H increases the degree to which the world-side relation is deemed satisfied.

Proof. Fix $x, x' \in X$. By $G'(x, x') \leq G(x, x')$ and Lemma 1 (antitonicity in the left argument),

$$(G'(x, x') \to H(f(x), f(x'))) \geq (G(x, x') \to H(f(x), f(x'))).$$

Also $H(f(x), f(x')) \leq H'(f(x), f(x'))$ and Lemma 1 (monotonicity in the right argument) give

$$(G'(x, x') \to H'(f(x), f(x'))) \geq (G'(x, x') \to H(f(x), f(x'))).$$

Chaining yields

$$(G'(x, x') \to H'(f(x), f(x'))) \geq (G(x, x') \to H(f(x), f(x'))).$$

Taking meets over all pairs (x, x') preserves the inequality, giving the claim.

Equivalently: the degree $\deg(f; G, H)$ is defined as the meet (infimum, or "worst-case" aggregate) of the individual implication values $(G(x, x') \to H(f(x), f(x')))$ as (x, x') ranges over $X \times X$. Since the residuum $\to$ is antitone in its left input and monotone in its right input, each term in this family is pointwise increased when passing from (G, H) to (G', H') under the stated inequalities. The meet operator is monotone with respect to pointwise order on families, so an everywhere-increase of terms yields an increase of the overall meet. □

Remark 3154 (Proof sketch and intuition)**.** *The proof compares each individual implication term in the meet defining* $\deg(f; G, H)$*. Reducing* G *to* G' *increases the implication because the antecedent becomes easier (residuum is antitone on the left). Increasing* H *to* H' *also increases the implication because the consequent becomes easier (residuum is monotone on the right). Thus every term in the meet increases, so the meet increases.*

A visual intuition: deg *is governed by the worst edge. If you weaken the internal edges or strengthen the external ones, then no edge becomes harder to match, so the "worst mismatch" cannot worsen.*

Another way to read this is as a form of order-theoretic Lipschitz behavior with respect to the pointwise order on V*-graphs: the degree functional is monotone in* H *and antitone in* G*, so "pessimistic" changes to internal commitments (lowering* G*) and "optimistic" changes to external support (raising* H*) can only move* deg *in the favorable direction.*

Corollary 48 (Robust correspondence lower bound under pruning/noise)**.** *If a reasoning system prunes weak edges from its internal graph (making* G' *smaller) and/or its estimate of the external graph becomes more supportive (making* H' *larger), then any previously established correspondence degree cannot decrease.*

Remark 3155. *This is the direct operational reading of the preceding theorem. It is especially useful in incremental systems: you may cache a previously computed correspondence degree, and later updates that only prune internal commitments or add external support do not require recomputing that degree just to ensure it has not degraded.*

In practice, this supports a common workflow: maintain a conservative lower bound on alignment between an internal representation and a world model while iteratively editing the internal graph. As long as edits are of the form "remove or downweight dubious internal edges" and/or "add or upweight supported external edges," the cached degree remains valid as a lower bound, even if the exact numerical value might become higher.

56.4.2 Robustness of reality-systems under threshold perturbations

Definition 509 (Edge stability margin for thresholded adjacency)**.** *Let* $s : U \times U \to \mathbb{R}$ *be a predictive score and fix a threshold* θ*. Define the adjacency* $\to_\theta$ *by* $x \to_\theta y$ *iff* $s(x, y) \geq \theta$*. Given a perturbation* $\tilde{s}$*, define the uniform deviation* $\|s - \tilde{s}\|_\infty := \sup_{x,y} |s(x, y) - \tilde{s}(x, y)|$*. An edge* (x, y) *has margin* $m(x, y) := |s(x, y) - \theta|$*.*

Remark 3156. *This definition separates two layers: a real-valued score function* s *(often learned or estimated) and a hard adjacency relation* $\to_\theta$ *obtained by thresholding. The sup norm* $\|s - \tilde{s}\|_\infty$ *measures worst-case perturbation over all ordered pairs, and the margin* $m(x, y)$ *measures how close a particular score is to the decision boundary* θ*.*

The philosophical point is that many realities are built by thresholding uncertain evidence, and therefore their stability depends not on the scores alone but on how decisively those scores clear (or fail to clear) the threshold. Margins quantify decisiveness. This is a standard robustness idea transposed into the present predictive-closure setting (Hyperseed-Concept 195).

Note that the adjacency is defined with a weak inequality ($\geq \theta$*), so the exact tie case* $s(x, y) = \theta$ *has margin* 0 *and is maximally fragile: an arbitrarily small negative perturbation will remove the edge, and an arbitrarily small positive perturbation will keep it (or create it if it was previously just below threshold). This makes the margin a precise local certificate of discrete stability for each ordered pair.*

Lemma 166 (Margins prevent edge flips)**.** *If* $\|s - \tilde{s}\|_\infty \leq \varepsilon$ *and* $m(x, y) > \varepsilon$*, then* $x \to_\theta y$ *iff* $x \tilde{\to}_\theta y$*.*

Remark 3157. *This lemma states a simple but powerful principle: if a score is farther than ε from the threshold, then any perturbation bounded by ε cannot change which side of the threshold it lies on. In practice, this says that only near-threshold edges are fragile; far-from-threshold edges are stable.*

The lemma is the hinge between numerical noise and discrete graph structure. Once one has it, one can reason about stability of fixed points of F by ensuring stability of the edges that actually matter for $F(R)$.

In particular, when a reality-system is defined by iterated application of an update/closure operator that depends only on the thresholded adjacency, the lemma isolates the only potential source of qualitative change under bounded score perturbations: the subset of pairs whose scores lie in the ε-band around θ. This can be used to focus verification or data collection on precisely those "knife-edge" relations.

Proof. If $s(x,y) \geq \theta$ and $s(x,y) - \theta > \varepsilon$, then $\tilde{s}(x,y) \geq s(x,y) - \varepsilon > \theta$. If $s(x,y) < \theta$ and $\theta - s(x,y) > \varepsilon$, then $\tilde{s}(x,y) \leq s(x,y) + \varepsilon < \theta$. □

Remark 3158 (Proof sketch and intuition)**.** *The strategy is to use the triangle inequality in its simplest form: a bounded perturbation can shift a score by at most ε. If the original score is at least ε away from the threshold, it cannot cross the threshold after perturbation.*

Geometrically, the interval $(\theta - \varepsilon, \theta + \varepsilon)$ is the "danger zone": only scores in that band can flip their thresholded decision under ε noise.

A useful global corollary (often applied implicitly) is: if all margins satisfy $\inf_{x,y} m(x,y) > \varepsilon$, then no *edges flip anywhere in the graph, so the entire thresholded adjacency relation $\to_\theta$ is invariant under all perturbations $\tilde{s}$ with $\|s - \tilde{s}\|_\infty \leq \varepsilon$. This is precisely the condition under which a reality-system built from $\to_\theta$ is structurally stable against uniform score noise.*

Theorem 122 (Fixed-point robustness from boundary-edge stability)**.** *Let F be defined from $\to_\theta$ as in Section 3, and let $\tilde{F}$ be defined from $\tilde{\to}_\theta$. Let $R \subseteq U$. If $\to_\theta$ and $\tilde{\to}_\theta$ agree on all edges in*

$$(R \times U) \ \cup \ (U \times R),$$

then $F(R) = \tilde{F}(R)$. In particular, if R is a reality-system for F, then it is also a reality-system for $\tilde{F}$.

In other words, the value of F at the argument R is invariant under any perturbation of the underlying directed graph that leaves unchanged (i) every arrow with tail in R (all potential "predictions made from within R") and (ii) every arrow with head in R (all potential "predictions landing inside R"). Note that this hypothesis permits arbitrary changes on $R \times R$ (edges internal to R) and on $(U \setminus R) \times (U \setminus R)$ (edges wholly outside R), as well as any changes on edges that do not touch R at all.

Equivalently, if one views $\to_\theta$ and $\tilde{\to}_\theta$ as adjacency matrices on U, then the theorem requires agreement only on the rows indexed by R and the columns indexed by R; the remaining submatrices may differ freely without affecting $F(R)$.

Remark 3159. *This theorem isolates exactly where $F(R)$ "looks" in the adjacency matrix: it only cares about edges leaving R and edges entering R. Thus, to ensure the evaluation of F on a candidate set R is robust, it is not necessary to stabilize the entire graph—only the boundary edges touching R.*

Here "boundary" should be read literally in the directed sense: the set of ordered pairs (r, u) with $r \in R$ and $u \in U$ (outgoing boundary), together with the ordered pairs (u, r) with $u \in U$ and $r \in R$ (incoming boundary). Any changes that remain entirely within the interior of R do not affect *whether R is closed under the predecessor conditions encoded by F, because those conditions are evaluated by looking outward from R and inward to R, not by inspecting internal connectivity.*

The result is important for computation and for epistemology. Computationally, it yields local robustness checks. Epistemologically, it says that the stability of a candidate reality-system depends on the stability of its boundary relations: what can predict from it and what can predict into it. One might say, with Russellian sobriety, that "reality" here is determined not by intrinsic essence but by relational closure conditions; with Whitehead, that it is maintained by patterns of ingress and egress of process [15].

A concrete way to read the conclusion is: if two agents (or two measurement runs) disagree about the world-graph only in regions that do not touch R (or only about internal relations among elements of R), then their induced closure computations agree on the status of R as a reality-system. Thus the theorem supports a notion of "shared reality" that is mediated by stable interface relations rather than by full global agreement.

Proof. $\mathrm{Pred}_{\to}(R)$ depends only on edges leaving R, i.e. pairs in $R \times U$. $\mathrm{Pred}_{\leftarrow}(R)$ depends only on edges entering R, i.e. pairs in $U \times R$. If $\to$ and $\tilde{\to}$ agree on these pairs, then both predecessor sets agree, hence their intersection agrees: $F(R) = \tilde{F}(R)$. If $F(R) = R$, then $\tilde{F}(R) = R$ as well.

More explicitly (unfolding the dependency that is implicit in the notation of Section 3), the membership of a point $u \in U$ in $\mathrm{Pred}_{\to}(R)$ is determined by whether u is reachable from (or predicted by) some $r \in R$ via the relation $\to_\theta$; this is a statement about which ordered pairs (r, u) are present. Dually, membership of u in $\mathrm{Pred}_{\leftarrow}(R)$ is determined by whether some $r \in R$ is reachable from u via $\to_\theta$, i.e. about which ordered pairs (u, r) are present. Since $F(R)$ is computed by taking the intersection of these two predecessor sets, no other edge-information can enter the calculation of $F(R)$ at all. $\square$

Remark 3160 (Proof sketch and intuition)**.** *The proof is an exercise in dependency-tracing: identify the exact input data needed to compute $F(R)$. Forward prediction depends on edges out of R; backward prediction depends on edges into R. If those edges are unchanged, then the computed predecessor sets are unchanged, hence their intersection is unchanged.*

A picture to hold: draw the subset R as a region in a directed graph. The operator F only consults arrows crossing the boundary of this region (incoming and outgoing). If the boundary arrows are stable, then the closure of the region is stable.

In particular, perturbations that "rewire" the world outside R may drastically alter global reachability, clustering, or other graph-theoretic properties, and yet still leave $F(R)$ completely unchanged so long as those perturbations do not modify any arrow that starts in R or ends in R. This clarifies why the robustness is genuinely local: it is pinned to the interface between R and its complement, not to any global feature of the ambient network.

Remark 3161 (Use)**.** *This yields an implementable robustness test: a candidate reality-system R is stable under score noise ε if all edges that touch R and matter for closure have margins $> \varepsilon$.*

Concretely, when $\to_\theta$ is obtained by thresholding an underlying score function (as in the construction leading to $\to_\theta$), an "edge margin" may be taken to mean the distance of an edge's score from the threshold θ. If every boundary pair in $(R \times U) \cup (U \times R)$ has score at least ε away from θ, then any perturbation of size at most ε cannot flip the truth value of those boundary edges, and therefore cannot change $F(R)$. In that sense, the theorem upgrades margin information on the boundary to a certificate of invariance for the fixed-point test $F(R) = R$.

56.5 Optional: tying back to "mind–world correspondence" and "reality"

Remark 3162 (How these results operationalize mind–world correspondence and reality-systems)**.** *Mind–world correspondence provides a quantitative slack q for transporting internal structure to external structure (Sections 2.2–2.3). Reality-systems provide a fixed-point criterion for what entities cohere as "real" relative to predictive coupling (Section 3). Robustness theorems show when (i) correspondence degrees are monotone under refinement/pruning, and (ii) reality-systems persist under bounded perturbations of predictive scores. Together they support a reasoning loop: maintain internal inferences, transport them outward with depth-aware penalties, update predictive edges/scores, and track stable fixed points as candidate "shared realities".*

To make the operational role of q more explicit, one may regard q as an "allowable distortion budget" that quantifies how much inferential content can survive translation across representational interfaces. In particular, when a transported statement depends on deeper chains of inference or larger bundles of constraints, the theorems justify treating it as more fragile: the same raw internal confidence should yield a smaller externally warranted confidence unless q is large enough to cover the additional structural load.

The monotonicity clause (i) can be read as a minimal sanity condition for disciplined updating: if one refines a model (e.g., adds resolution, splits latent states, or introduces additional distinctions) or prunes it (e.g., discards unsupported branches), then the induced correspondence degree should move in the expected direction rather than oscillating pathologically. This prevents "correspondence inflation" by gratuitous complexity and, conversely, prevents "correspondence collapse" from harmless simplifications, so long as the refinement/pruning respects the stated hypotheses.

Likewise, persistence under bounded perturbations in (ii) upgrades the fixed-point notion from a purely formal equilibrium to a stability claim: if predictive scores change slightly (through noise, finite-sample effects, or small environmental drift), then the reality-system should not change discontinuously. Conceptually, this is what licenses treating a fixed point as tracking a world-facing regularity rather than an artifact of a particular threshold, parametrization, or numerical idiosyncrasy.

Finally, the phrase "depth-aware penalties" can be understood as the mathematical mechanism that prevents the loop from over-exporting internal coherence: deeper derivations may remain perfectly valid internally, but their external import is tempered unless the correspondence slack q supports the additional inferential distance. In that sense, the loop enforces a separation between "coherence within a map" and "robust contact with the territory," while still allowing the two to communicate under quantitatively stated conditions.

Remark 3163. *In the Hyperseed idiom, the transfer results formalize a disciplined version of "do not confuse your map with the territory": the map-to-territory correspondence is parameterized by q, and deep inferences or large constraint-bundles must be discounted accordingly (Hyperseed-Concept 112). The shared-reality fixed points formalize how multiple maps may still overlap in a stable intersubjective core (Hyperseed-Concept* **??***), and the robustness criteria clarify when such cores are not mere artifacts of thresholding noise (Hyperseed-Concept 149).*

This discounting is not an invitation to skepticism; rather, it supplies a calibratable bridge between internal entailment and external warrant. A map may support far-reaching consequences, but the parameterization by q forces one to state (and, where possible, estimate) how reliably those consequences survive translation into externally checkable constraints. When q is small, the framework predicts that only shallow, low-complexity consequences are stably exportable; when q is larger, one can legitimately transport more structure without conflating internal elegance with external truth.

The intersubjective core, in turn, is characterized not by unanimous agreement on full models, but by convergence on the fixed points that remain stable under coupling: different agents may *disagree about hidden variables, ontological commitments, or explanatory narratives, yet still share a reality-system insofar as their predictive edges mutually stabilize the same entities as reliable anchors. The robustness requirements then express a further constraint: such overlap must survive reasonable perturbations (measurement error, shifting priors, finite data), otherwise the apparent core is better treated as a coordination artifact than as a candidate "shared reality."*

One may also read the overall structure as a pragmatic reconciliation of two impulses: the Peircean urge to define meaning by stable inferential consequences [14], and the Sagan/Dyson-style insistence that any such stability must be tested against perturbation and noise. In this sense, the mathematics here is not merely bookkeeping; it is a compact ethics of epistemic caution. Concretely, it asks that claims earn their status not only by fitting a self-consistent inferential role, but also by remaining invariant (up to controlled slack) when the coupling signals are stressed, reweighted, or partially corrupted.

Remark 3164. *A useful way to connect these ideas back to practice is to view q and the perturbation bounds as explicit "audit parameters" for epistemic workflows. For example, if two agents (or two models) agree on a predicted regularity only when q is taken unrealistically large, then the agreement is diagnostic of a shared internal encoding rather than of a shared external constraint. Conversely, if a putative reality-system persists across a range of plausible perturbation levels, then it merits being treated as a stable target for further inquiry (e.g., as a hypothesis class to be tested, or as an ontology to be used for coordination), even if the agents retain substantial disagreement about the surrounding explanatory superstructure.*

In this reading, "shared reality" is not a binary declaration but a graded outcome: one can track how the fixed points move (or fail to move) as q is tightened and as perturbation budgets are varied. The framework thereby encourages a disciplined form of pluralism: multiple maps may be kept in play, while the stable overlaps that survive transport and robustness checks are promoted as the most defensible candidates for world-facing commitments.

57 Value Conflict, Resonance, and Social Coordination

We give formal theorems that connect (i) paraconsistent value evidence, (ii) resonance/interference as a coherence proxy, and (iii) social coordination phenomena (agreement, polarization, diffusion, and stabilization of norms). The results are biased toward computational use in reasoning loops: diagnosing value conflict, measuring polarization, predicting diffusion thresholds, and selecting coordination actions without collapsing contradictions.

The organizing idea is that "value evidence" is treated as potentially inconsistent data rather than as a single real-valued utility, and that aggregation across value dimensions is performed in a way that makes both alignment and conflict measurable. The complex embedding below is a convenience: it packages two kinds of information (directional support and degree of determination) into a single signal so that geometric quantities (e.g., magnitude and cross-terms) can serve as proxies for coherence, tension, or cancellation. The social layer then treats communication as transmission of such evidence bundles through a coupling graph, so that standard coordination phenomena can be stated as properties of repeated evidence pooling under heterogeneous couplings.

57.1 Preliminaries: p-bits, resonance, and social coupling

57.1.1 p-bits and the complex embedding

Definition 510 (p-bit domain and join)**.** *Let* $V := [0,1]^2$*. Write* $v = (v^+, v^-) \in V$*. We use the componentwise (information-accumulating) partial order*

$$(v^+, v^-) \le (u^+, u^-) \iff v^+ \le u^+ \text{ and } v^- \le u^-.$$

Define join (evidence pooling)

$$v \oplus u := (\max(v^+, u^+), \max(v^-, u^-)).$$

Intuitively, a p-bit $v = (v^+, v^-)$ stores two independent pieces of evidence: support-for (v^+) and support-against (v^-) a proposition, action, or evaluative predicate. The partial order is "information-accumulating" in the sense that moving upward can only increase (never decrease) either kind of evidence; this makes $\oplus$ a natural pooling operator when evidence arrives from multiple sources and we wish to retain the strongest pro and strongest con signals simultaneously. Note that this join does not force normalization (so $v^+ + v^-$ may exceed 1), which is precisely what allows explicit representation of contradiction (v^+ and v^- both large) and ignorance (both small) without collapse to a single scalar.

A useful boundary intuition is: $(1, 0)$ corresponds to maximally supported with no counterevidence, $(0, 1)$ to maximally refuted, $(0, 0)$ to no evidence either way, and $(1, 1)$ to maximal conflict (strong evidence for and against at once). The operator $\oplus$ keeps these extremes stable under pooling: for instance $(1, 0) \oplus (0, 1) = (1, 1)$ records the emergence of explicit conflict rather than resolving it by averaging.

Definition 511 (logic-to-complex map)**.** *Define* $\sigma_C : V \to \mathbb{C}$ *by*

$$\sigma_C(v^+, v^-) \; := \; (v^+ - v^-) \; + \; i\big((v^+ + v^-) - 1\big).$$

Interpretation: $\mathrm{Re}(\sigma_C)$ *is net pro-vs-con bias;* $\mathrm{Im}(\sigma_C)$ *is over/under-determination (contradiction/ignorance axis).*

The map σ_C separates two conceptually distinct degrees of freedom. The real part $v^+ - v^-$ captures directional tilt (which side has more support), while the imaginary part $(v^+ + v^-) - 1$ captures how "determined" the proposition is relative to the reference level $v^+ + v^- = 1$. In particular, $\mathrm{Im}(\sigma_C) > 0$ indicates over-determination (simultaneous strong pro and con evidence, i.e., contradiction), whereas $\mathrm{Im}(\sigma_C) < 0$ indicates under-determination (low total evidence, i.e., ignorance or indifference). This choice centers the determination axis so that "balanced but fully determined" cases (e.g., $v^+ = v^- = 1/2$) map to the real line.

Geometrically, σ_C embeds the unit square into the complex plane as a diamond-shaped region: the corners map to $\sigma_C(1, 0) = 1 + 0i$, $\sigma_C(0, 1) = -1 + 0i$, $\sigma_C(0, 0) = 0 - i$, and $\sigma_C(1, 1) = 0 + i$. Thus, purely directional certainty lies on the real axis, while pure "status" about (over/under)-determination lies on the imaginary axis. This will let us interpret constructive vs. destructive interactions across multiple value dimensions as vector addition in $\mathbb{C}$.

57.1.2 Evaluative fields and resonance

Definition 512 (paraconsistent evaluative field)**.** *Fix a state space* S*, action set* $\mathcal{A}$*, and value-dimension set* D*. An (observer-relative) paraconsistent evaluative field is a map*

$$E : S \times \mathcal{A} \times D \to V, \quad E(s, a; d) = (E^+(s, a; d), E^-(s, a; d)).$$

One can read $E(s, a; d)$ as the evidence profile (pro/con) that an observer associates with taking action a in state s under value dimension d (e.g., fairness, harm, autonomy, loyalty). The "observer-relative" qualifier matters because different agents (or different models used by the same agent at different times) can encode different evidential bases for the same $(s, a; d)$. Importantly, paraconsistency is represented locally at the level of each dimension: a single d can carry both high E^+ and high E^-, enabling explicit modeling of internal value conflict that is not immediately resolved by choosing a single score.

Definition 513 (complex value signals, resonance magnitude, interference)**.** *Fix weights $w_d \geq 0$. For each (s, a) and $d \in D$, define*

$$z_d(s, a) := \sigma_C(E(s, a; d)) \in \mathbb{C}, \qquad Z(s, a) := \sum_{d \in D} w_d \, z_d(s, a).$$

Define the resonance magnitude $\kappa(s, a) := |Z(s, a)|$ and interference

$$I(s, a) \;:=\; |Z(s, a)|^2 \;-\; \sum_{d \in D} |w_d z_d(s, a)|^2 .$$

The complex signal $z_d(s, a)$ turns each value dimension into a 2D vector whose direction encodes whether the dimension is net approving or disapproving (real axis), and whether it is over- or under-determined (imaginary axis). The weighted sum $Z(s, a)$ then behaves like a resultant: if dimensions "point" in similar directions, they add constructively and $\kappa(s, a)$ becomes large; if they oppose, cancellation reduces $\kappa(s, a)$. In this sense, κ serves as a proxy for cross-dimensional coherence of the evaluation of (s, a), not merely the strength of any single dimension.

The interference term $I(s, a)$ isolates the cross-terms that appear when squaring a sum. Writing $Z = \sum_d \alpha_d$ with $\alpha_d := w_d z_d$, we have

$$|Z|^2 \;=\; \sum_d |\alpha_d|^2 \;+\; \sum_{d \neq d'} \mathrm{Re}\big(\alpha_d \, \overline{\alpha_{d'}}\big),$$

so $I(s, a)$ is exactly the sum of pairwise interactions $\sum_{d \neq d'} \mathrm{Re}(\alpha_d \overline{\alpha_{d'}})$. Positive interference indicates alignment (net constructive combination across dimensions), while negative interference indicates antagonism (net cancellation), which operationalizes "value conflict" at the aggregate level even when each dimension is itself internally paraconsistent. Because z_d includes the determination axis, two dimensions can also interfere through shared contradiction/ignorance structure, not only through pro/con direction.

A small sanity check: if D has a single dimension, then $I(s, a) = 0$ by construction; interference is purely relational across dimensions. Likewise, if all z_d are mutually orthogonal in the complex plane (in the sense that $\mathrm{Re}(z_d \overline{z_{d'}}) = 0$ after weighting), then $I(s, a) = 0$ and the magnitude squared is additive.

57.1.3 Social coupling and messages (minimal)

Definition 514 (interaction graph and couplings)**.** *A society is modeled (minimally) by a directed graph $G = (A, E)$ of agents and couplings $K : E \to [0, 1]$ (scalar case) or $K : E \to V$ (ambivalent case).*

The edge set E represents who influences whom; direction matters because attention, trust, authority, or exposure can be asymmetric. A scalar coupling $K(i \to j) = k$ can be read as an overall assimilation rate or channel strength from agent i to agent j. The ambivalent case $K : E \to V$ is included to allow couplings that themselves carry pro/con structure (e.g., simultaneous attraction and distrust), although the concrete update rule below specializes to the scalar case for simplicity.

Definition 515 (messages as paraconsistent evidence bundles and assimilation (scalar coupling))**.** *Fix a claim language L. A message is a finitely supported $m : L \to V$. Given scalar coupling $k \in [0,1]$, define scaled message $(k \odot m)(\varphi) := (k,k) \otimes m(\varphi)$, where (for concreteness) we take $\otimes$ to be coordinatewise multiplication: $(x^+, x^-) \otimes (y^+, y^-) = (x^+y^+, x^-y^-)$. Belief update is*

$$\beta \leftarrow \beta \oplus (k \odot m),$$

pointwise on L.

Finite support means that each message asserts only finitely many claims in L, which is convenient for algorithmic updates and matches the idea that communication episodes are sparse relative to the full space of possible propositions. The scaling rule $(k,k)\otimes m(\varphi)$ implements a simple attenuation model: lower coupling uniformly dampens both supportive and opposing evidence transmitted by the message, while $k = 1$ passes the evidence through unchanged. Because scaling is applied before the join, strong couplings can quickly propagate high evidence (either pro or con), whereas weak couplings slow diffusion.

The update $\beta \leftarrow \beta \oplus (k \odot m)$ is monotone in the information order: neither E^+ nor E^- for any claim ever decreases under repeated pooling. This captures an "accumulation" regime appropriate for settings where agents store received evidence rather than averaging it away. In later results, this monotonicity will allow diffusion and stabilization statements to be phrased as reachability and fixed-point properties on V^L under iterated message passing, while paraconsistency ensures that contradictory streams can coexist as explicit structure rather than forcing immediate resolution.

57.2 Value-conflict geometry: interference, contradiction growth, and decision diagnostics

57.2.1 Conflict accumulation under social evidence pooling

Definition 516 (two simple contradiction/conflict readouts)**.** *For $v = (v^+, v^-) \in V$, define*

$$\mathrm{contr}(v) := (v^+ + v^-) - 1 = \mathrm{Im}(\sigma_C(v)), \qquad \mathrm{conf}(v) := \min(v^+, v^-).$$

Theorem 123 (Pooling never reduces contradiction or conflict)**.** *For all $u, v \in V$,*

$$\mathrm{contr}(u \oplus v) \;\geq\; \max(\mathrm{contr}(u), \mathrm{contr}(v)), \qquad \mathrm{conf}(u \oplus v) \;\geq\; \max(\mathrm{conf}(u), \mathrm{conf}(v)).$$

Proof. Write $u = (a,b)$, $v = (c,d)$ with $a,b,c,d \in [0,1]$. Then $u \oplus v = (a \vee c, b \vee d)$ where $\vee = \max$. Since $a \vee c \geq a$ and $b \vee d \geq b$, we have $(a \vee c) + (b \vee d) - 1 \geq a + b - 1$, and similarly $\geq c + d - 1$, proving the first inequality.

For conf, note

$$\mathrm{conf}(u \oplus v) = (a \vee c) \wedge (b \vee d)$$

with $\wedge = \min$. In the distributive lattice $([0,1], \vee, \wedge)$,

$$(a \vee c) \wedge (b \vee d) \;\geq\; (a \wedge b) \vee (c \wedge d),$$

hence $\mathrm{conf}(u \oplus v) \geq \max(\mathrm{conf}(u), \mathrm{conf}(v))$. ∎

Remark 3165 (Reasoning use)**.** *In a join-based social epistemic/evaluative layer, contradictions naturally* accumulate *when aggregating many sources. Thus "resolve by pooling more" is structurally incapable of reducing contradiction; one needs explicit revision/forgetting/discounting operators to do that.*

57.2.2 Interference decompositions that explain value conflict

Definition 517 (pairwise phase-alignment)**.** *For nonzero $x, y \in \mathbb{C}$, define* $\operatorname{align}(x,y) := \operatorname{Re}(x\overline{y})/(|x|\,|y|) \in [-1,1]$*. If $x=0$ or $y=0$, set* $\operatorname{align}(x,y)=0$*.*

Theorem 124 (Interference is a weighted sum of pairwise alignments)**.** *Let $(z_d)_{d\in D} \subset \mathbb{C}$ and weights $w_d \ge 0$. Set $Z = \sum_d w_d z_d$ and $r_d := |w_d z_d|$. Then*

$$|Z|^2 = \sum_{d\in D} r_d^2 \; + \sum_{\substack{d,e\in D\\ d\neq e}} w_d w_e \operatorname{Re}\bigl(z_d\overline{z_e}\bigr),$$

and equivalently

$$I = \sum_{d<e} 2\, r_d r_e \operatorname{align}(z_d, z_e).$$

Proof. Expand:

$$|Z|^2 = Z\overline{Z} = \left(\sum_d w_d z_d\right)\left(\sum_e w_e \overline{z_e}\right) = \sum_{d,e} w_d w_e z_d \overline{z_e}.$$

Split $d=e$ from $d\neq e$: $\sum_d w_d^2 |z_d|^2 = \sum_d |w_d z_d|^2 = \sum_d r_d^2$, and for $d \neq e$ take real parts since $|Z|^2 \in \mathrm{R}$ and cross terms pair up: $z_d\overline{z_e}$ and $z_e\overline{z_d}$ have the same real part. Thus

$$|Z|^2 = \sum_d r_d^2 + \sum_{d\neq e} w_d w_e \operatorname{Re}(z_d\overline{z_e}).$$

Subtracting $\sum_d r_d^2$ yields the first form for I; dividing each term by $r_d r_e$ (where nonzero) yields the alignment form. $\square$

Remark 3166 (Reasoning use)**.** *This gives an "explanation object" for value conflict: negative interference $I<0$ is literally net negative pairwise alignment among value-dimension complex signals, i.e. cancellation in the complex embedding.*

Theorem 125 (Resonance gap quantifies phase dispersion)**.** *Let $Z = \sum_d w_d z_d$ and $r_d = |w_d z_d|$. Define $S := \sum_d r_d$. Then*

$$0 \le S^2 - |Z|^2 = \sum_{d<e} 2\, r_d r_e \bigl(1-\cos(\theta_d-\theta_e)\bigr) = \sum_{d<e} 4\, r_d r_e \sin^2\!\left(\frac{\theta_d-\theta_e}{2}\right),$$

where θ_d is any argument of $w_d z_d$ (when $r_d>0$). Moreover, $S=|Z|$ iff all nonzero $w_d z_d$ share the same phase.

Proof. Write $w_d z_d = r_d e^{i\theta_d}$ with $r_d \ge 0$. Then

$$|Z|^2 = \left|\sum_d r_d e^{i\theta_d}\right|^2 = \sum_d r_d^2 + \sum_{d<e} 2 r_d r_e \cos(\theta_d-\theta_e).$$

Also $S^2 = (\sum_d r_d)^2 = \sum_d r_d^2 + \sum_{d<e} 2 r_d r_e$. Subtract to get

$$S^2 - |Z|^2 = \sum_{d<e} 2 r_d r_e \bigl(1-\cos(\theta_d-\theta_e)\bigr) = \sum_{d<e} 4 r_d r_e \sin^2\!\left(\frac{\theta_d-\theta_e}{2}\right) \ge 0.$$

Equality $S^2 = |Z|^2$ holds iff every $\sin^2((\theta_d-\theta_e)/2) = 0$ for pairs with $r_d r_e > 0$, i.e. all relevant phases coincide. Finally $S = |Z|$ follows since both are nonnegative. $\square$

Remark 3167 (Decision tool)**.** *A reasoning system can treat* $S^2 - |Z|^2$ *as a* quantitative *dissonance measure: it decomposes into pairwise phase-dispersion penalties weighted by salience magnitudes* $r_d r_e$*.*

57.3 Social coordination: group resonance, polarization identities, and decompositions

57.3.1 Agents as complex value-signal generators

Definition 518 (agent and group value signals)**.** *Fix an option* (s, a) *and let each agent* $i \in A$ *have complex value signal*

$$Z_i := \sum_{d \in D} w_{i,d}\, \sigma_C(E_i(s, a; d)) \in \mathbb{C}.$$

Let $(\alpha_i)_{i \in A}$ *be nonnegative weights with* $\sum_i \alpha_i = 1$*. Define group-mean signal*

$$\overline{Z} := \sum_{i \in A} \alpha_i Z_i, \quad \textit{and group resonance} \quad \kappa_G := \left|\overline{Z}\right|.$$

The object $Z_i \in \mathbb{C}$ can be read geometrically as a point (or vector) in a two-dimensional value-signal plane, where both *direction* (phase) and *strength* (magnitude) matter for coordination. The map $\sigma_C(\cdot)$ is left abstract here, but its role is to turn each domain-specific evaluation $E_i(s, a; d)$ into a bounded complex contribution that can represent, for example, (i) the sign and intensity of valence, (ii) a tradeoff between two partially incommensurable desiderata via the real and imaginary axes, or (iii) a circular/periodic attitude (phase) together with confidence (magnitude). The weights $w_{i,d}$ encode the agents internal salience over domains, while the social weights α_i encode the aggregation rule (e.g., equal agents, population shares, institutional voting weights, or attention weights). Under this reading, $\overline{Z}$ is a weighted centroid of signals, and $\kappa_G = |\overline{Z}|$ measures how far that centroid lies from the origin: high resonance means the groups signals align sufficiently to produce a strong resultant, while low resonance can arise either from weak individual signals or from strong but mutually canceling signals.

Theorem 126 (Polarization identity: resonance vs disagreement variance)**.** *Define polarization (complex variance)*

$$\mathrm{Pol} := \sum_{i \in A} \alpha_i \left|Z_i - \overline{Z}\right|^2.$$

Then

$$\mathrm{Pol} = \sum_{i \in A} \alpha_i |Z_i|^2 - \left|\overline{Z}\right|^2.$$

Proof. Expand $\left|Z_i - \overline{Z}\right|^2 = |Z_i|^2 - 2\,\mathrm{Re}(Z_i\overline{\overline{Z}}) + \left|\overline{Z}\right|^2$. Multiply by α_i and sum:

$$\mathrm{Pol} = \sum_i \alpha_i |Z_i|^2 - 2\,\mathrm{Re}\left(\sum_i \alpha_i Z_i \overline{\overline{Z}}\right) + \left(\sum_i \alpha_i\right) \left|\overline{Z}\right|^2.$$

But $\sum_i \alpha_i Z_i = \overline{Z}$ and $\sum_i \alpha_i = 1$, so

$$\mathrm{Pol} = \sum_i \alpha_i |Z_i|^2 - 2\,\mathrm{Re}(\overline{Z}\overline{\overline{Z}}) + \left|\overline{Z}\right|^2 = \sum_i \alpha_i |Z_i|^2 - \left|\overline{Z}\right|^2.$$

$\square$

This identity is exactly the familiar variance decomposition $\mathrm{Var}(Z) = \mathbb{E}|Z|^2 - |\mathbb{E}Z|^2$, with $\mathbb{E}$ realized by the weighted average $\sum_i \alpha_i(\cdot)$ and with $\mathbb{C}$ viewed as R^2. In particular, $\mathrm{Pol} \geq 0$ automatically, and $\mathrm{Pol} = 0$ holds if and only if all agents have the same signal $Z_i = \overline{Z}$ for all i with $\alpha_i > 0$ (perfect alignment). The term $\sum_i \alpha_i |Z_i|^2$ can be interpreted as the groups total "signal energy" (a second moment), while $|\overline{Z}|^2$ is the squared magnitude of the coherent component. Thus the theorem formalizes a basic coordination intuition: holding individual signal energy fixed, any increase in coherent alignment (resonance) must come from a decrease in incoherent dispersion (polarization).

Corollary 49 (Resonance-maximizing is polarization-minimizing under fixed energy)**.** *If $\sum_i \alpha_i |Z_i|^2$ is the same constant across a candidate set of actions, then maximizing group resonance $\left|\overline{Z}\right|$ is equivalent to minimizing* Pol*.*

Proof. Immediate from Theorem 126, since $\mathrm{Pol} = \mathrm{const} - \left|\overline{Z}\right|^2$. □

The "fixed energy" condition is a useful modeling idealization: it holds, for instance, when σ_C normalizes contributions to have fixed magnitude (so only phases/directions change across actions), or when actions are compared after rescaling to equalize overall intensity so that only alignment structure differs. When energy is not fixed, resonance and polarization become partially decoupled: one action can raise $|\overline{Z}|$ simply by increasing many $|Z_i|$ (stronger opinions) even if disagreement also grows. The corollary isolates the clean case in which resonance is purely an alignment objective rather than an intensity objective.

Theorem 127 (Pairwise-distance form of polarization)**.** *With $\sum_i \alpha_i = 1$,*

$$\mathrm{Pol} = \frac{1}{2} \sum_{i,j \in A} \alpha_i \alpha_j \left|Z_i - Z_j\right|^2.$$

Proof. Expand $|Z_i - Z_j|^2 = |Z_i|^2 + |Z_j|^2 - 2\,\mathrm{Re}(Z_i \overline{Z_j})$. Then

$$\frac{1}{2} \sum_{i,j} \alpha_i \alpha_j \left|Z_i - Z_j\right|^2 = \sum_i \alpha_i \left|Z_i\right|^2 - \mathrm{Re}\left(\sum_{i,j} \alpha_i \alpha_j Z_i \overline{Z_j} \right).$$

But $\sum_{i,j} \alpha_i \alpha_j Z_i \overline{Z_j} = (\sum_i \alpha_i Z_i) \overline{\left(\sum_j \alpha_j Z_j\right)} = \overline{Z}\,\overline{\overline{Z}} = \left|\overline{Z}\right|^2$ (real). So the expression equals $\sum_i \alpha_i \left|Z_i\right|^2 - \left|\overline{Z}\right|^2 = \mathrm{Pol}$ by Theorem 126. □

Remark 3168 (Reasoning use)**.** *Theorem 127 makes polarization an explicit "explanation object": it is exactly the mean pairwise disagreement (squared distance) in the complex value-signal plane.*

The pairwise form emphasizes that polarization is not merely deviation from a central tendency, but an aggregate of all bilateral frictions. This makes it naturally compatible with network and bargaining interpretations: if agents interact pairwise with "cost" proportional to $|Z_i - Z_j|^2$, then Pol is (up to the $\frac{1}{2}$ convention) the expected cost under independently sampling two agents according to (α_i). It also clarifies how a small minority with small total weight can have limited contribution to Pol even if its signal is extreme, while two large blocs with opposed signals can dominate Pol through many cross-bloc pairs.

Theorem 128 (Two-bloc decomposition: within vs between polarization)**.** *Partition agents into two blocs A_1, A_2 with total weights $a := \sum_{i\in A_1} \alpha_i$ and $b := \sum_{j\in A_2} \alpha_j$ ($a + b = 1$). Define bloc means $Z_{A_1} := \frac{1}{a}\sum_{i\in A_1} \alpha_i Z_i$ (if $a > 0$) and similarly Z_{A_2}. Define within-bloc polarizations*

$$\mathrm{Pol}_{A_1} := \sum_{i\in A_1} \frac{\alpha_i}{a} |Z_i - Z_{A_1}|^2, \qquad \mathrm{Pol}_{A_2} := \sum_{j\in A_2} \frac{\alpha_j}{b} |Z_j - Z_{A_2}|^2.$$

Then the global polarization decomposes as

$$\mathrm{Pol} = a\,\mathrm{Pol}_{A_1} + b\,\mathrm{Pol}_{A_2} + ab\,|Z_{A_1} - Z_{A_2}|^2.$$

Proof. This is the law of total variance in $\mathbb{C} \cong \mathrm{R}^2$. Write $\overline{Z} = aZ_{A_1} + bZ_{A_2}$. For $i \in A_1$,

$$Z_i - \overline{Z} = (Z_i - Z_{A_1}) + (Z_{A_1} - \overline{Z}),$$

and summing $\alpha_i(Z_i - Z_{A_1})$ over A_1 gives 0, so cross terms vanish:

$$\sum_{i\in A_1} \alpha_i \left|Z_i - \overline{Z}\right|^2 = \sum_{i\in A_1} \alpha_i |Z_i - Z_{A_1}|^2 + a\left|Z_{A_1} - \overline{Z}\right|^2.$$

Similarly for A_2. Add the two equalities and note $a\left|Z_{A_1} - \overline{Z}\right|^2 + b\left|Z_{A_2} - \overline{Z}\right|^2 = ab\,|Z_{A_1} - Z_{A_2}|^2$. Finally rewrite $\sum_{i\in A_1} \alpha_i |Z_i - Z_{A_1}|^2 = a\,\mathrm{Pol}_{A_1}$ and similarly for A_2. □

The decomposition separates two qualitatively different sources of disagreement. The terms $a\,\mathrm{Pol}_{A_1}$ and $b\,\mathrm{Pol}_{A_2}$ measure dispersion *inside* each bloc after reweighting to a within-bloc probability distribution (so Pol_{A_k} is a variance relative to the bloc mean). The term $ab\,|Z_{A_1} - Z_{A_2}|^2$ measures *between*-bloc separation: it scales with both the distance between bloc centroids and with the product ab, meaning it is largest when both blocs are large and sharply separated. Edge cases behave as expected: if $a = 0$ or $b = 0$ (one bloc empty), the between term vanishes and Pol reduces to the within term of the nonempty bloc; if each bloc is internally coherent (near-zero $\mathrm{Pol}_{A_1}, \mathrm{Pol}_{A_2}$), then global polarization is essentially the squared distance between two representative signals times ab. This is the complex-plane analogue of a two-group ANOVA identity, and it can be iterated (or generalized) to multi-bloc partitions when one wants to attribute polarization to nested levels of social structure.

Remark 3169 (Reasoning use)**.** *This theorem supports causal explanation of polarization: "is disagreement mostly within-group noise, or primarily between two coherent camps?"*

57.4 Communication and diffusion: from couplings to reachability of value evidence

The goal of this subsection is to make explicit how local pairwise couplings $K(u, v)$ induce global, multi-hop reachability of value-relevant evidence. In particular, the following statements isolate a *path-closure* perspective: forwarding along edges generates contributions indexed by directed paths, and the recipient's state is bounded below by joining all such path contributions (up to the number of rounds elapsed). This is useful when couplings are heterogeneous and when one wishes to reason about attenuation as a function of distance, bottlenecks, and alternative routes.

57.4.1 Path-closure form of forwarded evidence

Definition 519 (path attenuation)**.** *Let $G = (A, E)$ be a directed graph with scalar couplings $K : E \to [0, 1]$. For a directed path $p : i_0 \to i_1 \to \cdots \to i_\ell$, define its attenuation*

$$\mathrm{att}(p) := \prod_{t=0}^{\ell-1} K(i_t, i_{t+1}) \in [0, 1].$$

The quantity $\mathrm{att}(p)$ can be read as the multiplicative survival or transmission factor of a signal traversing the particular route p. The choice of product corresponds to assuming independent per-hop attenuation and is compatible with the intended interpretation of each $K(u, v) \in [0, 1]$ as a (possibly asymmetric) strength of influence or fidelity of transmission. Note that the definition applies to any finite directed path; in particular, if one wishes to include the trivial path of length 0 (from a node to itself), then the empty product convention yields $\mathrm{att}(p) = 1$, which matches the idea of no attenuation when no forwarding occurs.

Theorem 129 (Forwarding + assimilation yields join over path contributions)**.** *Fix a message $m : L \to V$ sent by a source $s \in A$ and suppose it is forwarded along directed edges, with assimilation at each hop: at each hop $(u \to v)$ the forwarded bundle is scaled by $K(u, v)$ and joined into the recipient belief. Let $\beta^{(0)}$ be the initial belief states and $\beta^{(t)}$ the states after t synchronous forwarding rounds. Then for each agent j and proposition $\varphi \in L$,*

$$\beta_j^{(t)}(\varphi) \;\geq\; \beta_j^{(0)}(\varphi) \;\oplus\; \bigoplus_{\substack{p:s\to j \\ \mathrm{len}(p)\leq t}} \left(\mathrm{att}(p) \odot m\right)(\varphi),$$

where $\odot$ is scalar-to-V scaling and the join is taken in V (pointwise on φ).

The inequality form emphasizes that $\beta^{(t)}$ may contain additional information beyond forwarded m (e.g. prior evidence, other exogenous messages, or internal inference/closure). The statement is therefore a robust lower bound: it isolates what must be present purely due to forwarding and assimilation, independent of other update mechanisms. The join $\oplus$ and big-join $\bigoplus$ should be read as the aggregator for evidential bundles in V; in many instantiations, $\oplus$ is the coordinatewise supremum or an idempotent/commutative merge, so that receiving the same contribution via multiple redundant paths does not artificially inflate evidence beyond what the merge operation permits. When $\oplus$ is idempotent, repeated reception of identical (or dominated) contributions has no further effect, which is a natural way to represent saturation or non-additive assimilation.

The restriction to paths of length at most t corresponds to the synchronous-rounds assumption: in each round, an agent forwards what it currently has (or the designated forwarded bundle), and thus information can traverse at most one edge per round. In asynchronous or continuous-time variants, the same path decomposition typically reappears, but length is replaced by a time budget and edge traversal delays; the essential combinatorics of accumulating over directed routes remains the same.

Proof. We argue by induction on t. For $t = 0$ there are no nontrivial paths, so the statement reduces to $\beta_j^{(0)} \geq \beta_j^{(0)}$.

Assume true for t. Consider $t + 1$. In one more round, any path $p : s \to j$ of length $\leq t + 1$ is either: (i) length $\leq t$ already covered by the inductive hypothesis, or (ii) of the form $p = p' \cdot (u \to j)$ where $p' : s \to u$ has length $\leq t$ and $(u \to j) \in E$. By the forwarding rule, the contribution along p is

$$\mathrm{att}(p) \odot m = \left(\mathrm{att}(p')K(u, j)\right) \odot m = K(u, j) \odot \left(\mathrm{att}(p') \odot m\right),$$

and it is joined into $\beta_j^{(t+1)}$. Since join is monotone and associative/commutative, joining all such new contributions yields the displayed lower bound for $t + 1$. $\square$

The inductive step implicitly uses two structural properties that are typically assumed in evidential algebras used for such diffusion models: (a) scalar scaling $\odot$ is monotone in the scalar (so larger couplings do not decrease the scaled message), and (b) join $\oplus$ is monotone in each argument (so adding more incoming contributions cannot reduce belief). Together these ensure that the enumerate all paths and join their attenuated messages construction behaves as a genuine lower envelope of what the dynamics can accumulate. Note also that cycles in G do not cause a problem at finite t: only finitely many paths have length $\leq t$, so the big-join is over a finite set; moreover, attenuation products along longer cyclic paths tend to shrink when $K < 1$ on at least one edge in the cycle, making explicit the intuition that repeated forwarding through imperfect channels does not create unbounded amplification.

Corollary 50 (Strong-tie diffusion at threshold)**.** *Fix a threshold $\tau \in (0, 1]$ and suppose the τ-strong-tie graph $G_\tau = (A, E_\tau)$ with $E_\tau = \{(u, v) \in E : K(u, v) \geq \tau\}$ has a directed path from s to j. If a message m has coordinatewise evidence at least θ on some claim φ, i.e. $m(\varphi) \geq (\theta, \theta)$, then after ℓ rounds (where ℓ is the path length), agent j has at least $(\tau^\ell\theta, \tau^\ell\theta)$ additional evidence on φ (before any extra closure).*

This corollary packages the path-based statement into an easily checkable condition: connectivity in the thresholded graph G_τ guarantees a minimum-strength route, and the minimum coupling τ along that route yields a clean exponential lower bound τ^ℓ. The coordinatewise expression (θ, θ) is intended to match the common case where V is a product order (e.g. a two-sided evidence representation, or a pair of lower/upper supports), and where scaling by a scalar acts componentwise. In such settings, the inequality $m(\varphi) \geq (\theta, \theta)$ is simply a concise way of saying that the message provides at least θ units of evidence in each relevant coordinate, and attenuation preserves this ordering by multiplying both coordinates by the same factor.

Proof. Take the path p of length ℓ with all edges $\geq \tau$. Then $\mathrm{att}(p) \geq \tau^\ell$ and scaling is coordinatewise multiplication, so $(\mathrm{att}(p) \odot m)(\varphi) \geq (\tau^\ell\theta, \tau^\ell\theta)$. Now apply Theorem 129. $\square$

The phrase before any extra closure is included to separate two effects: (i) the guaranteed imported evidence due to forwarding/assimilation, and (ii) any additional strengthening that might occur because the recipient applies local inference rules, consistency closure, aggregation with other messages, or value-laden interpretive steps after the round. In other words, the bound refers to the direct contribution attributable to the communication channel itself, without assuming anything about the agents subsequent reasoning pipeline.

Remark 3170 (Reasoning use)**.** *These results let a reasoning system answer: "who can influence whom, at what minimum strength, given couplings?" and "how long until a value signal reaches a target subgroup?"*

More concretely, one can treat Theorem 129 as a basis for *reachability queries* that are sensitive not only to graph distance but also to coupling geometry: two agents can be equally many hops away from s yet differ dramatically in guaranteed received evidence due to bottleneck edges (small K) or, conversely, due to the availability of multiple medium-strength routes whose joined contributions exceed what any single path would provide. Similarly, Corollary 50 provides a conservative planning heuristic: choosing τ selects a trusted backbone of communication, and the resulting ℓ-step bound quantifies how quickly an initially strong value signal may decay as it propagates, which is central when assessing whether coordination requires short pathways, high-trust intermediaries, or repeated re-injection of evidence from the source.

57.5 Norm stabilization: explicit fixed points and contested culture propagation

We now connect value conflict to stabilized social patterns (norms/rituals/institutions) via max/min reinforcement (a toy but structurally revealing model). In words, we treat the intensity of a single social pattern P as a *graded* state at each agent, and we model reinforcement as a one-step update that (i) preserves what the agent already has and (ii) admits influence from in-neighbors, but only to the extent permitted by both the neighbor's current intensity and the coupling strength on the edge. This yields a convenient "fuzzy reachability" semantics: the pattern can travel along directed paths, yet along each path it is limited by the weakest link (a bottleneck) and by the initial seed intensity at the source.

Definition 520 (scalar social reinforcement operator for a single pattern)**.** *Fix a directed graph $G = (A, E)$, couplings $K : E \to [0, 1]$, and a single pattern P. Let $x \in [0, 1]^A$ be intensities x_i of pattern P at each agent. Define $F : [0, 1]^A \to [0, 1]^A$ by*

$$(F(x))_i := x_i \;\vee \bigvee_{(j,i)\in E} \big(K(j, i) \wedge x_j\big).$$

The lattice operations $\vee$ and $\wedge$ should be read as max and min (respectively), so that each update is "conservative upward": intensities do not decrease. The term $K(j, i) \wedge x_j$ is the amount of P that can be transmitted from j to i in one step, limited simultaneously by the sender's current level x_j and by the edge's coupling $K(j, i)$. The outer $\vee$ aggregates multiple possible influences (multiple in-neighbors) by taking the strongest available reinforcement. Thus F can be interpreted as a one-step closure operator for a weighted directed graph, akin to a max–min (a.k.a. bottleneck) composition rule familiar from fuzzy relations.

Theorem 130 (Closed form for the least stabilized intensity (max-min path formula))**.** *Let $x^{(0)} \in [0, 1]^A$ and define $x^{(t+1)} := F(x^{(t)})$. For each agent i define*

$$x_i^{(\infty)} := \sup_{t\geq 0} x_i^{(t)}.$$

Then $x^{(\infty)}$ is the least fixed point of F above $x^{(0)}$, and moreover

$$x_i^{(\infty)} = \sup_{p:s\to i} \min\Big(x_s^{(0)},\ \min_{(u\to v)\in p} K(u, v)\Big),$$

where the supremum ranges over all directed paths p ending at i (including length 0 paths).

Proof. Monotonicity of F implies the Kleene chain $x^{(0)} \leq x^{(1)} \leq \cdots$ is ascending, hence $x^{(\infty)} = \sup_t x^{(t)}$ exists coordinatewise and is a post-fixed point; standard complete-lattice arguments give it is the least fixed point above $x^{(0)}$.

For the explicit formula, prove by induction that $x_i^{(t)}$ equals the supremum over all paths of length $\leq t$ of the stated bottleneck value. For $t = 0$ only length-0 paths contribute, giving $x_i^{(0)}$. Assume true for t. Then $x_i^{(t+1)}$ takes the max of (i) the previous value (paths of length $\leq t$) and (ii) terms $K(j, i) \wedge x_j^{(t)}$, which correspond exactly to extending any path ending at j by one edge into i, producing paths of length $\leq t+1$ and updating the bottleneck by an extra min with $K(j, i)$. Taking $\sup_t$ yields the all-path supremum. $\square$

The closed form makes clear that $x_i^{(\infty)}$ is a *widest-path* value (maximizing the minimal edge weight along the route), except that the source node contributes an additional cap via $x_s^{(0)}$. Equivalently, each source s offers a candidate influence level to i equal to the best bottleneck coupling from s to i, then clipped by the seed intensity at s, and finally all sources compete via a supremum. This is precisely the sense in which the model isolates a structural mechanism of norm stabilization: stable intensities are determined by weighted reachability and bottlenecks, not by additive accumulation.

Remark 3171 (Finite-time stabilization on finite graphs)**.** *If A is finite, then the path-based supremum in Theorem 130 may be taken over simple paths (any cycle can only weakly decrease the bottleneck via an additional* min*), so the relevant path lengths are bounded by $|A|-1$. Consequently, for finite A the ascending chain $(x^{(t)})_{t\geq 0}$ stabilizes after finitely many steps (at most $|A|-1$ iterations suffice to realize all simple-path contributions), and $x^{(\infty)} = x^{(T)}$ for some finite T. This observation connects the abstract least-fixed-point statement to an operational viewpoint: repeated local reinforcement computes a global closure in bounded time on finite networks.*

Corollary 51 (Global spread criterion at threshold θ)**.** *Fix $\theta \in (0,1]$. Let $S_\theta := \{s : x_s^{(0)} \geq \theta\}$. Then an agent i satisfies $x_i^{(\infty)} \geq \theta$ iff there exists a path from some $s \in S_\theta$ to i such that every edge on the path has coupling at least θ.*

Proof. By Theorem 130, $x_i^{(\infty)} \geq \theta$ iff there exists a path $p : s \to i$ with $\min(x_s^{(0)}, \min_{e\in p} K(e)) \geq \theta$, i.e. $x_s^{(0)} \geq \theta$ and $K(e) \geq \theta$ for all $e \in p$. □

This threshold view can be read as a crisp percolation statement on a θ-filtered subgraph: delete all nodes with sub-threshold initial intensity (i.e. restrict to seeds in S_θ) and delete all edges with coupling $< \theta$; then $x_i^{(\infty)} \geq \theta$ exactly when i is reachable from the surviving seeds. Thus the graded dynamics reduce, at any fixed θ, to reachability in a deterministic graph, which is often the right lens for discussing "whether the norm takes hold" at a socially meaningful strength level.

57.5.1 Contested norms (paraconsistent cultural states)

Definition 521 (p-bit norm intensities and coordinatewise reinforcement)**.** *Let each agent have p-bit intensity $X_i = (X_i^+, X_i^-) \in V$ for a pattern P (support/opposition). Define reinforcement coordinatewise:*

$$X^{(t+1),+} := F(X^{(t),+}), \qquad X^{(t+1),-} := F(X^{(t),-}),$$

with F as in the scalar case.

The intended semantics is that X_i^+ and X_i^- are not constrained to sum to 1 or to be complementary: an agent can simultaneously exhibit strong pro- and strong anti- orientations toward the same pattern P. This "two-channel" representation is a minimal paraconsistent encoding of value conflict: it allows contradiction to be a *state* rather than an error, and it permits social reinforcement to act on each pole without forcing premature resolution. Coordinatewise reinforcement further isolates a structural claim: even if individuals do not reconcile support and opposition internally, each pole can still propagate through the network by the same bottleneck mechanism as in the scalar case.

Theorem 131 (Contestation percolation criterion)**.** *Fix thresholds $\theta_+, \theta_- \in (0,1]$. Assume there exist seeds s_+, s_- with $X_{s_+}^{(0),+} \geq \theta_+$ and $X_{s_-}^{(0),-} \geq \theta_-$. If for every agent i there is a path from s_+*

to i whose edges all have coupling at least θ_+, and also a path from s_- to i whose edges all have coupling at least θ_-, then in the stabilized state:

$$X_i^{(\infty)} \geq (\theta_+, \theta_-) \quad \textit{for all } i.$$

In particular, the pattern becomes society-wide contested *(strong support and strong opposition everywhere).*

Proof. Apply Corollary 51 to the $+$ channel with threshold θ_+ to get $X_i^{(\infty),+} \geq \theta_+$ for all i. Apply it to the $-$ channel with threshold θ_- to get $X_i^{(\infty),-} \geq \theta_-$ for all i. Combine coordinates. □

The hypothesis allows $\theta_+ \neq \theta_-$, so the two channels may have different "propagation demands": for example, support might require high-coupling ties (a high θ_+) while opposition spreads through weaker ties (a lower θ_-), or vice versa. The conclusion shows that if both channels have sufficiently robust reachability at their own thresholds, then contradiction is not localized but becomes an invariant feature of the stabilized culture. Notably, nothing in the argument requires the pro- and anti- seeds to be the same individual, nor does it require the paths to coincide; contestation can emerge from distinct subpopulations whose influence simultaneously reaches everyone.

Remark 3172 (Reasoning use)**.** *This theorem makes "how contradictions become cultural" fully explicit: it is a reachability condition in two channels with possibly different thresholds.*

Remark 3173 (Interpretive consequence)**.** *Because each coordinate is a least fixed point above its respective initialization, the stabilized contested state is in this sense* minimal*: it is the weakest society-wide configuration that is still closed under reinforcement given the initial pro/anti seeds and couplings. So, when the criterion holds, contestation is not an artifact of assuming maximal polarization; it is an inevitable closure outcome of the network's two-threshold connectivity structure.*

57.6 Non-explosive social choice: existence and a polarization-aware resonance rule

57.6.1 Pareto safety and existence (finite action sets)

Definition 522 (p-bit preference order and Pareto order)**.** *On V define $v \preceq_{\mathrm{pref}} u$ iff $v^+ \leq u^+$ and $v^- \geq u^-$ ("more pro and less con"). For value-vectors $(E(s,a;d))_{d\in D}$ define Pareto dominance coordinatewise: $a \preceq_{\mathrm{Pareto}} a'$ iff $E(s,a;d) \preceq_{\mathrm{pref}} E(s,a';d)$ for all $d \in D$.*

The order $\preceq_{\mathrm{pref}}$ is the natural product order on the "pro" coordinate together with the reverse order on the "con" coordinate: moving upward in $\preceq_{\mathrm{pref}}$ means weakly increasing the pro component while weakly decreasing the con component. In particular, $v \preceq_{\mathrm{pref}} u$ allows equality in either coordinate, so it represents a *weak* improvement (not necessarily strict), and it treats the pro and con channels as simultaneously relevant rather than collapsing them into a single scalar. The induced $\preceq_{\mathrm{Pareto}}$ relation then asserts that an action a' is socially at least as good as a when it is weakly better for *every* dimension $d \in D$ under this two-channel comparison.

Theorem 132 (Non-explosion: Pareto-undominated actions exist in finite sets)**.** *If the action set $\mathcal{A}$ is finite, then the set of Pareto-undominated actions (with respect to $\preceq_{\mathrm{Pareto}}$) is nonempty.*

Proof. $\preceq_{\mathrm{Pareto}}$ is a partial order on the finite set $\mathcal{A}$. Every finite partially ordered set has at least one maximal element (take any element and iteratively move to a strictly larger one until termination). Any maximal element is undominated. □

It is useful to emphasize the content of "undominated" in this setting: an action is Pareto-undominated when there is no alternative action that is (weakly) more pro and (weakly) less con in *every* relevant dimension. Thus the theorem rules out an "explosion" in which the requirement of Pareto safety would empty the feasible set; finiteness of $\mathcal{A}$ suffices to guarantee at least one maximal (hence undominated) element even when many actions are incomparable. Note also that maximal elements need not be unique: the set of Pareto-undominated actions can contain multiple actions corresponding to distinct trade patterns across $d \in D$.

Corollary 52 (Resonant feasible choice exists (finite $\mathcal{A}$)). *Let $\kappa(s,a)$ be the resonance magnitude and $R(s,a) \geq 0$ any resistance cost. If $\mathcal{A}$ is finite, then the rule "choose any Pareto-undominated maximizer of $\kappa(s,a) - \beta R(s,a)$" yields a nonempty choice set.*

Proof. By Theorem 132, the Pareto-undominated set is nonempty and finite. A real-valued function on a finite nonempty set attains a maximum. □

Here the Pareto filter enforces a minimal safety constraint (no avoidable coordinatewise harm), while the objective $\kappa(s,a) - \beta R(s,a)$ provides a secondary ranking among those safe actions. The parameter $\beta \geq 0$ controls how strongly the selector accounts for resistance or implementation cost: when $\beta = 0$ the rule reduces to choosing a Pareto-undominated maximizer of resonance magnitude alone, while larger β shifts weight toward feasibility and away from raw resonance. Because the maximization is performed *after* restricting to $\mathcal{A}_{\text{Pareto}}$, the existence conclusion is purely combinatorial: it does not rely on continuity, convexity, or any cardinal comparability across dimensions beyond the partial-order structure.

57.6.2 A coordination selector that explicitly targets polarization

Definition 523 (polarization-aware resonant coordination rule). *Fix a finite action set $\mathcal{A}$. Let $\overline{Z}(a)$ be the group-mean complex signal and* $\mathrm{Pol}(a)$ *the polarization for action a. Define a selector*

$$a^{\star} \in \arg \max_{a \in \mathcal{A}_{\text{Pareto}}} \left(\left|\overline{Z}(a)\right|^2 - \gamma \,\mathrm{Pol}(a) - \beta R(a) \right),$$

where $\mathcal{A}_{\text{Pareto}}$ is the (socially) Pareto-undominated set and $\gamma, \beta \geq 0$.

The objective separates three considerations: (i) $\left|\overline{Z}(a)\right|^2$ rewards coherent alignment in the aggregated (mean) complex signal, (ii) $\mathrm{Pol}(a)$ penalizes dispersion or disagreement across individuals (as formalized earlier), and (iii) $R(a)$ captures any additional resistance term (institutional friction, switching cost, or similar). The squared magnitude $|\cdot|^2$ is convenient because it is non-negative, scales quadratically with signal strength, and interacts algebraically with polarization via the identity in Theorem 133; operationally, it treats phase disagreement as directly reducing group-level coherence even when individuals have large magnitudes.

Theorem 133 (The selector is an explicit trade between coherence and polarization). *Assume $\sum_i \alpha_i = 1$. For each action a,*

$$\left|\overline{Z}(a)\right|^2 - \gamma \,\mathrm{Pol}(a) = (1+\gamma) \left|\overline{Z}(a)\right|^2 - \gamma \sum_i \alpha_i \left|Z_i(a)\right|^2.$$

Hence increasing γ penalizes actions whose apparent group resonance is "faked" by high individual magnitudes with large disagreement.

Proof. By Theorem 126, $\mathrm{Pol}(a) = \sum_i \alpha_i |Z_i(a)|^2 - \left|\overline{Z}(a)\right|^2$. Substitute:

$$\left|\overline{Z}\right|^2 - \gamma\,\mathrm{Pol} = \left|\overline{Z}\right|^2 - \gamma\left(\sum_i \alpha_i |Z_i|^2 - \left|\overline{Z}\right|^2\right) = (1+\gamma)\left|\overline{Z}\right|^2 - \gamma\sum_i \alpha_i |Z_i|^2 .$$

□

The rearrangement makes clear that γ changes the *relative* valuation of two quantities: the aggregate coherence $\left|\overline{Z}(a)\right|^2$ and the average individual energy $\sum_i \alpha_i |Z_i(a)|^2$. When individuals are strongly activated but point in conflicting directions, $\sum_i \alpha_i |Z_i(a)|^2$ can remain large while $\left|\overline{Z}(a)\right|^2$ collapses due to cancellation; the $-\gamma\sum_i \alpha_i |Z_i(a)|^2$ term then ensures such actions are down-ranked as γ increases. Conversely, when individuals are both strong *and* aligned, the penalty term is offset by the boost on $\left|\overline{Z}(a)\right|^2$, so high-coherence actions remain attractive even for moderate γ.

Remark 3174 (Reasoning use)**.** *This gives a concrete knob: γ interpolates between "maximize shared alignment" (small γ) and "avoid high-magnitude but divisive actions" (large γ), all while preserving a Pareto safety filter.*

A useful way to read the interpolation is through limiting cases: at $\gamma = 0$ the selector reduces (up to the resistance term) to maximizing $\left|\overline{Z}(a)\right|^2$, i.e. pure coherence among Pareto-safe actions, whereas for large γ the selector increasingly prefers actions that keep individual magnitudes modest unless they translate into genuine mean alignment. Because the maximization is restricted to $\mathcal{A}_{\mathrm{Pareto}}$, the polarization-aware trade is applied only after eliminating actions that are avoidably worse for everyone in the p-bit sense; thus polarization control is not allowed to justify selecting an action that is coordinatewise dominated by another available option.

57.7 Summary of what these theorems buy a reasoning system

- (Thm. 123) **A structural diagnosis of contradiction growth** under join-based social evidence aggregation: contradiction will not shrink without explicit revision machinery. This means that any architecture that only "adds" information from multiple sources (e.g., by monotone pooling, union, or join-style merges) will accumulate inconsistencies as a predictable byproduct of scale, rather than as a rare bug. Operationally, the theorem motivates separating (i) an aggregation layer that is allowed to be inconsistency-tolerant from (ii) an explicit revision layer that can retract, downweight, or quarantine claims, and it clarifies that merely collecting more evidence is not, by itself, a remedy for contradiction.

- (Thm. 124, Thm. 125) **Explainable value conflict**: negative interference decomposes into pairwise anti-alignment; dissonance is phase dispersion energy. The key gain here is interpretability: when global conflict is observed, the decomposition identifies which pairs of value components (or agents, depending on the representation) are responsible for the negative terms, rather than attributing the phenomenon to an opaque aggregate score. Treating dissonance as a dispersion energy also yields a diagnostic handle: one can distinguish "low resonance because everyone is weak" from "low resonance because strong components are out of phase," which in turn suggests different interventions (strengthening shared commitments versus reducing misalignment among salient commitments).

- (Thm. 126–128) **A principled polarization metric** with (1) resonance–variance identity, (2) pairwise distance meaning, and (3) two-bloc causal decomposition. These properties jointly make polarization measurable in a way that is both mathematically constrained and socially legible: the resonance–variance identity ties polarization to a familiar notion of spread, the pairwise interpretation supports local explanations ("which pairs are far apart"), and the two-bloc decomposition separates within-bloc coherence from between-bloc separation. For a reasoning system, this matters because it enables monitoring and control: one can penalize polarization while still allowing diversity, and one can attribute changes in a polarization score to identifiable shifts in group structure rather than to arbitrary metric artifacts.

- (Thm. 129–Cor. 50) **Diffusion predictions** from couplings: who influences whom, with what attenuation, and under what strong-tie thresholds. In concrete terms, the coupling/path characterization turns a qualitative influence story into a quantitative forecast: influence is traced along paths, aggregated by the relevant join/closure, and discounted by attenuation so that long or weak chains contribute less. The strong-tie thresholds provide a crisp criterion for when influence is expected to persist versus die out, which supports design choices such as pruning unreliable edges, identifying bottlenecks, or targeting interventions to edges that dominate the effective diffusion.

- (Thm. 130–131) **Stabilization and contested culture** as explicit max-min path closures in two channels. The explicit max–min structure provides a computationally implementable closure operator: stabilization emerges from maximizing over paths while respecting the weakest link along each path, and contestation arises when the two channels (e.g., supportive vs. opposing, or affirmation vs. negation) percolate differently. For a reasoning system, this yields a way to represent "cultural" or "normative" persistence without assuming consensus: stable patterns can be traced to robust pathways, while contested regions are precisely those where comparable-strength pathways exist for incompatible signals.

- (Thm. 132–133) **Non-explosive coordination choices** that keep conflicts visible yet select robustly: Pareto safety + resonance + polarization penalty + effort. The point is not merely that a selector exists, but that it can be tuned to avoid two common failure modes: (i) suppressing disagreement by collapsing to a brittle single objective, or (ii) amplifying disagreement by optimizing a criterion that rewards extremity. By combining Pareto safety (no dominated moves), resonance (coordination quality), a polarization penalty (social risk), and an effort term (implementation cost), the system can make choices that remain justifiable under multiple evaluative lenses, while still surfacing the underlying tradeoffs rather than hiding them.

These results function together as an end-to-end toolkit: aggregation theorems clarify what information fusion will inevitably do without revision; interference and polarization identities make conflicts diagnosable rather than mysterious; diffusion and closure results predict how signals and norms propagate and stabilize; and the selection theorems provide a disciplined way to act under plural objectives without either erasing disagreement or letting it spiral. As a consequence, the reasoning system can (i) represent incompatible evidence without immediate collapse, (ii) explain *why* conflict appears in terms of specific anti-alignments and dispersion, (iii) anticipate network-mediated amplification or attenuation, and (iv) commit to coordination decisions that are robust, auditable, and sensitive to polarization externalities.

58 Embedding the Cultural-Probabilistic-Pragmatic Model of Science in Hyperseed

We formalize the Cultural/Pragmatic Probabilism (CPP) philosophy and model of science — "science as weakest selection across evidential, cultural-simplicity, and pragmatic-usefulness channels" — inside the Hyperseed formalization of science as empirically coupled belief-system dynamics [1, 20]. We then prove a family of structural theorems useful to reasoning systems: (1) CPP is representable as Hyperseed science plus two additional weakness channels; (2) scientific updates are path-independent (batching/commutativity), enabling caching and method flexibility; (3) Pareto-dominance and robustness regions yield decision tools under uncertain channel weights; (4) modularity/independence yields domain decomposition theorems; (5) state-dependent science is reducible to ordinary science on an expanded experiment space; and (6) "paradigm innovation" reduces to ordinary model selection on a lifted hypothesis space.

In this embedding, the key interpretive move is to treat "acceptance" or "preferred status" of a hypothesis not as a primitive binary judgment but as an emergent consequence of iterative update dynamics operating on a structured belief state. Hyperseed provides the ambient machinery for this: a scientific community (or an individual reasoner) maintains a population of candidate hypotheses/models together with degrees of endorsement, and these endorsements are repeatedly revised in response to interaction with an experiment space that is coupled to the world via observation. The CPP proposal then enters by specifying *multiple* concurrent evaluation channels, each channel inducing its own notion of weakness/selection pressure, and the operative scientific update is the resulting weakest-selection aggregation across these channels.

Concretely, the evidential channel captures ordinary empirical adequacy (e.g., fit to data, predictive accuracy, calibration, likelihood-based scoring, or other statistical loss proxies); the cultural-simplicity channel captures pressures toward communicability and compressibility (e.g., shorter descriptions, fewer free parameters, alignment with shared conceptual schemas, and lower cognitive/organizational cost of transmission); and the pragmatic-usefulness channel captures goal-directed performance (e.g., actionable interventions, engineering effectiveness, decision quality, and downstream utility in situated tasks). The philosophy of CPP is that these three channels are jointly constitutive of scientific practice as actually executed: in real scientific ecosystems, hypotheses survive not only by fitting existing data, but by being adoptable, teachable, and useful under constraints of limited time, attention, and resources.

Hyperseed's language of *weakness channels* is particularly apt here because it allows each criterion to be represented as a morphism from hypotheses into an ordered space of "weakness" values, with selection realized by comparing hypotheses according to the induced order. The pluralism of CPP thus becomes a statement about a *vector* (or family) of weakness functionals rather than a single scalar score. This matters for reasoning systems because different deployments may instantiate the channels differently: e.g., evidential weakness might be computed from Bayesian posterior risk, cultural weakness from description length or program-size priors, and pragmatic weakness from expected utility or regret on a task distribution. The embedding theorem in (1) is therefore not merely a representational convenience: it guarantees that a reasoning system can treat CPP-style multi-criterion assessment as a standard Hyperseed object by adding channels, rather than rewriting the underlying notion of science.

The remaining theorems articulate computational and conceptual consequences of this representation. Path-independence in (2) is read as an algebraic statement that the order in which evidence and other channel-relevant updates are processed does not affect the resulting closure (under the specified update operator), which legitimizes batching, streaming, parallelization, and caching strategies in implementations. The Pareto and robustness results in (3) formalize the commonplace observation that channel trade-offs are often underdetermined: if the relative weights among evidential, cultural, and pragmatic criteria are uncertain or context-sensitive, then one should reason in terms of Pareto-frontiers and regions of weight-space in which a hypothesis remains admissible or optimal. The modularity results in (4) capture when and how domains can be decomposed: if the experiment space and hypothesis structure factorize, then multi-channel weakness can factorize as well, allowing separate sub-sciences to be updated independently and then recombined without loss. The state-dependent reduction in (5) addresses the fact that in many realistic settings, what counts as an "experiment" depends on prior commitments (e.g., instrument choice, measurement protocol, or adaptive experimental design); the reduction shows that such endogenous experiment selection can be simulated by ordinary Hyperseed science on a suitably expanded space that treats state as part of the experimental context. Finally, the paradigm-innovation result in (6) makes precise a key aspiration of CPP-friendly meta-science: even changes that look like shifts in the space of admissible models can be represented as ordinary selection once one moves to a lifted hypothesis space that contains both models and model-generators (or representational frameworks) as first-class candidates.

Remark 3175. *The philosophical stance here is intentionally pluralistic: the "scientific quality" of a model is not reduced to a single scalar such as likelihood, but is treated as a synthesis of (at least) three partially incommensurable criteria. In the idiom of Hyperseed, these criteria are implemented as* weakness channels *(cf. Hyperseed-Concept 202) [3, 2]. The formal results below show that this pluralism can nevertheless be made algebraically tame: we can compute closures, batch evidence, factorize domains, and reason about robustness without sacrificing rigor.*

A further motivation for making the channels explicit (rather than folding them into a single aggregate score from the outset) is that scientific disagreement often arises from channel emphasis *rather than from factual dispute: two communities may share the same evidence yet differ in how much cultural simplicity or pragmatic usefulness should constrain acceptance. The multi-channel formalization keeps these sources of disagreement visible and manipulable, so that one can ask principled questions such as: which hypotheses are stable across a range of cultural/pragmatic pressures; which are fragile to small changes in the balance of criteria; and which are non-dominated in the sense that improving one channel necessarily worsens another. In this sense, the CPP-in-Hyperseed embedding is meant not only to generalize standard evidentialist accounts, but also to support transparent, auditable reasoning about trade-offs that are ubiquitous in real scientific and engineering workflows.*

58.1 Minimal Hyperseed science machinery (from above)

Definition 524 (Belief values and belief states)**.** *Fix a claim language L and a commutative unital quantale $(V, \leq, \oplus, \otimes, 0, 1)$. A belief state is a valuation $\beta : L \to V$, ordered pointwise.*

Remark 3176. *Intuitively, L is a set of statements an agent (or community) can talk about, and V is the space of* graded *truth-values, supports, or plausibilities (Hyperseed-Concepts 65, 64). A map $\beta : L \to V$ assigns to each claim $\varphi \in L$ a value $\beta(\varphi) \in V$ representing how strongly the agent currently endorses it. The pointwise order means: $\beta \leq \beta'$ iff for every claim φ, $\beta(\varphi) \leq \beta'(\varphi)$, i.e. β' contains at least as much support as β everywhere.*

A simple example is the "Boolean" case $V = \{0, 1\}$ with $\oplus = \vee$ and $\otimes = \wedge$, where a belief state is just a set of believed sentences. A more informative example is a numeric quantale such as $V = [0, 1]$ with $\oplus = \max$ and $\otimes = \times$, where $\beta(\varphi)$ can be read as a confidence and $\oplus$ as evidence pooling. This quantale structure is useful because it lets us define inference and closure abstractly, *while still admitting many concrete semantics (probabilistic, fuzzy, possibilistic, etc.; Hyperseed-Concept 139).*

Remark 3177. *The quantale assumptions encode two distinct design goals that matter for "science machinery." First, $(V, \leq)$ supplies an order in which "more supported" (or "less refuted") beliefs lie above weaker ones; this is what makes iteration and fixed points meaningful. Second, $\oplus$ and $\otimes$ separate two ways of aggregating information: $\oplus$ is typically used to combine* independent contributions to the same claim *(e.g. multiple lines of evidence), whereas $\otimes$ is typically used to propagate support* through *an inference step (e.g. a rule weight times the support of its premise). Commutativity and unitality make these aggregations robust under re-ordering and the presence of neutral elements, which is important when the "community" is distributed and updates arrive asynchronously.*

Definition 525 (Weighted inference and closure)**.** *Fix a set R of weighted inference rules. Let $F_R : V^L \to V^L$ be the one-step inference operator and let $\mathrm{CI}_R(\beta)$ be the least fixed point of F_R above β.*

Remark 3178. *The notation V^L denotes the set of all functions $L \to V$, i.e. all belief states; thinking set-theoretically, this is an exponential object (a "function space"). The operator F_R is the engine that applies the rules in R once: from current beliefs, it produces an expanded belief state containing whatever the rules can infer in one step, with weights combined using the quantale operations. The closure $\mathrm{CI}_R(\beta)$ is then the result of iterating this one-step procedure to saturation, taking the least fixed point that extends the starting information β.*

Concretely: if L contains claims φ, ψ and R contains a rule "from φ infer ψ with weight w", then $F_R(\beta)(\psi)$ will be at least $\beta(\varphi) \otimes w$, and closure iterates until no new support can be added. This construction is necessary because scientific reasoning is not merely a sequence of one-off updates; it is a process of repeatedly integrating evidence and its inferential consequences until reaching a stable state (Hyperseed-Concepts 150, 140).

Remark 3179. *The phrase "least fixed point above β" is doing two jobs at once. "Fixed point" captures the idea of* stability under the currently endorsed inference rules*: once closed, applying F_R again produces no change. "Least above β" captures* conservativeness*: closure should add exactly what is forced (by R and the algebra of V) and no more, so that $\mathrm{CI}_R(\beta)$ is the minimally-committal stable extension of β. This is the order-theoretic analogue of "close under consequences, but do not invent new premises."*

Theorem 134 (Closure exists; Cl_R is a closure operator)**.** *F_R is monotone on the complete lattice V^L, hence $\mathrm{Cl}_R(\beta)$ exists for all β (as the join of the Kleene chain). Moreover Cl_R is extensive, monotone, and idempotent.*

Remark 3180. *The notation in this subsection is meant to be read as follows: $\mathrm{CI}_R(\beta)$ names the least fixed point of F_R above β (as in the definition), and $\mathrm{Cl}_R(\beta)$ names the corresponding* closure operation *applied to β (as in the theorem). In standard lattice-theoretic treatments these coincide as maps $V^L \to V^L$; i.e. one may set $\mathrm{Cl}_R(\beta) \coloneqq \mathrm{CI}_R(\beta)$, with Cl_R emphasizing the algebraic "closure-operator" viewpoint and CI_R emphasizing the "closure by iterated inference" viewpoint.*

Remark 3181. *What this theorem says, in plain language, is that "closing under inference" is always well-defined: if you repeatedly apply your inference rules, you do not wander endlessly without a limit; instead you converge (in the lattice-theoretic sense) to a smallest stable belief state that contains your starting beliefs. The surprise here is not logical but architectural: once the* *algebraic conditions (complete lattice + monotone inference operator) are in place, closure becomes a reusable component in a reasoning system, independent of the particular content of L.*

This result is the backbone for later batching/commutativity claims: once closure is idempotent, intermediate closures can be postponed without changing the end result. It also connects to the broader fixed-point style used elsewhere in Hyperseed (e.g. stability analyses) [10].

Remark 3182. *The "complete lattice" hypothesis is automatically satisfied for many quantales used in practice: if V is complete (has all joins/meets), then the function space V^L inherits completeness pointwise (joins and meets are computed claim-by-claim). Under that identification, the Kleene chain mentioned in the theorem is the ascending sequence*

$$\beta \ \leq \ F_R(\beta) \ \leq \ F_R^2(\beta) \ \leq \ \cdots,$$

and its join is computed pointwise in V. This is one reason Hyperseed formulates the machinery in V^L: it reduces global questions about "community belief" to local aggregation at each claim $\varphi \in L$ while keeping the global fixed-point semantics intact.

Proof. To make the existence claim explicit, define the Kleene iterates $\beta_0 := \beta$ and $\beta_{n+1} := F_R(\beta_n)$ for $n \geq 0$. By monotonicity of F_R one has $\beta_n \leq \beta_{n+1}$ for all n, hence $(\beta_n)_{n\in\mathbb{N}}$ is an increasing chain in the complete lattice V^L. Let $\beta_\infty := \bigvee_{n\in\mathbb{N}} \beta_n$ (join taken in V^L, i.e. pointwise in V). Under the standard continuity conditions used in Kleene-style constructions, $F_R(\beta_\infty) = \beta_\infty$, so β_∞ is a fixed point above β, and by construction it is the least such fixed point; one may thus take $\mathrm{Cl}_R(\beta) := \beta_\infty$.

Extensiveness ($\beta \leq \mathrm{Cl}_R(\beta)$) follows from $\beta = \beta_0 \leq \bigvee_n \beta_n$. Monotonicity of Cl_R follows because $\beta \leq \beta'$ implies $\beta_n \leq \beta'_n$ for all n (by induction using monotonicity of F_R), hence $\bigvee_n \beta_n \leq \bigvee_n \beta'_n$. Idempotence ($\mathrm{Cl}_R(\mathrm{Cl}_R(\beta)) = \mathrm{Cl}_R(\beta)$) holds because $\mathrm{Cl}_R(\beta)$ is already a fixed point of F_R, so closing it again does not add anything further. □

Proof sketch. The strategy is the standard Knaster–Tarski/Kleene fixed-point picture: monotonicity guarantees that iterating F_R from β produces an increasing chain, and completeness guarantees that taking its join yields a fixed point. Extensiveness means closure contains the starting beliefs; monotonicity means more input evidence yields more closed beliefs; idempotence means "closing twice" is the same as "closing once," which is what makes batching and modularity work smoothly. □

Remark 3183. *A useful visual metaphor is to picture V^L as a landscape ordered by "information content," and F_R as a gravity-like operator that pulls a belief state upward to include consequences. Iteration follows a monotone ascent; the join of the Kleene chain is the least plateau where applying F_R no longer moves you.*

Remark 3184. *This "landscape" picture also clarifies why idempotence matters operationally. In a distributed setting, agents may alternate between (i) incorporating new evidence and (ii) propagating consequences. If closure were not idempotent, then the order and frequency of these phases would matter, and the system could exhibit artificial dependence on scheduling. Idempotence says that once a community has done the inferential bookkeeping to reach the plateau, repeating the same bookkeeping step is harmless; this is precisely the property that enables caching, memoization of derived claims, and stable modular composition of subtheories.*

Definition 526 (Hyperseed science: observation sets, models, empirical update)**.** *A (community-accepted) observation set consists of an experiment class E, an observation set O, and an observation map* $\mathrm{Obs} : E \to O$*, with a community acceptance criterion. A scientific model class is a set*

$\mathcal{M}$ *of candidate models whose predictive/causal claims are encoded in* L*. An empirical evidence increment is a map* $\varepsilon_{e,o} : L \to V$ *induced by experiment* e *and observation* $o = \mathrm{Obs}(e)$*. A scientific update step is:*

$$\beta \leftarrow \mathrm{Cl}_R(\beta \oplus \varepsilon_{e,o}).$$

Remark 3185. *This definition separates three layers that are often conflated in informal discussions of "the scientific method." The observation set* (E, O, Obs) *fixes what counts as a* repeatable *experimental intervention (*$e \in E$*) and what counts as an admissible readout (*$o \in O$*). The "community acceptance criterion" is included to acknowledge that real scientific communities do not treat all reported* (e, o) *pairs equally: issues of calibration, provenance, replication, and protocol compliance can gate whether a datum is allowed to enter the shared record at all.*

The model class $\mathcal{M}$ *specifies the hypothesis space whose members are intended to explain and predict observations; encoding predictive/causal claims in* L *means that model evaluation can be mediated through the same belief language used for other claims (background theory, methodological constraints, auxiliary hypotheses, etc.). Finally,* $\varepsilon_{e,o} : L \to V$ *is the bridge from raw outcomes to graded support over claims: it can be sparse (affecting only a small fragment of* L*) or rich (updating many linked claims at once), and it can represent positive evidence, negative evidence, or partial/ambiguous evidence depending on the structure of* V*.*

The update equation $\beta \leftarrow \mathrm{Cl}_R(\beta \oplus \varepsilon_{e,o})$ *makes explicit that "learning from data" is not just adding the evidence increment; it is adding it* and then propagating its consequences *via closure under* R*. In particular, the use of* $\oplus$ *emphasizes that evidence is aggregated with prior support in a way appropriate to the chosen quantale semantics, while* Cl_R *enforces the community's inferential commitments (methodological and theoretical) after each accepted observation.*

Remark 3186. *This definition formalizes "science" as a loop with three kinds of structure: (i)* what can be done *(experiments* E*), (ii)* what is registered *(observations* O *and the mapping* Obs*), and (iii)* how observations affect belief *(the increment* $\varepsilon_{e,o}$*), all mediated through communal norms about what counts as acceptable evidence (Hyperseed-Concepts* **??**, **??**, *91) [20]. The update equation says: merge the new empirical increment into the current belief state using* $\oplus$ *(an "evidence pooling" operator), then close under inference rules* R*.*

A simple example is: E *is a class of measurement procedures,* O *is a set of recorded outcomes, and* $\varepsilon_{e,o}$ *assigns high support in* V *to claims like "the outcome was* o*" and to model adequacy claims consistent with* o*. The closure step is what propagates the observation through the inferential web: from local measurement reports to broader theoretical commitments. This division of labor is useful because it separates* data acquisition *from* inferential assimilation.

One can also read the loop as a minimal abstraction of the social-epistemic workflow: E *encodes not only physical interventions but also protocolized practices (what a lab is allowed to do),* Obs *encodes both instrumentation and reporting conventions (what counts as a record), and* $\varepsilon_{e,o}$ *encodes the community's tacit "likelihood model" of which claims should be strengthened by which outcomes. In particular,* $\oplus$ *need not be additive or Bayesian: it can represent negotiated aggregation across agents or institutions (e.g., replication-weighted pooling), while the closure under* R *enforces whatever inferential commitments the community treats as mandatory (e.g., deductive closure, default rules, or domain-specific calculi). In this way the same formal skeleton can represent both individual updating and intersubjective stabilization, depending on how* $V, \oplus$*, and* R *are instantiated.*

58.2 CPP view of science (informal-to-formal bridge)

CPP characterizes scientific quality via three "weakness channels": (i) evidential weakness (no unwarranted predictive distinctions), (ii) cultural weakness (simplicity relative to paradigm primitives), (iii) pragmatic weakness (no practically irrelevant distinctions), and views a *paradigm* as a package specifying the semantics of evidence, simplicity, and pragmatic relevance.

The informal slogan "no unwarranted distinctions" can be read as a form of invariance requirement: scientific representations should identify (treat as equivalent) any differences that are not licensed by the relevant channel. In the evidential channel, the identification is driven by what can be discriminated by the experiment-observation interface; in the cultural channel, it is driven by what can be expressed economically in the community's representational repertoire; and in the pragmatic channel, it is driven by what makes a difference to intervention, decision, or control. On this reading, a paradigm does not merely choose *which theories are entertained*, but also chooses the *grain* at which the world is described and evaluated.

Remark 3187. *The word "weakness" is meant in a technical sense: a good scientific claim is often one that refrains from making unnecessary distinctions, thereby remaining robust under variation and resistant to overfitting [3, 2]. Evidential weakness corresponds to not asserting predictive structure beyond what the evidence warrants (Hyperseed-Concept 202). Cultural weakness corresponds to parsimony relative to the representational primitives a community treats as natural (Hyperseed-Concepts 91, 82). Pragmatic weakness corresponds to ignoring distinctions that do not alter action, control, or usefulness (Hyperseed-Concepts 191, 186).*

The notion of a paradigm as a "package" is not merely sociological decoration: formally, it is the claim that simplicity and usefulness are not absolute, but are functions of representational and practical context. This resonates with process-oriented and semiotic perspectives in which meaning is enacted by a community of interpreters rather than residing in symbols alone [15, 14].

In particular, a paradigm package fixes (at least implicitly) three kinds of typing information: (a) which observational reports are admissible and how they constrain models (the evidential semantics), (b) which descriptions count as short, natural, or "not ad hoc" (the cultural semantics), and (c) which distinctions are decision-relevant and at what scales costs and benefits are measured (the pragmatic semantics). When those background typings shift, two agents can agree on raw outcomes $o \in O$ yet disagree on which model comparisons are meaningful, because they are effectively computing weakness with respect to different equivalence relations over models. This is one formal route to the familiar phenomenon of incommensurability: disagreement can persist even when there is no disagreement about the syntactic data stream, because the paradigm changes the evaluative and inferential interpretation of that stream.

We now make this precise inside Hyperseed.

Definition 527 (CPP-paradigm (as data on top of Hyperseed science))**.** *A CPP-paradigm is a tuple*

$$P = (E, O, \mathrm{Obs}, \mathcal{M}, R, \mathrm{Comp}_P, \mathrm{Prag}_P, \lambda_c, \lambda_p, \mathrm{Adeq})$$

where:

- $(E, O, \mathrm{Obs}, \mathcal{M}, R)$ *is a Hyperseed science instance;*
- $\mathrm{Comp}_P : \mathcal{M} \to [0, \infty)$ *is a* cultural complexity cost *(paradigm-relative);*
- $\mathrm{Prag}_P : \mathcal{M} \to [0, \infty)$ *is a* pragmatic cost *(lower is more useful/actionable);*
- $\lambda_c, \lambda_p > 0$ *are channel weights;*
- $\mathrm{Adeq} : \mathcal{M} \to L$ *maps a model to a claim in* L *encoding "predictive adequacy."*

Given a belief state β, define evidential support

$$\mathrm{Supp}_\beta(m) \in [0,1]$$

as some monotone scalarization of $\beta(\mathrm{Adeq}(m))$ *(e.g. the plausibility projection). Define the CPP score:*

$$\mathsf{Score}_{P,\beta}(m) := \mathrm{Supp}_\beta(m)\; e^{-\lambda_c \mathrm{Comp}_P(m)}\; e^{-\lambda_p \mathrm{Prag}_P(m)}.$$

Remark 3188. *The tuple P is best read as "science plus two extra semantics." The Hyperseed core gives us evidence and inference $(E, O, \mathrm{Obs}, \mathcal{M}, R)$. CPP then adds two additional evaluative maps:* Comp_P *quantifies how complex a model is* in the representational language the paradigm finds natural *(Hyperseed-Concept 82), and* Prag_P *quantifies how costly or irrelevant the model is from an action-oriented perspective (Hyperseed-Concepts 191, 147). The weights λ_c, λ_p set the current "severity" of simplicity and usefulness constraints.*

The support functional $\mathrm{Supp}_\beta(m)$ *is deliberately abstract: it is any monotone way to turn the belief value $\beta(\mathrm{Adeq}(m)) \in V$ into a scalar in $[0,1]$. For example, if $V = [0,1]$ already, one can take* $\mathrm{Supp}_\beta(m) = \beta(\mathrm{Adeq}(m))$*. If V is multi-dimensional,* Supp_β *can pick out a plausibility coordinate. The product form of* $\mathsf{Score}_{P,\beta}$ *is a familiar log-linear "energy" model: the exponentials turn additive costs into multiplicative penalties, so that small cost differences are weighted smoothly but decisively.*

As a toy example, suppose two models m_1, m_2 explain the same data equally well so $\mathrm{Supp}_\beta(m_1) = \mathrm{Supp}_\beta(m_2)$*, but m_1 is far simpler in the paradigm's representational vocabulary: then m_1 wins by an Occam-like preference. Conversely, a slightly less-supported but dramatically simpler model can win if λ_c is large. This is precisely the intended formalization of CPP as a tri-channel "weakest selection" principle [20, 3].*

It is also useful to note what, concretely, can vary between paradigms in this formalization. Changing Comp_P *corresponds to changing which descriptions are treated as primitive or cheaply composable (for instance, preferring geometric over algebraic primitives, or preferring mechanistic modules over black-box function classes). Changing* Prag_P *corresponds to changing the task environment and the decision interface (for instance, whether interpretability, real-time computability, or controllability is prioritized). Changing the weights λ_c, λ_p corresponds to shifting how strongly simplicity and usefulness trade off against raw predictive support, which can encode differences between exploratory and production contexts. Finally, changing* Adeq *(or, upstream, the inference rules R that relate adequacy claims to other claims) corresponds to changing what counts as "the same predictions," e.g. whether calibration, counterfactual robustness, or mechanistic faithfulness is being demanded. In this sense, a paradigm shift can be modeled not only as a change of favored models in $\mathcal{M}$, but as a change in the scoring geometry over $\mathcal{M}$ induced by* $\mathrm{Comp}_P, \mathrm{Prag}_P, \lambda_c, \lambda_p$*, and the adequacy semantics.*

The log form makes the channel decomposition explicit: $\log \mathsf{Score}_{P,\beta}(m) = \log \mathrm{Supp}_\beta(m) - \lambda_c \mathrm{Comp}_P(m) - \lambda_p \mathrm{Prag}_P(m)$*. Thus evidential weakness is represented by the extent to which* Supp_β *refuses to separate models not distinguished by the evidence encoded in β and* Adeq*, while cultural and pragmatic weakness are represented by linear penalties that suppress distinctions that are expensive in the paradigm's description language or irrelevant to its task landscape. This makes contact with familiar Bayesian/MDL intuitions (support times an Occam factor) without committing the framework to a specific probabilistic semantics for β.*

58.3 Crosswalk theorem: CPP is Hyperseed science + two weakness channels

Theorem 135 (CPP-to-Hyperseed crosswalk)**.** *Every CPP-paradigm P determines:*

1. *a Hyperseed science instance $(E, O, \mathrm{Obs}, \mathcal{M}, R)$ with empirical updates $\beta \leftarrow \mathrm{Cl}_R(\beta \oplus \varepsilon_{e,o})$;*

2. *two additional (commutative) weakness channels* $m \mapsto e^{-\lambda_c \mathrm{Comp}_P(m)}$ *and* $m \mapsto e^{-\lambda_p \mathrm{Prag}_P(m)}$*;*

3. *a model selection operator* $\arg\max_{m\in\mathcal{M}} \mathsf{Score}_{P,\beta}(m)$ *implementing CPP "weakest selection" (maximally weak across the three channels). Conversely, any Hyperseed science instance equipped with two such channel maps and a monotone support functional* Supp_β *induces a CPP-paradigm.*

In particular, the crosswalk is functorial at the level of "data packaging": the CPP object P contains (or canonically generates) the Hyperseed tuple, and the only extra degrees of freedom needed to recover CPP from Hyperseed are (i) two scalar penalty/weight maps on $\mathcal{M}$ and (ii) a rule that converts the current belief state β (and the update history it encodes) into a scalar notion of evidential adequacy for each model. The adjective "commutative" here means that, when the channels are combined multiplicatively into a single score, their order of application is irrelevant: multiplying by $e^{-\lambda_c \mathrm{Comp}_P(m)}$ *and then by* $e^{-\lambda_p \mathrm{Prag}_P(m)}$ *yields the same weight as multiplying in the opposite order, so the two additional channels can be treated as symmetric modifiers of evidential support rather than as sequential filters.*

Remark 3189. *This theorem states that CPP is not an alien add-on to Hyperseed science: it is obtained by taking the Hyperseed empirical/inferential loop and multiplying in two further factors that encode cultural simplicity and pragmatic usefulness. The importance is practical: once CPP is expressed as "Hyperseed + extra channels," all the fixed-point/closure theorems and batching/modularity results that hold for Hyperseed can be reused for CPP-aligned scientific reasoning systems [19]. A useful way to read the statement is that the empirical channel provides a* support-like *term (coming from β and the observation process), while* Comp_P *and* Prag_P *provide* regularizing *terms; the CPP score* $\mathsf{Score}_{P,\beta}(m)$ *is then an aggregation that ranks models by simultaneously (a) fitting/being supported by evidence and (b) remaining culturally compressible and pragmatically serviceable. The exponential form* $e^{-\lambda\cdot}$ *is also conceptually clarifying: it turns an additive cost scale (complexity or pragmatics) into a multiplicative attenuation, so "more costly" models are* down-weighted *rather than categorically excluded, and the sensitivity of that downweighting is tuned by* λ_c, λ_p*.*

Conceptually, the crosswalk is also a modest unification claim: it says that disputes about "what counts as good science" can often be formalized as disputes about (i) the channel maps $(\mathrm{Comp}_P, \mathrm{Prag}_P)$ *and (ii) their weights, rather than disputes about the existence of a scientific update loop at all. Equivalently, within a fixed Hyperseed instance* $(E, O, \mathrm{Obs}, \mathcal{M}, R)$*, different CPP paradigms can be seen as different* prioritizations *of non-empirical constraints, and the theorem asserts that these prioritizations can be represented without changing the underlying update mechanism, only the selection criterion built on top of it.*

Proof. Immediate by unpacking the data. The Hyperseed part is $(E, O, \mathrm{Obs}, \mathcal{M}, R)$ and the empirical-update loop. The two exponentiated costs are $[0,1]$-valued weakness weights. The product score is a concrete monotone aggregation of the three channels. Conversely, given the Hyperseed instance plus channel maps plus Supp_β, one reconstructs $\mathsf{Score}_{P,\beta}$ and hence a CPP-paradigm structure. More explicitly, the "unpacking" direction amounts to observing that a CPP-paradigm already supplies (at minimum) (i) a space of possible evidential events (e, o), (ii) an observational interface Obs that yields update increments $\varepsilon_{e,o}$, (iii) a belief/update state β closed under Cl_R relative to the relevant constraint set R, and (iv) a model class $\mathcal{M}$ to be scored. The two additional channel maps are simply functions $\mathcal{M} \to (0,1]$ once exponentiated; their codomain and monotonicity properties ensure they can be multiplied into a total score without leaving the scalar range used for comparison. In the reconstruction direction, the monotone support functional Supp_β

plays the role of extracting the "empirical channel" contribution to $\mathsf{Score}_{P,\beta}(m)$; together with the two penalty factors, one obtains a well-defined model ranking on $\mathcal{M}$, and packaging this ranking together with the already-given Hyperseed update loop yields a CPP-paradigm in the sense used throughout the section. □

Proof sketch. The proof is a bookkeeping argument: a CPP-paradigm already contains the underlying Hyperseed science data, and the score is literally a product of three terms, two of which are exponentiated costs. Conversely, if you start with Hyperseed science and provide two extra channel penalties and a way to read evidential adequacy as a scalar support, you can package these ingredients back into the tuple P. One can also view the crosswalk as a change of emphasis: Hyperseed specifies how β changes when (e, o) arrives (via $\beta \leftarrow \mathrm{Cl}_R(\beta \oplus \varepsilon_{e,o})$), whereas CPP specifies how, at any given β, models $m \in \mathcal{M}$ are comparatively preferred once *all* three channels are accounted for. □

Remark 3190. *The key idea is that "weakness channels" are operationally just additional multiplicative weights in model selection. This is why they can be treated symmetrically with evidential support, even if their interpretation is sociocultural or pragmatic. In particular, multiplying by weakness weights implements a soft form of constraint: models are not rejected outright for being culturally complex or pragmatically unhelpful, but they are penalized in proportion to* $\mathrm{Comp}_P(m)$ *and* $\mathrm{Prag}_P(m)$*, and the hyperparameters* λ_c, λ_p *control how quickly those penalties dominate the overall score. This symmetry is also the technical reason that many Hyperseed arguments transfer: if a theorem only uses monotonicity and closure properties of the update-and-score pipeline (rather than any domain-specific interpretation of the score), then adding extra multiplicative channels preserves the relevant order structure needed by those arguments.*

58.4 Quantale unification theorem (optional but structurally useful)

Theorem 136 (Product quantale for multi-channel semantics)**.** *Let* $(V, \leq, \oplus, \otimes, 0, 1)$ *be a commutative unital quantale (evidence values). Let* $(W_c, \leq_c, \oplus_c, \otimes_c, 0_c, 1_c)$ *and* $(W_p, \leq_p, \oplus_p, \otimes_p, 0_p, 1_p)$ *be commutative unital quantales (cultural/pragmatic weakness values). Define* $Q := V \times W_c \times W_p$ *with pointwise order and operations:*

$$(a_0, a_1, a_2) \oplus (b_0, b_1, b_2) := (a_0 \oplus b_0,\ a_1 \oplus_c b_1,\ a_2 \oplus_p b_2),$$

$$(a_0, a_1, a_2) \otimes (b_0, b_1, b_2) := (a_0 \otimes b_0,\ a_1 \otimes_c b_1,\ a_2 \otimes_p b_2).$$

Then Q *is a commutative unital quantale. Hence all Hyperseed closure/fixed-point machinery lifts verbatim to tri-channel belief states* $\beta : L \to Q$*.*

More explicitly, the pointwise order is

$$(a_0, a_1, a_2) \leq (b_0, b_1, b_2) \quad \textit{iff} \quad a_0 \leq b_0,\ a_1 \leq_c b_1,\ a_2 \leq_p b_2,$$

and the bottom/top and unit elements in Q *are given by*

$$0_Q := (0, 0_c, 0_p), \qquad 1_Q := (1, 1_c, 1_p),$$

so that "doing nothing" in each channel corresponds to doing nothing in the product. In particular, arbitrary joins in Q *are computed coordinatewise: for any family* $\{(a_0^i, a_1^i, a_2^i)\}_{i \in I} \subseteq Q$ *one has*

$$\bigoplus_{i \in I} (a_0^i, a_1^i, a_2^i) = \left(\bigoplus_{i \in I} a_0^i,\ \bigoplus_{i \in I} a_1^i,\ \bigoplus_{i \in I} a_2^i \right),$$

where each $\bigoplus$ is taken in its respective coordinate quantale. This is the structural reason that the fixed-point/closure constructions (which only ever require monotonicity, joins, and $\otimes$ distributing over joins) can be reused without alteration.

Remark 3191. *Informally: instead of keeping evidence, cultural simplicity, and pragmatic usefulness as separate scoring systems glued together ad hoc, we can bundle them into a single algebraic value space Q and run one unified inference/closure pipeline. The pointwise definition is exactly what one would guess: to combine two tri-channel values, combine each channel in its own way.*

This matters because it allows the entire "science as closure under rules" apparatus to operate on richer value types without modification. In other words, once we know how to do closure for beliefs valued in a quantale, we automatically know how to do closure for beliefs valued in a product of quantales. This is a common categorical theme: products preserve structure, and here the preserved structure is precisely what fixed-point iteration needs.

A useful interpretive detail is that the pointwise order on Q is a Pareto-style order: $(a_0, a_1, a_2) \leq (b_0, b_1, b_2)$ precisely when every *channel is at least as good (in the appropriate sense) as before. This avoids prematurely collapsing multi-channel comparisons into a single scalar; if a later stage of the framework needs an overall preference, it can be obtained by adding an external aggregator (e.g. a weighted map $Q \to V$), but the closure computation itself remains purely structural and monotone in each coordinate.*

Concretely, one can instantiate V as an "evidence" quantale such as $([0,1], \leq, \max, \cdot, 0, 1)$ or $([0,\infty], \geq, \min, +, \infty, 0)$ (depending on whether one reads values as strength or cost), while W_c and W_p may encode cultural/pragmatic penalties or weaknesses with their own combination laws. The theorem guarantees that, regardless of these modeling choices, the combined tri-channel semantics stays within the same algebraic class needed by Hyperseed.

Proof. Products of complete lattices are complete lattices with pointwise joins. Commutativity/associativity/unit for $\otimes$ hold coordinatewise. Distributivity of $\otimes$ over arbitrary joins holds coordinatewise because each factor is a quantale.

For clarity on the distributivity step: if $x = (x_0, x_1, x_2) \in Q$ and $\{y^i\}_{i\in I} \subseteq Q$ with $y^i = (y_0^i, y_1^i, y_2^i)$, then using coordinatewise definitions,

$$x \otimes \left(\bigoplus_{i\in I} y^i\right) = \left(x_0 \otimes \bigoplus_{i\in I} y_0^i,\ x_1 \otimes_c \bigoplus_{i\in I} y_1^i,\ x_2 \otimes_p \bigoplus_{i\in I} y_2^i\right),$$

and each coordinate equals the join of the corresponding products because $\otimes$, $\otimes_c$, and $\otimes_p$ distribute over arbitrary joins in their respective quantales. Reassembling the coordinates yields

$$x \otimes \left(\bigoplus_{i\in I} y^i\right) = \bigoplus_{i\in I}(x \otimes y^i),$$

and similarly on the other side (commutativity makes left/right distribution equivalent here, but the argument is coordinatewise in any case). ☐

Proof sketch. One checks the quantale axioms component-by-component. Completeness holds because joins/meets in a product are computed coordinatewise. The distributivity axiom holds because each coordinate distributes over joins in its own quantale, so the triple does as well. The lifting claim then follows because the closure construction only uses these axioms.

In Hyperseed terms: if the closure operator (or rule-application operator) is built from monotone combinations of $\oplus$ (joins) and $\otimes$ (rule composition, aggregation, or propagation), then replacing V

by Q simply means doing the same computation three times in parallel, one per channel. Thus any Knaster–Tarski-style fixed-point existence and any iterative approximation scheme (e.g. iterating from 0_Q and taking joins at limits) carries over immediately. $\square$

Remark 3192. *Geometrically, you can imagine Q as a three-axis space: evidence on one axis, cultural simplicity on another, pragmatic utility on a third. Closure and inference then become motions that are monotone in each coordinate, so fixed-point convergence is preserved.*

It can also be helpful to view Q as encoding a frontier *of admissible beliefs rather than a single score: rule closure will propagate constraints and supports across the three coordinates simultaneously, and the pointwise order ensures that adding information in one channel cannot "hide" a loss in another channel. When later projecting to decisions (e.g. selecting hypotheses), one may impose additional selection criteria, but the internal logical/algebraic step of achieving closure stays faithful to the multi-dimensional semantics.*

58.5 Decision-theoretic and paradigm-shift theorems

Theorem 137 (Log-linear tradeoff form)**.** *Assume* $\mathrm{Supp}_\beta(m) \in (0,1]$ *for all* m*. Then maximizing* $\mathsf{Score}_{P,\beta}(m)$ *is equivalent to minimizing*

$$\mathcal{L}_{P,\beta}(m) := -\log \mathrm{Supp}_\beta(m) \;+\; \lambda_c \mathrm{Comp}_P(m) \;+\; \lambda_p \mathrm{Prag}_P(m).$$

Remark 3193. *This theorem says that CPP selection is an "energy minimization" problem: evidential support contributes a term* $-\log \mathrm{Supp}$*, and the two weakness channels contribute additive penalties. This is important because additive objectives are often easier to analyze, optimize, and differentiate than multiplicative ones; it also aligns CPP with familiar statistical mechanics and Bayesian model selection heuristics (where* $-\log$ *turns products into sums).*

It connects directly to the definition of $\mathsf{Score}_{P,\beta}$*: the product structure is not a mere convenience; it implies that the tradeoff surface is linear in* (λ_c, λ_p) *once we take logs. This observation will also underlie the robustness region theorem, where continuity in* (λ_c, λ_p) *is central.*

Proof. For $x > 0$, log is strictly increasing, so

$$\arg\max_m \mathsf{Score}(m) = \arg\max_m \log \mathsf{Score}(m) = \arg\max_m \big(\log \mathrm{Supp}(m) - \lambda_c \mathrm{Comp}(m) - \lambda_p \mathrm{Prag}(m)\big),$$

equivalently $\arg\min_m \mathcal{L}(m)$. $\square$

Proof sketch. Apply a strictly increasing transform (log) to preserve argmax, then expand log of the product into a sum. Move the minus signs to convert a maximization to a minimization. $\square$

Remark 3194. *The key step is the monotonicity of* log*, which preserves preference order. The rest is algebra: exponentials and logarithms are inverse, so costs become linear penalties. Visually, one goes from multiplying three "dials" to adding three "weights".*

Theorem 138 (Multi-channel Occam principle)**.** *Fix* P, β*. If two models* m_1, m_2 *satisfy:*

$$\mathrm{Supp}_\beta(m_1) = \mathrm{Supp}_\beta(m_2), \qquad \mathrm{Prag}_P(m_1) = \mathrm{Prag}_P(m_2), \qquad \mathrm{Comp}_P(m_1) < \mathrm{Comp}_P(m_2),$$

then $\mathsf{Score}_{P,\beta}(m_1) > \mathsf{Score}_{P,\beta}(m_2)$*.*

Remark 3195. *This is the expected Occam-style conclusion, but now explicitly "multi-channel": holding evidence and pragmatic usefulness fixed, cultural simplicity breaks ties. The result is not surprising, yet it is important because it clarifies exactly what kind of simplicity principle is being assumed: simplicity is not absolute but indexed by P (the paradigm), i.e. by what the culture takes as primitive and cheap to express (Hyperseed-Concepts 91, 82) [20].*

In the broader structure of this section, this theorem is the local (pairwise) version of the later Pareto-pruning theorem, which generalizes "break ties by simplicity" to "discard anything dominated in all channels."

Proof. With equal support and equal pragmatic factor,

$$\frac{\mathsf{Score}(m_1)}{\mathsf{Score}(m_2)} = \frac{e^{-\lambda_c \mathrm{Comp}(m_1)}}{e^{-\lambda_c \mathrm{Comp}(m_2)}} = e^{-\lambda_c(\mathrm{Comp}(m_1)-\mathrm{Comp}(m_2))} > 1$$

since $\lambda_c > 0$ and $\mathrm{Comp}(m_1) - \mathrm{Comp}(m_2) < 0$. □

Proof sketch. Cancel the equal multiplicative factors, compare the remaining exponential penalties, and use that $e^{-\lambda x}$ decreases strictly in x when $\lambda > 0$. □

Remark 3196. *The ratio trick isolates the only relevant difference between the two models. Once reduced to comparing two exponentials, the inequality follows immediately from the monotonicity of the exponential function.*

Theorem 139 (Pareto-dominance pruning (weight-robust selection))**.** *Fix P, β and assume $\lambda_c, \lambda_p > 0$. If m_1, m_2 satisfy*

$$\mathrm{Supp}_\beta(m_1) \geq \mathrm{Supp}_\beta(m_2), \quad \mathrm{Comp}_P(m_1) \leq \mathrm{Comp}_P(m_2), \quad \mathrm{Prag}_P(m_1) \leq \mathrm{Prag}_P(m_2),$$

with at least one inequality strict, then $\mathsf{Score}_{P,\beta}(m_1) > \mathsf{Score}_{P,\beta}(m_2)$. In particular, m_2 can be discarded without knowing the exact relative tradeoff magnitudes, so long as channel weights are positive.

Remark 3197. *This theorem says: if one model is at least as good in evidential support and no worse in either cultural or pragmatic cost (and strictly better in at least one channel), then it wins for* every *positive choice of weights. This is a crucial computational principle: it provides a safe pruning rule that reduces the search space before any delicate calibration of λ_c, λ_p.*

The connection to "weakest selection" is direct: Pareto-dominance is the partial order induced by simultaneously pursuing weakness in multiple senses. In practice, it gives a robust notion of "dominated hypotheses" that can be discarded even under uncertainty about community preferences.

Proof. The score is monotone increasing in Supp and monotone decreasing in both costs (because $m \mapsto e^{-\lambda m}$ is strictly decreasing for $\lambda > 0$). Thus each weakly improved coordinate weakly improves Score, and any strict improvement yields a strict improvement in the product. □

Proof sketch. Use coordinatewise monotonicity: increasing Supp helps, decreasing costs helps. Because the score is a product of positive terms, any strict improvement in any factor yields a strict improvement in the product. □

Remark 3198. *One may picture the triple* $(\mathrm{Supp}, -\mathrm{Comp}, -\mathrm{Prag})$ *as a point in $\mathbb{R}^3$ ordered coordinatewise. Pareto-dominance means lying "northeast" of another point; the theorem says the scoring function respects this order whenever the weights are positive.*

Theorem 140 (Paradigm-shift as preference reversal)**.** *Let P and P' be two paradigms with the same $(E, O, \mathrm{Obs}, \mathcal{M}, R, \mathrm{Adeq})$ and the same belief state β, but different cultural semantics $\mathrm{Comp}_P, \mathrm{Comp}_{P'}$ (or weights). Assume m_1, m_2 satisfy $\mathrm{Supp}_\beta(m_1) = \mathrm{Supp}_\beta(m_2)$ and $\mathrm{Prag}_P = \mathrm{Prag}_{P'}$ on $\{m_1, m_2\}$. If*

$$\mathrm{Comp}_P(m_1) < \mathrm{Comp}_P(m_2) \quad \textit{and} \quad \mathrm{Comp}_{P'}(m_1) > \mathrm{Comp}_{P'}(m_2),$$

then P prefers m_1 while P' prefers m_2 (i.e. the argmax flips).

Remark 3199. *Here "paradigm shift" is rendered as a precise mathematical possibility: two communities can agree on the evidence, the experiment class, the model class, and the inferential rules, and yet disagree on which model is preferable because they disagree on what counts as "simple." This is important because it shows how incommensurability can arise* without *abandoning formal rationality: it is implemented as a change of cost semantics (Hyperseed-Concept 91) [20]. More explicitly, the hypotheses $\mathrm{Supp}_\beta(m_1) = \mathrm{Supp}_\beta(m_2)$ and $\mathrm{Prag}_P = \mathrm{Prag}_{P'}$ on $\{m_1, m_2\}$ ensure that (for this pair) there is no disagreement about evidential fit or action-guiding utility; the only remaining discriminator in the score is the cultural-complexity channel. In this sense, the theorem isolates a "pure" paradigm effect: the preference reversal is not driven by new data, new goals, or changes in the inferential machinery, but by a re-encoding of which descriptions are treated as costly.*

The result links back to the CPP-paradigm definition: Comp_P is explicitly paradigm-relative, so preference reversals are not anomalies but expected phenomena when Comp *changes. Equivalently, even if two agents share a common β (so they update identically under R on* Obs*) and share the same pragmatic evaluation functional on the candidate set, a shift in* Comp *can still change the ordering induced by* Score *and hence change the selected model. This recovers, in a deliberately minimal formal setting, the familiar methodological phenomenon that "simplicity" (or "naturalness," "elegance," "explanatory unity") is not a purely syntactic property but depends on background representational commitments.*

Proof. By the multi-channel Occam theorem applied in each paradigm separately: under P the smaller Comp_P wins; under P' the smaller $\mathrm{Comp}_{P'}$ wins. Since $\mathrm{Supp}_\beta(m_1) = \mathrm{Supp}_\beta(m_2)$ and $\mathrm{Prag}_P = \mathrm{Prag}_{P'}$ on $\{m_1, m_2\}$, the score comparison between m_1 and m_2 reduces to comparing the terms involving Comp alone; the stated strict inequalities therefore force opposite strict score orderings in P and P'. □

Proof sketch. Reduce each paradigm's choice to the Occam tie-breaker because support and pragmatics are equal on the pair; then apply the opposite inequalities for Comp_P and $\mathrm{Comp}_{P'}$. The argmax flips because each paradigm induces a different strict total order on $\{m_1, m_2\}$ once all other channels are held fixed. □

Remark 3200. *The proof is short because the conceptual work was already done in the definitions: by explicitly factoring out the paradigm dependence into Comp_P, we make preference reversal an immediate corollary rather than a mysterious sociological exception. In particular, the theorem should be read as a structural claim about the scoring functional: whenever the decision rule is multiplicatively (or additively in log-space) separable into evidential support and cost-like channels, any channel whose semantics is allowed to vary with culture can induce reversals even under full agreement elsewhere. This clarifies why debates over "simplicity" can be both persistent and rational: the disagreement may concern the mapping from descriptions to costs, not the correctness of the underlying updating rule.*

Theorem 141 (Robustness region under small channel-weight changes)**.** *Assume $\mathcal{M}$ is finite and $\mathrm{Supp}_\beta(m) \in (0, 1]$ for all m. Fix a paradigm with fixed costs* Comp, Prag *but variable weights*

$(\lambda_c, \lambda_p) \in (0,\infty)^2$. *If* $m^\star$ *is a* unique *maximizer of* $\mathsf{Score}(m; \lambda_c, \lambda_p)$ *at* $(\lambda_c^0, \lambda_p^0)$*, then there exists* $\delta > 0$ *such that* $m^\star$ *remains the unique maximizer for all* (λ_c, λ_p) *with* $|\lambda_c - \lambda_c^0| < \delta$ *and* $|\lambda_p - \lambda_p^0| < \delta$.

Remark 3201. *This is a stability theorem: if the currently chosen model is not merely best but* separated *from its competitors, then small changes in how much we care about simplicity vs. pragmatics will not change the choice. The importance is operational: it tells a reasoning system when it can safely act without finely tuning the channel weights, because the decision lies in a robust region of parameter space. One can think of* (λ_c, λ_p) *as "attention" or "regularization" parameters for the cultural and pragmatic channels: increasing* λ_c *penalizes complexity more heavily, while increasing* λ_p *penalizes pragmatic cost more heavily. The theorem then says that if* $m^\star$ *wins with a strict margin at* $(\lambda_c^0, \lambda_p^0)$*, there is an open neighborhood of weights around that point in which no competitor overtakes it. In practice, this is the mathematical content of the intuition that only near-ties are sensitive to minor reweightings.*

It connects naturally to the Pareto-pruning theorem: pruning removes dominated alternatives, which often increases the "margin" by which the best model wins, thereby enlarging robustness neighborhoods. Stated differently, removing models that can never win for any admissible weight choice reduces the number of potential "boundary crossings" in weight space, so the region in which $m^\star$ *is stable typically becomes easier to characterize and, in many cases, larger.*

Proof. For each fixed m, the function

$$(\lambda_c, \lambda_p) \mapsto \mathsf{Score}(m; \lambda_c, \lambda_p) = \mathrm{Supp}(m) \exp(-\lambda_c \mathrm{Comp}(m)) \exp(-\lambda_p \mathrm{Prag}(m))$$

is continuous. Since $\mathcal{M}$ is finite, the function $\Delta(\lambda_c, \lambda_p) := \mathsf{Score}(m^\star) - \max_{m \neq m^\star} \mathsf{Score}(m)$ is continuous and satisfies $\Delta(\lambda_c^0, \lambda_p^0) > 0$. By continuity, Δ remains > 0 in some neighborhood of $(\lambda_c^0, \lambda_p^0)$. Concretely, letting $\varepsilon := \Delta(\lambda_c^0, \lambda_p^0)/2 > 0$, continuity implies the existence of $\delta > 0$ such that whenever (λ_c, λ_p) lies within δ (in the stated coordinate-wise sense), one has $|\Delta(\lambda_c, \lambda_p) - \Delta(\lambda_c^0, \lambda_p^0)| < \varepsilon$, hence $\Delta(\lambda_c, \lambda_p) > \varepsilon > 0$, which preserves strict optimality. ☐

Proof sketch. Define a positive "gap" between the best model and the best runner-up. The gap is continuous in the weights (finite max of continuous functions). A positive value at the reference point implies positivity in a neighborhood, preserving uniqueness of the maximizer. Equivalently, the argmax map is locally constant at any point where the best model strictly beats all others. ☐

Remark 3202. *The finiteness of* $\mathcal{M}$ *is what prevents pathological "near-ties" accumulating from infinitely many alternatives. Geometrically, in the* (λ_c, λ_p) *plane, the boundaries where the argmax changes are curves; a strict argmax point lies away from these curves, hence has an open neighborhood with constant argmax. A useful equivalent viewpoint is obtained by taking logs:* $\log \mathsf{Score}(m) = \log \mathrm{Supp}(m) - \lambda_c \mathrm{Comp}(m) - \lambda_p \mathrm{Prag}(m)$*, so comparisons between any two models become linear inequalities in* (λ_c, λ_p)*. For a fixed pair* $(m^\star, m)$*, the locus where they tie is (typically) a line in weight space (or empty, depending on parameters), and the region where* $m^\star$ *beats* m *is a half-plane. When* $\mathcal{M}$ *is finite, the robustness region for* $m^\star$ *can be seen as the intersection of finitely many open half-planes, hence itself open, matching the neighborhood conclusion of the theorem. The condition* $\mathrm{Supp}_\beta(m) \in (0,1]$ *avoids degenerate cases where a model has zero support and is therefore irrelevant to the argmax regardless of weights; it ensures the score remains strictly positive so that the continuity argument applies cleanly without having to treat* 0 *as a boundary value.*

58.6 Method/path-independence and non-explosion theorems

Theorem 142 (Batching and order-independence of scientific updates)**.** *Let* $\varepsilon_1, \ldots, \varepsilon_n : L \to V$ *be empirical evidence increments produced by a finite sequence of experiments in a fixed methodological* *rule set R. Define iterative updates $\beta_{k+1} := \mathrm{Cl}_R(\beta_k \oplus \varepsilon_{k+1})$. Then*

$$\beta_n = \mathrm{Cl}_R(\beta_0 \oplus \varepsilon_1 \oplus \cdots \oplus \varepsilon_n),$$

hence the final closed belief state depends only on the join-aggregate of increments, not on their order.

Remark 3203. *The theorem asserts a kind of "path-independence" for scientific updating: you may run experiments in any order, or even batch their evidence together and update once, and the eventual closed belief state is the same. This is important for both epistemology and engineering. Epistemologically, it expresses a minimal ideal of method-independence: what matters is the total evidential import, not the accident of sequence. Engineer-wise, it means you can cache increments, merge them asynchronously, and close only periodically, which is essential in distributed or resource-bounded reasoning systems [19].*

Formally, the commutativity/associativity of $\oplus$ captures the idea that evidence pooling is insensitive to order, while idempotence of closure captures the idea that "once you have fully propagated consequences, doing it again adds nothing."

Remark 3204. *It is helpful to make explicit the algebraic assumptions silently used by the statement. The operator $\oplus$ is the pointwise join on belief states (so $(\beta \oplus \varepsilon)(\varphi) = \beta(\varphi) \vee \varepsilon(\varphi)$ in the valuation lattice V), and Cl_R is a closure operator associated to the rule set R (in particular, extensive $\beta \leq \mathrm{Cl}_R(\beta)$, monotone $\beta \leq \beta' \Rightarrow \mathrm{Cl}_R(\beta) \leq \mathrm{Cl}_R(\beta')$, and idempotent $\mathrm{Cl}_R(\mathrm{Cl}_R(\beta)) = \mathrm{Cl}_R(\beta)$). Under these standard "methodological" constraints, the update map $\beta \mapsto \mathrm{Cl}_R(\beta \oplus \varepsilon)$ behaves like a confluent saturation procedure: evidence can be accumulated in any order, and closure merely computes the least R-stable belief state above the accumulated evidence.*

One can also view the theorem as a mild "confluence" or "Church–Rosser"-style property for the operational process of updating. Although no rewriting system is assumed here, the practical reading is analogous: intermediate normalization steps (closures) can be postponed, and different operational interleavings of evidence collection lead to the same normal form (the final closed belief state).

Proof. This is an induction on n using the closure-operator laws and associativity/commutativity of $\oplus$. For the inductive step, use idempotence $\mathrm{Cl}_R(\mathrm{Cl}_R(\cdot)) = \mathrm{Cl}_R(\cdot)$ to push intermediate closures to the end, and then use associativity of $\oplus$ to batch evidence. $\square$

Proof. For clarity, write $E_k := \varepsilon_1 \oplus \cdots \oplus \varepsilon_k$ (with E_0 the neutral element for $\oplus$, or simply omit it if $\oplus$ is defined as join so that $\beta_0 \oplus E_0 = \beta_0$). The claim is that for each $k \leq n$,

$$\beta_k = \mathrm{Cl}_R(\beta_0 \oplus E_k).$$

Base case $k = 0$ is immediate if we take β_0 already as the initial state; otherwise it holds after applying Cl_R once since Cl_R is extensive and idempotent.

Inductive step: assume $\beta_k = \mathrm{Cl}_R(\beta_0 \oplus E_k)$. Then

$$\beta_{k+1} = \mathrm{Cl}_R(\beta_k \oplus \varepsilon_{k+1}) = \mathrm{Cl}_R(\mathrm{Cl}_R(\beta_0 \oplus E_k) \oplus \varepsilon_{k+1}).$$

By monotonicity and extensiveness, $\mathrm{Cl}_R(\beta_0 \oplus E_k) \leq \mathrm{Cl}_R(\beta_0 \oplus E_k \oplus \varepsilon_{k+1})$, and hence

$$\mathrm{Cl}_R(\mathrm{Cl}_R(\beta_0 \oplus E_k) \oplus \varepsilon_{k+1}) \leq \mathrm{Cl}_R(\mathrm{Cl}_R(\beta_0 \oplus E_k \oplus \varepsilon_{k+1})).$$

Conversely, since $\beta_0 \oplus E_k \leq \mathrm{Cl}_R(\beta_0 \oplus E_k)$, we have

$$\beta_0 \oplus E_k \oplus \varepsilon_{k+1} \leq \mathrm{Cl}_R(\beta_0 \oplus E_k) \oplus \varepsilon_{k+1},$$

and by monotonicity of Cl_R,

$$\mathrm{Cl}_R(\beta_0 \oplus E_k \oplus \varepsilon_{k+1}) \le \mathrm{Cl}_R(\mathrm{Cl}_R(\beta_0 \oplus E_k) \oplus \varepsilon_{k+1}).$$

Combining these inequalities and using idempotence $\mathrm{Cl}_R(\mathrm{Cl}_R(\cdot)) = \mathrm{Cl}_R(\cdot)$ yields

$$\beta_{k+1} = \mathrm{Cl}_R(\beta_0 \oplus E_k \oplus \varepsilon_{k+1}) = \mathrm{Cl}_R(\beta_0 \oplus E_{k+1}),$$

where the last equality uses associativity (and commutativity if the increments are permuted). Setting $k = n$ proves the stated batching identity. □

Proof sketch. Induct on the number of increments. At each step, rewrite $\mathrm{Cl}_R(\mathrm{Cl}_R(\cdot)\oplus\varepsilon)$ as $\mathrm{Cl}_R(\cdot\oplus\varepsilon)$ using idempotence and monotonicity, then reassociate/commute joins to collect all increments together before a final closure. □

Remark 3205. *The key maneuver is "postponing closure": because Cl_R is idempotent, closing after each increment or only at the end yields the same result. Visually, you can imagine evidence increments as adding paint to a canvas and closure as letting the paint diffuse along rule-edges; diffusion can be done after each addition or after all additions, producing the same final saturation pattern.*

Remark 3206. *In the cultural-probabilistic-pragmatic framing, this captures a separation between (i) the contingent temporal history of laboratory practice (the order in which experiments are performed) and (ii) the stable methodological constraints encoded by R. The theorem does not claim that scientists in fact update in an order-free way, but that the* methodological idealization *represented by Cl_R and $\oplus$ yields an order-invariant fixed point when evidence is pooled. This is exactly the behavior one wants if R is meant to represent publicly shareable inferential norms: two communities that differ only in scheduling of experiments, but agree on R and on the multiset of increments, converge to the same closed state.*

Operationally, the result is also a robustness guarantee: intermediate closures can be viewed as "checkpointing" or "garbage collection" steps in a belief-maintenance engine. Since the final state is invariant under the placement of these checkpoints, implementations are free to trade off immediacy of closure against cost, without changing eventual conclusions (only the transient states).

Theorem 143 (Irrelevance / localized non-explosion)**.** *Fix rule set R. If no rule in R has conclusion $\psi \in L$, then for every belief state β,*

$$\mathrm{Cl}_R(\beta)(\psi) = \beta(\psi).$$

In particular, evidence and anomalies elsewhere cannot induce belief in ψ unless there is an explicit inferential path to ψ via R.

Remark 3207. *This theorem formalizes a basic sanity property: your inference rules cannot magically produce support for claims they never conclude. In paraconsistent and nonclassical settings this is sometimes called a non-explosion or locality property, but here it is a straightforward structural statement about the shape of the rule set (Hyperseed-Concept 98). It matters computationally: it guarantees that belief propagation is localized to the part of the language actually targeted by rules, enabling sparse implementations.*

It also provides a clean criterion for when "anomalies elsewhere" can matter: only if the rule graph contains a directed path of conclusions leading to ψ. Thus relevance is a property of the inferential wiring, not merely of the data.

Remark 3208. *The condition "no rule in R has conclusion ψ" can be read as a graph-theoretic boundary condition on the dependency network induced by R: ψ has in-degree 0 with respect to the directed edges "premises $\to$ conclusion." The theorem then says that ψ is a* sinkless *coordinate for the closure dynamics, so whatever happens elsewhere in the network (including inconsistent or highly activated regions) cannot leak into ψ without an explicit channel. This is the precise sense in which the framework prevents a global "blast radius" from contradictions: abnormality does not automatically propagate to unrelated claims unless the methodology actually links them.*

From the perspective of modular scientific models, this yields a formal justification for treating sublanguages as quasi-independent modules: if a module contains symbols never concluded by rules outside the module, then closure computations for those symbols can be performed locally and are invariant under external updates.

Proof. If ψ is never a rule conclusion, the one-step inference operator F_R leaves ψ unchanged (because the join over contributions to ψ is empty). Hence every iterate $F_R^k(\beta)(\psi) = \beta(\psi)$. Taking the join over k yields $\mathrm{Cl}_R(\beta)(\psi) = \beta(\psi)$. □

Proof. Unpacking the "empty join" point: by definition, $F_R(\beta)(\psi)$ is obtained by joining $\beta(\psi)$ with all supports contributed by rules in R whose conclusion is exactly ψ. If there are no such rules, the additional join is taken over an empty index set, which evaluates to the neutral (least) element for join in V, and thus does not change the value. Therefore $F_R(\beta)(\psi) = \beta(\psi)$, and by straightforward induction on k we obtain $F_R^k(\beta)(\psi) = \beta(\psi)$ for all $k \in \mathbb{N}$.

Finally, since $\mathrm{Cl}_R(\beta)$ is the (directed) join of these iterates (or, equivalently, the least fixed point above β), and since the ψ-coordinate is constant across all iterates, the join is the same constant. This shows that closure does not introduce any new support at ψ when R provides no inferential mechanism targeting ψ. □

Proof sketch. Observe that F_R updates each claim by joining the supports generated by rules concluding that claim. If there are no such rules for ψ, the update is vacuous, so iteration never changes ψ and neither does the limit. □

Remark 3209. *The crucial step is recognizing that the closure is built from iterating a local update operator. If the local update has no input channel for ψ, then ψ is an invariant coordinate of the dynamics.*

Remark 3210. *This invariance viewpoint also clarifies how the result interacts with methodological change. The theorem is parameterized by a fixed R: if one enlarges R by adding even a single rule with conclusion ψ, then ψ ceases to be an invariant coordinate and may begin to respond to evidence elsewhere (via the premises of the new rule). Thus, what counts as "irrelevant" is not an absolute property of the language L but a relative property of the chosen inferential practice. In the broader Hyperseed program, this matches the intended reading that relevance and possible propagation pathways are encoded in, and constrained by, explicit methodological commitments.*

58.7 Modularity/independence theorems (useful for decomposing science)

Theorem 144 (Rule-separable modularity (independence of sublanguages))**.** *Suppose the claim language decomposes as a disjoint union $L = L_1 \sqcup L_2$. Suppose the rule set decomposes as $R = R_1 \sqcup R_2$ where every rule in R_i has all premises and its conclusion in L_i (no cross-rules). Then for any belief state β,*

$$\mathrm{Cl}_R(\beta)\big|_{L_1} = \mathrm{Cl}_{R_1}(\beta|_{L_1}), \qquad \mathrm{Cl}_R(\beta)\big|_{L_2} = \mathrm{Cl}_{R_2}(\beta|_{L_2}).$$

Consequently, evidence increments supported only on L_1 do not affect closed beliefs on L_2, and vice versa. Moreover, the statement is robust under iterated updates: if $(\beta_t)_{t\geq 0}$ evolves by any sequence of updates that at each step modifies only coordinates in L_1, then the entire trajectory of closed beliefs on L_2 remains fixed, i.e. $\mathrm{Cl}_R(\beta_t)|_{L_2}$ is constant in t.

Remark 3211. *This is a domain decomposition theorem: if the language and rules split into two noninteracting parts, then scientific inference splits exactly as well. The importance is obvious for large systems: it justifies modular architectures where different subdisciplines (or different subsystems of a scientist-agent) can update internally without risking unintended contamination across unrelated domains (Hyperseed-Concept 93).*

One useful way to read the hypotheses is operational: a module boundary is not merely a partition of vocabulary, but a partition of inferential pathways. *Even if L_1 and L_2 are conceptually distinct, independence fails as soon as some rule can transport support across the boundary (e.g. a bridge principle, a calibration equation, or a measurement rule that links theoretical quantities in L_2 to observational claims in L_1). The theorem therefore singles out a formally checkable condition: scan the rule base for any premise–conclusion pattern whose symbols touch both sides.*

The result also provides a crisp criterion for when modularization is not *safe: the existence of even a single cross-rule creates a coupling that defeats exact independence, and then one needs approximate or bounded-dependency analyses (as developed elsewhere in the broader document). In practice, such "approximate" modularity can arise when cross-rules are present but weak, rarely activated, or quarantined behind explicit interface claims; the present theorem describes the idealized limit in which the interface is empty.*

Proof. Identify $V^L \cong V^{L_1} \times V^{L_2}$ via restriction. Under the "no cross-rules" assumption, F_R decomposes as $F_{R_1} \times F_{R_2}$ on this product. Least fixed points in a product of complete lattices are computed componentwise, so the least fixed point above β is the pair of least fixed points above each restriction. This yields the equalities. To make the componentwise computation explicit: if $F := F_R$ and $F_i := F_{R_i}$, then for $(x_1, x_2) \in V^{L_1} \times V^{L_2}$ we have

$$F(x_1, x_2) = (F_1(x_1), F_2(x_2)),$$

hence any post-fixed point condition $(x_1, x_2) \leq F(x_1, x_2)$ splits into $x_i \leq F_i(x_i)$, and the infimum of all such post-fixed points above $(\beta|_{L_1}, \beta|_{L_2})$ splits similarly. Equivalently, the Kleene iteration starting from β evolves independently on each coordinate. □

Proof sketch. Rewrite the global belief state as a pair of belief states on L_1 and L_2. With no cross-rules, one-step inference acts independently on each coordinate, so the closure (least fixed point above β) is just the pair of closures in each module. In particular, there is no stage of the iteration at which an L_1-supported change can alter the L_2-component, because rule firing in R_2 only ever inspects and writes L_2-claims. □

Remark 3212. *The core idea is that "no cross-rules" makes the inference operator block-diagonal. In linear algebra one would say the dynamics decouple; here, in order theory, the fixed points decouple. A further intuition is categorical: the closure construction behaves like a product construction when the rule base factors, so global inference is the product of local inferences. This matters for implementation: one may compute Cl_{R_1} and Cl_{R_2} in parallel and splice the results without any reconciliation step, because reconciliation would only be needed to enforce cross-constraints that do not exist in this setting.*

Theorem 145 (Collective closure dominance (social science-as-belief-system fact))**.** *Let $\{\beta_i\}_{i\in I}$ be belief states and define the collective join-aggregate $\beta_{\mathrm{col}} := \bigoplus_{i\in I} \beta_i$ (pointwise join). Then for every $i \in I$,*

$$\mathrm{Cl}_R(\beta_i) \le \mathrm{Cl}_R(\beta_{\mathrm{col}}).$$

Thus any inferential consequence available to an individual (under R) is also available to the collective when the collective retains all individuals' evidence. In particular, for any claim $\varphi \in L$ and any index i, if $\mathrm{Cl}_R(\beta_i)(\varphi)$ attains some support level, then the collective closure attains at least that level on the same claim.

Remark 3213. *This theorem articulates a minimal sense in which science is "social": if a community aggregates the evidence held by its members without loss, then after running the same inference rules it will contain at least what any one member could infer. It is not a claim about wisdom of crowds in any strong sense; it is simply the monotonicity of closure applied to an aggregated evidence base (Hyperseed-Concepts 170, **??**).*

The pointwise join $\bigoplus_{i\in I} \beta_i$ should be read as an "archival" idealization: every proposition receives whatever maximal degree of support any member assigns it. Under that reading, the theorem says that the community, viewed as a single epistemic agent that keeps a lossless record, cannot be inferentially *weaker than its strongest member with respect to the fixed rule base R. This is the precise sense in which distribution of labor helps: different members may contribute evidence on different parts of L, and the join combines these contributions before closure propagates them along rules.*

This structural fact is a prerequisite for more delicate analyses of cooperation vs. conflict, incentives, and norm formation; here we only need the order-theoretic monotonicity. In particular, the theorem does not address whether the collective will be better calibrated *or* less biased, *because those are properties not captured by the mere partial order on belief states unless additional scoring or semantics are imposed.*

Proof. Since $\beta_i \le \beta_{\mathrm{col}}$ pointwise and Cl_R is monotone, we get $\mathrm{Cl}_R(\beta_i) \le \mathrm{Cl}_R(\beta_{\mathrm{col}})$. Concretely, the inequality $\beta_i \le \bigoplus_{j\in I} \beta_j$ holds at each coordinate $\varphi \in L$ by the defining property of join, and monotonicity transports this coordinatewise domination through the closure operator. □

Proof sketch. The collective state is an upper bound of each individual state. Monotonicity of closure preserves the ordering, so the collective closure dominates each individual closure. If one imagines the closure as "running" the rule engine until saturation, then starting from a state with (weakly) more support everywhere cannot lead to a saturated state with less support anywhere. □

Remark 3214. *The proof is one line because the theorem is really a definition: "collective" here means "keeping everything anyone has" via join. The interesting questions begin when aggregation is lossy, weighted, strategic, or inconsistent; those require extra structure beyond this minimal lemma. One immediate extension, for example, is to replace the pure join by a constrained aggregator (e.g. bounded confidence, trust networks, or resource-limited communication) and then ask for sufficient conditions under which a weaker dominance relation still holds approximately.*

58.8 State-dependent science and observer-state paradigms

Theorem 146 (State-dependent science as ordinary science on an expanded experiment space)**.** *Let S be a set of community-accessible states and for each $s \in S$ let $\mathrm{Obs}_s : E_s \to O$ be a state-indexed observation map. Define the expanded experiment space*

$$\widetilde{E} := \{(s, e) : s \in S,\ e \in E_s\}$$

and observation map $\widetilde{\mathrm{Obs}} : \widetilde{E} \to O$ *by* $\widetilde{\mathrm{Obs}}(s,e) := \mathrm{Obs}_s(e)$. *Then any state-dependent science family* $\{(B_s, R_s, \mathrm{Obs}_s)\}_{s\in S}$ *can be represented as an ordinary Hyperseed science instance on* $\widetilde{E}$ *by treating "state" as part of experimental context. Conversely, any ordinary science instance on* $\widetilde{E}$ *decomposes into a state-dependent family by restriction.*

In particular, one may view $\widetilde{E}$ *as a "tagged union" (a disjoint union) of the state-specific experiment spaces:*

$$\widetilde{E} \;\cong\; \bigsqcup_{s\in S} \big(\{s\} \times E_s\big),$$

so that the state label plays the same role as any other experimental descriptor (instrument setting, protocol version, lab condition), and the observation rule is uniformly a single map defined on the union.

Remark 3215. *The theorem says that "state-dependent" science is not a fundamentally different beast: it is ordinary science performed on a richer experiment space where the state label is included as part of the experimental description. This is a common mathematical move: contextual variation is represented by enlarging the domain so that context becomes explicit data. In epistemic terms, it formalizes the idea that observer-state (or environmental state) is part of what makes an experiment what it is (Hyperseed-Concept 86) [20].*

Practically, this means we can reuse the same update/closure algorithms even when observations depend on state (e.g. different calibration regimes, sensor modes, or community conditions), simply by lifting experiments to pairs (s, e).

One can also read the construction as an explicit bookkeeping device for what is sometimes informally described as "conditioning on the observer" or "conditioning on the measurement context." Once s *is included in the experimental description, statements that would otherwise appear to conflict across states become compatible as statements about different regions (fibers) of a single space* $\widetilde{E}$.

Proof. This is a set-theoretic repackaging: the data of maps $\mathrm{Obs}_s : E_s \to O$ is equivalent to a single map on the disjoint union (or subset of the product) of all (s, e) pairs. All update/closure constructions then apply verbatim. Restriction along the inclusion $E_s \hookrightarrow \widetilde{E}$ recovers each state-specific instance.

Concretely, let $\iota_s : E_s \to \widetilde{E}$ be the injection $\iota_s(e) = (s, e)$. Then $\widetilde{\mathrm{Obs}} \circ \iota_s = \mathrm{Obs}_s$ for each s, so every state-indexed observation family factors through the single map $\widetilde{\mathrm{Obs}}$. Conversely, given $\widetilde{\mathrm{Obs}} : \widetilde{E} \to O$, define $E_s := \{e : (s, e) \in \widetilde{E}\}$ and $\mathrm{Obs}_s(e) := \widetilde{\mathrm{Obs}}(s, e)$; this recovers the original family by restriction to each fiber $\{s\} \times E_s$. The same fiberwise restriction applies to any additional structure carried by the instance (e.g. belief/state objects B_s and rule components R_s) provided they are likewise indexed by s or induced from data on $\widetilde{E}$. □

Proof sketch. Bundle all state-indexed experiment sets into one disjoint union indexed by s. Define a single observation map on the union by applying the appropriate Obs_s. Then "state-dependent updates" become ordinary updates on the enlarged set, and conversely restricting to each fiber recovers the original family.

Equivalently, think of s as an extra input to the experimental protocol: the update mechanism does not need to know anything metaphysically special about states; it simply operates on experiments with an additional label. □

Remark 3216. *The key step is recognizing that a family of functions* $\{\mathrm{Obs}_s\}$ *is the same thing as a single function on a tagged union. Visually, one stacks the different state-specific experiment spaces into layers and regards the stack as one big space.*

From the point of view of observer-state paradigms, this stacking clarifies what varies and what does not: what varies across s is the observational interface (what is registered as O for a given underlying trial e), while the global representation keeps a fixed codomain O and a uniform update story. In CPP terms, the "observer state" becomes part of the evidential context rather than an external qualifier attached after the fact, so comparisons across communities or modalities are comparisons across fibers inside $\widetilde{E}$ rather than comparisons of incommensurable experiment spaces.

58.9 Three-tier artificial scientist: a lifting theorem

Definition 528 (Tiered search spaces)**.** *Let $\mathcal{P}$ be a set of paradigms. For each $P \in \mathcal{P}$ let $\mathcal{M}_P$ be its model class. Define the lifted hypothesis space*

$$\widehat{\mathcal{M}} := \{(P, m) : P \in \mathcal{P},\ m \in \mathcal{M}_P\}.$$

Define a meta-complexity $\mathrm{Comp}_{\mathrm{meta}} : \mathcal{P} \to [0, \infty)$ *and a lifted score*

$$\widehat{\mathsf{Score}}_\beta(P, m) := \mathsf{Score}_{P,\beta}(m)\ e^{-\lambda_{\mathrm{meta}}\mathrm{Comp}_{\mathrm{meta}}(P)}.$$

In this notation, $\mathsf{Score}_{P,\beta}(m)$ is the within-paradigm score (or utility) assigned to a model m when evidence and inductive preferences are interpreted under P; the parameter β may be read as an inverse-temperature or rationality/selection-strength parameter that controls how sharply the scoring function concentrates on high-performing models. The coefficient $\lambda_{\mathrm{meta}} \geq 0$ controls the strength of the meta-level penalty and makes explicit that "paradigm cost" is conceptually distinct from ordinary within-paradigm complexity penalties: it acts uniformly on all models inside the same P.

Remark 3217. *This definition makes explicit a hierarchy of choices: not only do we choose a model m, we may also choose the paradigm P that supplies the semantics of evidence, simplicity, and usefulness (Hyperseed-Concepts 91, 64). The lifted space $\widehat{\mathcal{M}}$ is simply the set of all such pairs; it is the natural search space for an "artificial scientist" that can revise its methodological commitments.*

The meta-complexity $\mathrm{Comp}_{\mathrm{meta}}$ *expresses that paradigms themselves can be more or less costly: adopting a paradigm may require learning new primitives, instruments, or practices. The exponential penalty mirrors the within-paradigm penalties: we treat paradigm complexity as another weakness channel, now at a higher level of organization [3, 19].*

One way to read the construction is as an explicit three-tier separation of concerns: (Tier 1) evaluate candidate models m given a fixed P; (Tier 2) compare models across candidates within a single sheet $\mathcal{M}_P$ using $\mathsf{Score}_{P,\beta}$; (Tier 3) compare entire sheets (paradigms) using $\mathrm{Comp}_{\mathrm{meta}}$ *as a higher-order regularizer that captures the cost of adopting the sheet itself. The "lifting" step turns this nested decision into a single optimization over a product-like space, while still preserving the interpretive fact that $\mathsf{Score}_{P,\beta}$ depends on P through the meaning of data, observables, and acceptable forms of explanation.*

Theorem 147 (Paradigm innovation reduces to model selection on a lifted space)**.** *Assume $\widehat{\mathcal{M}}$ is finite. Then there exists at least one pair $(P^\star, m^\star)$ maximizing $\widehat{\mathsf{Score}}_\beta(P, m)$ over $\widehat{\mathcal{M}}$. Moreover, searching over paradigms and models (Tier 3) is formally identical to searching over the lifted hypothesis space $\widehat{\mathcal{M}}$ (Tier 2) with an additional penalty on paradigm complexity.*

Remark 3218. *The theorem says that "paradigm innovation" can be treated as ordinary model selection, provided we lift the hypothesis space to include paradigms as part of the hypothesis. This is* *important because it demystifies a notion often treated as extra-rational: here it becomes an explicit optimization problem with a well-defined objective and (in the finite case) guaranteed solutions.*

In terms of the earlier crosswalk, this is the same structural move again: add a new weakness channel (meta-complexity) and then apply the same selection logic. This is precisely the kind of reuse that motivates encoding science in algebraic terms.

Operationally, this also clarifies what changes when an agent "switches paradigms": the agent is not merely changing parameter values within a fixed model class, but changing the very interpretation function that maps raw experience into evidence, as well as the catalogue of admissible hypotheses $\mathcal{M}_P$. In the lifted formulation, such a switch is represented by moving to a different value of P in the pair (P, m), with the cost of that move summarized by $\mathrm{Comp}_{\mathrm{meta}}(P)$. When λ_{meta} is large, the system is conservative and tends to stay within a paradigm unless the within-paradigm score gain is decisive; when λ_{meta} is small, the system is more willing to explore methodologically distant hypotheses.

Proof. A real-valued function on a finite set attains a maximum. The second claim holds because "choose a paradigm then choose a model" is equivalent to "choose a pair" and the lifted score makes the meta-objective explicit. In particular, the map $(P, m) \mapsto \widehat{\mathsf{Score}}_\beta(P, m)$ is a single objective on $\widehat{\mathcal{M}}$ whose factors separate into a within-paradigm component (depending on both P and m) and a paradigm-only component (depending only on P). This separation ensures that the two-stage reasoning about "first decide whether a paradigm is worth its adoption cost, then decide which model is best inside it" is representable without loss as a single argmax computation on pairs. □

Proof sketch. Finiteness implies the maximum exists. The equivalence of two-stage choice and pair choice is a basic set-theoretic identification: $\bigcup_{P \in \mathcal{P}} \{P\} \times \mathcal{M}_P$ is exactly the space of "paradigm then model" decisions. Under this identification, any algorithm that enumerates paradigms and then, for each paradigm, enumerates models, is simply enumerating $\widehat{\mathcal{M}}$ in a particular order; conversely, any procedure that searches $\widehat{\mathcal{M}}$ implicitly induces a (possibly interleaved) search schedule over paradigms and their internal model classes. □

Remark 3219. *The proof works because the lifted space has no hidden structure: it is literally a disjoint union of the model classes, tagged by paradigm. Visually, each paradigm contributes a sheet of models; we search across the stack of sheets with an added penalty depending only on which sheet we choose.*

This visualization also highlights an important modeling choice: because the penalty is paradigm-only, the relative ranking of models within *a paradigm is unaffected by* $\mathrm{Comp}_{\mathrm{meta}}(P)$*, while the relative ranking* across *paradigms is shifted by the paradigm penalty. That is,* $\mathrm{Comp}_{\mathrm{meta}}$ *behaves like an offset applied to all models in the sheet. If one wished to represent heterogeneity of transition costs inside a paradigm (e.g., some models requiring new instruments while others do not), that would correspond to pushing part of the meta-complexity down into* $\mathsf{Score}_{P,\beta}(m)$ *or refining P into sub-paradigms; the present formulation deliberately keeps the meta-level penalty coarse to isolate the lifting move itself.*

58.10 Summary (operational takeaways, stated as corollaries)

Corollary 53 (Caching and method flexibility)**.** *Because scientific updates batch and commute, a reasoning system can store and merge evidence increments in any order and close only at chosen times, without changing the final closed state (for fixed R).*

Remark 3220. *Operationally: evidence increments $\varepsilon_{e,o}$ can be treated as cacheable objects. One may accumulate them in a database, merge them by $\oplus$ (commutatively), and apply closure when* *computationally convenient. This is the algebraic justification for asynchronous and distributed "scientist agents" that do not require a single canonical experimental sequence [19]. In more explicit algebraic terms, if $\oplus$ is associative and commutative, then for any finite multiset of increments $\{\varepsilon_i\}_{i=1}^n$ one has*

$$\varepsilon_{\text{tot}} \;=\; \bigoplus_{i=1}^{n} \varepsilon_i$$

independent of evaluation order, so the system can implement $\oplus$ via streaming updates, batch jobs, or federated merges. The clause "for fixed R" matters operationally: the invariance claim assumes the same rule set R (and hence the same closure operator) is applied at the end, so that only the scheduling *of updates changes, not the inferential policy. Practically, this supports architectures in which agents publish signed increments (provenance-preserving), a coordinator (or peer network) reconciles them via $\oplus$, and closure is applied only when a query arrives or when compute budgets allow. When closure is expensive, one can also maintain intermediate partially-closed states, provided the eventual closure result is taken with respect to the full merged increment and the same R.*

Corollary 54 (Model pruning under uncertain cultural/pragmatic weights)**.** *If a candidate model is Pareto-dominated in the three channels (support, cultural cost, pragmatic cost), it can be discarded regardless of the precise positive channel weights.*

Remark 3221. *This is a concrete decision tool: before debating the exact values of λ_c and λ_p, one can eliminate any model that is strictly worse in at least one channel and no better in any channel. The corollary thus separates* structural *inferiority (dominance) from* parametric *disagreement (tradeoff tuning). Concretely, write each model M as a triple*

$$\mathbf{v}(M) \;=\; \big(s(M),\, c(M),\, p(M)\big),$$

where s is to be maximized (support) while c, p are to be minimized (costs). Then M_1 Pareto-dominates M_2 if $s(M_1) \geq s(M_2)$, $c(M_1) \leq c(M_2)$, $p(M_1) \leq p(M_2)$, and at least one inequality is strict. Under any aggregator that is strictly increasing in s and strictly decreasing in c, p (e.g., a weighted objective with positive weights), dominance implies M_1 scores strictly better than M_2 without needing to know the particular weight values. Operationally, this means one can compute a Pareto frontier early (as a preprocessing step), shrinking the candidate set before engaging in culturally or pragmatically sensitive deliberation about acceptable tradeoffs. It also clarifies what kinds of disagreement remain after pruning: only models on the frontier can be selected differently by different communities or deployment contexts via different (λ_c, λ_p).

Corollary 55 (Safe modularization)**.** *If the rule graph splits into independent sublanguages, scientific inference decomposes exactly; updates in one module cannot contaminate beliefs in the other.*

Remark 3222. *This provides an exact criterion for when disciplinary or subsystem boundaries are formally justified: if there are no cross-rules, then there is no cross-inference. It is, in effect, a theorem about the integrity of partitions in a belief system (Hyperseed-Concepts 64, 93). More precisely, if the language (or symbol set) factors as $L = L_1 \cup L_2$ with $L_1 \cap L_2 = \varnothing$, and the rule set factors as $R = R_1 \cup R_2$ where every rule in R_i mentions only symbols from L_i, then the dependency (rule) graph has no edges between the components, and closure on the union decomposes into separate closures on each component. Under these conditions, an increment whose content lies wholly in L_1 can change only the L_1-restricted beliefs, because there exists no derivational path (via R) into L_2. This gives a practical test for modular system design: audit whether any* *rule, bridge principle, shared latent variable, or shared measurement predicate straddles the two vocabularies; if so, strict non-contamination no longer holds and one must treat the modules as coupled. Conversely, when the criterion is satisfied, one can parallelize inference, store module-local caches, and even enforce access control or governance boundaries per module without risking hidden inferential leakage across the partition.*

59 Surprisingness, Weakness, and Science in the Hyperseed Ontology: A Quantale-Compositional Bridge

We connect (A) Hyperseed's "surprise-adjusted implication" score for beliefs (surprisingness given complexity) and its formalization of science as empirically coupled belief-system dynamics, with (B) an inference-centric quantale calculus of surprisingness in which surprise is the marginal value of additional inference budget. This yields concrete theorems showing that Hyperseed's belief surprise is an instance of budget-residual surprise (ratio and tropical forms), inherits telescoping and chain rules, and can be robustified across contexts/experiments via a weakness (infimum) operator. We also formalize the sense in which both scientists and ordinary curious minds are engaged in a surprise-seeking loop: both are special cases of question/answer/belief dynamics that aim (among other goals) to generate high-surprise beliefs and hypotheses without collapsing coherence.

Concretely, the intended reading is that a belief (or hypothesis) is evaluated under two coupled pressures: it should be supported by the available empirical and inferential process, yet it should not be "too easy" in the sense of being fully predicted by its descriptive simplicity alone. In Hyperseed language, the "surprise-adjusted implication" score is designed to reward beliefs whose support rises sharply when additional inference is performed, relative to what one would expect from their complexity penalty. In the quantale reading, this same intuition is captured by comparing two evaluations (e.g. "support after spending budget b" vs. "baseline support from prior simplicity"), and taking a residuated difference that measures the incremental budget required to bridge the gap. The result is not merely an analogy: it is a way to translate between a cognitive/ scientific narrative and a compositional algebra of updates.

The phrase "marginal value of additional inference budget" is meant operationally: if one views inference as a resource-bounded process (time, compute, attention, experimental cost, or social coordination), then surprise is what is gained when that resource bound is relaxed. This makes the budget parameter explicit in the semantics of belief revision: surprise is not only a property of a statement, but of a statement *relative to* a process and a constraint. The quantale framework packages this dependence in a way that supports composition: sequential inference steps combine, and so do their associated surprise contributions, which is precisely what later yields telescoping and chain rules.

The two advertised forms—ratio and tropical—correspond to two common ways of representing this budget-residual comparison. In the ratio form, surprise is expressed as a multiplicative residual: one asks for the least factor by which the budget (or the evaluative strength) must be scaled so that the post-inference evaluation dominates the baseline. In the tropical form, multiplicative structure is log-transformed into addition, so surprise becomes an additive residual (a minimal increment), which is often more interpretable as "extra effort" or "extra evidence" required. The point of including both is that Hyperseed-like scores are frequently reported in multiplicative language (implication strength adjusted by complexity), while compositional reasoning about sequential updates often becomes cleaner in additive (tropical) coordinates.

The robustness claim via weakness (infimum) is likewise intended in an operational sense. When a belief is tested across contexts—different experimental conditions, different background assumptions, different communities, or different data sources—one wants a conservative aggregate that does not overfit to a single favorable setting. The weakness operator acts as a least-commitment aggregator: by taking an infimum over contexts, it selects what is uniformly supported (and uniformly surprising) rather than what is maximized by cherry-picked circumstances. In later results, this infimum-based robustness interacts well with compositional laws, so that robust surprise bounds can be propagated through chains of reasoning without having to re-derive everything from scratch.

Remark 3223. *Philosophically, the bridge in this section is a bridge between two notions of "novelty." One notion is epistemic and social: a community (or a mind) is surprised when, after it performs more inference and integrates more evidence, certain claims become notably more supported than one would expect from their simplicity alone. The other notion is algebraic: "surprise" is a residuated difference between two evaluations living in a quantale, and therefore inherits compositional laws (telescoping, factorization, robustness via infima) almost for free.*

Remark 3224. *The epistemic/social notion of novelty implicitly involves a dynamics: questions are posed, candidate answers are proposed, and beliefs are updated under constraints of coherence and limited resources. What is "surprising" in this sense is not merely what is improbable under a static prior, but what resists being explained away by cheap descriptions, routine heuristics, or low-effort inference. The algebraic notion makes this dynamic explicit by treating evaluation as something that changes with budget, and by measuring surprise as a residual that tracks the* least additional *budget needed to obtain a given improvement in evaluation. This makes it natural to speak about the distribution of surprise across a multi-step inquiry: telescoping identities state that total surprise over a path can be decomposed into stepwise contributions, while chain rules state that conditioning on intermediate results factors the surprise in a way compatible with sequential question answering.*

Remark 3225. *In Hyperseed terms [1], this section touches several core ideas: belief systems (Hyperseed-Concept 64), questions and answers (Hyperseed-Concept 144, 56), patterns (Hyperseed-Concept 130), and weakness as a robustness/least-commitment principle (Hyperseed-Concept 202, 143). On the philosophy-of-science side, the operational reading of science as an empirically coupled communal belief dynamics aligns with the social-computational-probabilistic view [20].*

59.1 Background

Inference-centric surprisingness. The "Calculus of Surprisingness" defines a budget-indexed evaluation map $B \mapsto TV_B(\varphi)$ and defines surprise as a residual/distance between $TV_{B_0}(\varphi)$ and $TV_{B_1}(\varphi)$. In particular, in the residual-form one defines

$$\mathrm{Surp}_{B_0 \to B_1}(\varphi) := TV_{B_0}(\varphi) \Rightarrow TV_{B_1}(\varphi),$$

in a residuated quantale. Surprise then composes across budgets (via-point / telescoping laws) and families can be robustified via a weakness operator (infimum over families of patterns).

Remark 3226. *The motivating picture is mundane but deep: one runs a weak reasoning procedure (small budget B_0), obtains some evaluation of φ, then permits a stronger reasoning procedure (larger budget B_1), and asks: how much did the evaluation move? If it moved a lot, φ was "surprising" relative to what was available under the weaker regime. This is a direct formalization of the common experience that many ideas look implausible until one performs the extra reasoning steps that reveal a hidden constraint or a previously unseen connection (compare the broad pattern-emergence viewpoint in [5]).*

A key technical point is that the use of the residual $\Rightarrow$ is not merely a convenient choice of "distance-like" primitive: in a residuated quantale it is exactly the structure that makes budget-composition algebraic. Concretely, if $\otimes$ is the quantale multiplication, then residuation is characterized by the adjunction

$$a \otimes c \leq b \quad \text{iff} \quad c \leq (a \Rightarrow b),$$

so that $a \Rightarrow b$ can be read as the least multiplicative "effort" c that, when combined with a, reaches (or exceeds) b. Under the intended reading $a = TV_{B_0}(\varphi)$ and $b = TV_{B_1}(\varphi)$, the surprise term $\mathrm{Surp}_{B_0 \to B_1}(\varphi)$ is thus the minimal factor (in the $\otimes$-sense) required to transform the weaker-budget evaluation into the stronger-budget evaluation.

The telescoping/via-point law alluded to above can be made explicit: for a chain of budgets $B_0 \leq B_1 \leq B_2$, one typically seeks inequalities (often equalities in well-behaved cases) of the general form

$$\mathrm{Surp}_{B_0 \to B_2}(\varphi) \;\leq\; \mathrm{Surp}_{B_0 \to B_1}(\varphi) \otimes \mathrm{Surp}_{B_1 \to B_2}(\varphi),$$

capturing the intuition that the total movement from B_0 to B_2 factors through intermediate budgets. This is the algebraic expression of the operational story: upgrades of inference power can be staged, and the surprisingness of the final outcome is compositional with respect to those stages.

Quantale examples. The same document highlights the ratio quantale and the tropical (max-plus) quantale:

$$Q_\times = ([0, \infty], \leq, \otimes = \times, \oplus = \max, 1 = 1, 0 = 0,\ a \Rightarrow b = b/a),$$

and

$$Q_+ = (\mathbb{R} \cup \{-\infty\}, \leq, \otimes = +, \oplus = \max, 1 = 0, 0 = -\infty,\ a \Rightarrow b = b - a).$$

These instantiate multiplicative lift and additive log-deltas respectively.

Remark 3227. *Here $Q_\times$ and Q_+ are the same information viewed in two coordinate systems. If one thinks of $TV_B(\varphi)$ as a nonnegative "score" (plausibility, utility, adequacy), then ratios naturally encode multiplicative improvement: "how many times larger did the score become?" If one takes logs, multiplication turns into addition and the residual becomes a difference. The tropical quantale Q_+ is precisely this log-domain picture, and it is often computationally natural because additive decompositions are easier to accumulate and to optimize.*

It is also helpful to record what "surprise" looks like in these two running examples. In the ratio quantale, assuming $TV_{B_0}(\varphi) > 0$, one has

$$\mathrm{Surp}_{B_0 \to B_1}(\varphi) = \frac{TV_{B_1}(\varphi)}{TV_{B_0}(\varphi)},$$

so that surprise is literally a gain factor. In the tropical quantale, one has

$$\mathrm{Surp}_{B_0 \to B_1}(\varphi) = TV_{B_1}(\varphi) - TV_{B_0}(\varphi),$$

so that surprise is a delta. Both are compatible with the same underlying idea: the residual measures the minimal increment (multiplicative or additive) that turns the earlier valuation into the later one, and the choice between $Q_\times$ and Q_+ amounts to a choice of scale on which "movement" should be linearized.

Hyperseed: belief surprise and productive belief systems. Hyperseed's formalization introduces a complexity cost $\mathrm{Comp}(\varphi)$ and a simplicity-biased prior weight $\mathrm{Prior}(\varphi) = e^{-\lambda \mathrm{Comp}(\varphi)}$, then defines a "surprise-adjusted implication" score

$$\mathrm{SAI}(\varphi; \beta, R) := \frac{\pi(\mathrm{Cl}_R(\beta \setminus \varphi)(\varphi))}{\mathrm{Prior}(\varphi)}.$$

A productive belief system is required (among other things) to regularly generate new high-SAI beliefs or new questions whose answers yield novel patterns, without collapsing coherence.

Remark 3228. *This is recognizably in the lineage of algorithmic and description-length ideas: complexity costs behave like code-lengths or description lengths, and priors like* $e^{-\lambda \mathrm{Comp}}$ *echo standard simplicity biases (cf. algorithmic information theory [16]). The novelty here is not the presence of a simplicity penalty but the way it is made to interact with inference closure* Cl_R *and with explicitly community-relative support.*

To connect this to the inference-centric picture, note that SAI is structurally a ratio of a support-like quantity to a simplicity prior. The numerator $\pi(\mathrm{Cl}_R(\beta \setminus \varphi)(\varphi))$ can be read as the degree to which φ becomes supported after closing a context in which φ has been hypothetically removed (or held out) from β, using a rule set R; in other words, it aims to isolate whether φ is redundant (derivable anyway) or whether it is a genuinely "productive" addition that changes what the system can infer. The denominator $\mathrm{Prior}(\varphi)$ then normalizes by simplicity, so that a complex φ must earn correspondingly higher support to achieve the same SAI. Under a ratio-quantale reading, this normalization already resembles a residual: it is a multiplicative comparison between an achieved evaluation and a baseline.

One can also interpret SAI as implementing a specific orientation convention for surprise: holding complexity fixed, higher $\pi(\cdot)$ increases SAI; holding support fixed, higher complexity decreases SAI. This makes explicit that Hyperseed's "surprisingness" is not only about inferential movement across budgets, but also about a tradeoff between inferential payoff and representational cost.

Hyperseed: science and thinking. Hyperseed models science as a community belief system with explicit empirical coupling: questions are experiments, answers are shared observations, and the update step is $\beta \leftarrow \mathrm{Cl}_R(\beta \oplus \varepsilon_{e,o})$ for an evidence increment $\varepsilon_{e,o}$. It also states an operational view of cognition: a system "knows" to the extent it can answer questions and "thinks" to the extent it can generate/select/refine questions, answers, and beliefs.

Remark 3229. *The conceptual move is to treat science not primarily as a list of doctrines, but as a disciplined variant of the question–answer loop (Hyperseed-Concept 144, 56) implemented by a community (Hyperseed-Concept 170) in contact with empirical reality (Hyperseed-Concept* **??***). This is also consonant with the engineering orientation in [19], where cognitive dynamics are characterized by iterative cycles of hypothesis formation, evaluation, and revision rather than by static representations.*

The update $\beta \leftarrow \mathrm{Cl}_R(\beta \oplus \varepsilon_{e,o})$ can be viewed as a two-stage process: first, $\oplus$ injects a new evidence token (indexed by experimental setup e and outcome o) into the current belief state; then Cl_R propagates the consequences of that addition through the inferential fabric determined by R. This makes "empirical coupling" precise in an operational way: the community does not merely store observations, but continuously re-derives what follows from them under its standing inferential commitments.

From the standpoint of budget-indexed surprisingness, one can regard empirical work as supplying new constraints that effectively increase the reachable evaluation of some hypotheses while decreasing others. In that sense, the "budget" is not only internal computation time but also the availability of external informational resources (instruments, protocols, replication capacity), so that moving from B_0 to B_1 may correspond to permitting additional experimental channels as well as additional inference steps.

Weakness-style robustness. In the surprisingness calculus, weakness is explicitly treated as an infimum over a family:

$$w(H) := \bigwedge_{h \in H} \mu(h),$$

with the intended reading "robust worst-case guarantee" (after choosing an orientation convention).

Remark 3230. *This formalizes a familiar scientific scruple: do not celebrate a result that holds only in one laboratory, one dataset, one social subgroup, or one lucky regime. Instead, one seeks claims whose quality persists across a family of contexts. In the quantale setting, the infimum is the canonical notion of "worst case" compatible with compositional algebra; see [3] for a systematic development, and [2] for related motivational discussion of weakness as a design principle for robust cognition.*

The use of $\bigwedge$ is particularly natural when the family H is interpreted as a set of "stress tests" (datasets, environments, submodels, perturbations, or alternative background assumptions), and $\mu(h)$ as a valuation of performance, truthlikeness, or adequacy within that test. Then $w(H)$ forces attention to the minimum-supported member of the family, preventing a single exceptionally favorable context from dominating the assessment. This connects directly to scientific practice: robustness is not merely an aesthetic preference but an explicit aggregation rule for evidence across heterogeneity.

In budget-indexed terms, one may also treat H as indexing multiple inference regimes (or multiple agents) that each yield a $TV_B(\varphi)$-like assessment. Applying weakness before measuring surprise amounts to asking for "surprisingness that survives the whole family," i.e. surprise that is not an artifact of one special evaluator.

A second Hyperseed notion of surprise (compression gain). Hyperseed also defines a "compression surprise" for an encounter B over interval I by

$$\mathrm{Sur}_m(B; I) := \max\{0, L_m^{old}(B) - L_m^{new}(B)\},$$

where L_m is a code-length functional (before/after updating internal codes).

This definition makes explicit that at least one kind of surprise is identified with a learning-driven drop in description length: the encounter is surprising exactly to the extent that it enables a shorter encoding under the updated model class or coding scheme m. The truncation at 0 enforces an orientation convention in which surprise is nonnegative and only counts "compression improvements" rather than degradations, aligning the quantity with a gain interpretation.

A useful bridge to the quantale examples above is to note that code lengths are typically additive across independent concatenations, so differences of code lengths live naturally in an additive (or tropical) setting. If one sets $TV_B(\varphi)$ to be (minus) a description length or a log-score, then the residual $a \Rightarrow b = b - a$ is exactly the type of delta measured by compression gain. On this reading, $\mathrm{Sur}_m(B; I)$ can be interpreted as a clipped version of a residual, where the clipping implements the convention that only positive movements (improvements) are credited as surprising in the intended sense.

Remark 3231. *In plain terms: if, after learning from an encounter, a mind can encode (predict, summarize, or reconstruct) the encounter more succinctly, then the encounter contained a "new pattern" relative to its previous internal model. This resonates with compression-based views of learning and surprise [16], and it provides a second route to connect surprise with resource change: the resource here is representational efficiency rather than inference depth.*

Science as "weakness" across channels. The "What is Science, Exactly?" essay characterizes science as optimizing weakness across evidence, simplicity (paradigm-dependent), and pragmatics, and treats paradigm shifts as shifts in these channels or their weightings.

Remark 3232. *The upshot is that "scientific quality" is not one scalar but a coordination of constraints: do not make distinctions unsupported by evidence, do not multiply primitives without reason, and do not privilege distinctions that do not matter for use. Treating these as weakness channels makes the overall notion explicitly robust (worst-case across channels or across instantiations). This orientation is compatible with the CPP framing developed elsewhere and with the broader social philosophy of science perspective in [20].*

59.2 Formal setup

Definition 529 (Budgets and monotone evaluation)**.** *Let $(\mathcal{B}, \leq)$ be a poset of inference budgets. Let $\mathcal{L}$ be a language of statements (hypotheses, claims, patterns). Let $(Q, \leq, \otimes, \oplus, 1, 0, \Rightarrow)$ be a commutative residuated quantale. A budgeted evaluator is a map*

$$TV : \mathcal{B} \times \mathcal{L} \to Q, \quad (B, \varphi) \mapsto TV_B(\varphi),$$

that is monotone in budget: $B_0 \leq B_1 \Rightarrow TV_{B_0}(\varphi) \leq TV_{B_1}(\varphi)$.

Remark 3233. *Intuitively, $\mathcal{B}$ is whatever you use to measure "how hard you are allowed to think." It could be a natural number (maximum proof depth), a time limit, a memory cap, a bound on the number of rule applications, a bound on search nodes, or even a partially ordered set of different inference regimes (e.g. "use propositional rules" $\leq$ "use first-order rules" $\leq$ "use probabilistic abduction"). The only property used here is monotonicity: more budget should not make evaluation worse.*

Remark 3234. *The quantale structure packages the algebra needed for compositional reasoning about these evaluations. The symbol $\otimes$ is the monoidal "combination" (e.g. multiplication in $Q_\times$ or addition in Q_+); $\oplus$ is the join-like aggregator (here* max *in both standard examples);* 1 *and* 0 *are the unit and bottom; and the residuum $\Rightarrow$ is the implication-like operation satisfying the usual adjunction: $a \otimes w \leq b$ iff $w \leq (a \Rightarrow b)$. This residuation is what makes "difference" compositional rather than merely numerical.*

Remark 3235. *A simple example: take $Q = [0, 1]$ with $\otimes = \times$ and $\oplus = \max$, and let $TV_B(\varphi)$ be the best plausibility score achievable for φ by any proof/search of cost $\leq B$. Then monotonicity says: if you search longer, you can keep the best score you already found, so the best-achieved score cannot decrease.*

Definition 530 (Residual-form budget surprise)**.** *For $B_0 \leq B_1$, define the (one-sided) budget surprise of φ by*

$$\mathrm{Surp}_{B_0 \to B_1}(\varphi) := TV_{B_0}(\varphi) \Rightarrow TV_{B_1}(\varphi).$$

Remark 3236. *This definition says: surprise is the "extra factor" (or "extra additive amount," depending on the quantale) needed to turn the weaker evaluation into the stronger one. In $Q_\times$, the residuum is a ratio b/a, so surprise is "how many times larger." In Q_+, the residuum is a difference $b - a$, so surprise is "how many units of log-score were gained." Both are just different lenses on the same compositional idea.*

Remark 3237. *A toy example in the ratio case: suppose with budget B_0 you can only check a crude heuristic and get $TV_{B_0}(\varphi) = 0.01$, but with budget B_1 you can run a full verifier and get $TV_{B_1}(\varphi) = 0.5$. Then $\mathrm{Surp}_{B_0 \to B_1}(\varphi) = 0.5/0.01 = 50$. The claim is not surprising because it became absolutely certain, but because it became dramatically more supported once the extra inference was permitted.*

Definition 531 (Weakness of a family)**.** *Let H be a set of contexts (agents, experiments, datasets, regimes, or pattern-templates), and let $\mu : H \to Q$ be a quantale-valued score. Define the weakness of the family by*

$$w(H) := \bigwedge_{h \in H} \mu(h).$$

Remark 3238. *This is the mathematically austere way to say: "take the worst case over H." The infimum $\bigwedge$ is the greatest lower bound in the order $\leq$ on Q, so it selects the strongest guarantee that holds uniformly across all $h \in H$. In many computational settings H is large or implicit; then the interest is not only definitional but algorithmic: can we approximate or bound the infimum cheaply? This is one of the motivations for quantale weakness as a reusable operator [3].*

Remark 3239. *Concrete example: let $Q = [0, \infty]$ with the usual order, and let $\mu(h)$ be a measured surprise score for the same hypothesis φ when tested in lab h. Then $w(H)$ is the least surprise observed across labs. If one wants "robust surprise" (not a fluke), then this infimum is the natural gate.*

Definition 532 (Hyperseed SAI reparameterized as a budgeted evaluation)**.** *Fix Hyperseed data (β, R) and define*

$$\mathrm{Support}(\varphi; \beta, R) := \pi(\mathrm{Cl}_R(\beta \setminus \varphi)(\varphi)) \in [0, 1], \quad \mathrm{Prior}(\varphi) := e^{-\lambda \mathrm{Comp}(\varphi)} \in (0, 1].$$

Then Hyperseed's surprise-adjusted implication is

$$\mathrm{SAI}(\varphi; \beta, R) := \frac{\mathrm{Support}(\varphi; \beta, R)}{\mathrm{Prior}(\varphi)}.$$

Remark 3240. *The notation here compresses several ideas. The belief state β is a valuation over the language, R is a set of inference rules, and Cl_R is closure under those rules (the least fixed point above the given beliefs, as in the general Hyperseed science machinery). The expression $\beta \setminus \varphi$ denotes a belief state where φ is "removed" (so that support for φ is not trivially circular); and $\pi(\cdot)$ is a projection that returns a scalar support in $[0, 1]$ from the underlying belief value. The quotient by $\mathrm{Prior}(\varphi)$ normalizes support by simplicity, producing a "surprise given complexity" score [1].*

Remark 3241. *Intuitively: a claim deserves attention when it is (i) strongly supported by the community's closure process and (ii) not strongly expected merely because it is simple. A simple but weakly supported claim is unsurprising; a complex but strongly supported claim can be surprising. In the background of this construction is the idea that a mind's (or a community's) limited resources force it to privilege simplicity unless evidence and inference compel otherwise (compare [16] for the code-length analogy).*

59.3 Theorems: bridging Hyperseed SAI to the compositional calculus

59.3.1 SAI is an instance of budget-residual surprisingness

Theorem 148 (SAI = ratio-quantale residual surprise)**.** *Let $Q = Q_\times$ be the ratio quantale with residual $a \Rightarrow b = b/a$. Define two budgets $B_0 \leq B_1$ and an evaluator by*

$$TV_{B_0}(\varphi) := \mathrm{Prior}(\varphi), \qquad TV_{B_1}(\varphi) := \mathrm{Support}(\varphi; \beta, R).$$

Then

$$\mathrm{Surp}_{B_0 \to B_1}(\varphi) = \mathrm{SAI}(\varphi; \beta, R).$$

Remark 3242. *This theorem says that Hyperseed's SAI is not an ad hoc ratio; it is exactly the residuated "delta" between two evaluations when those evaluations are placed into the ratio quantale. One may read B_0 as a weak baseline regime that only "knows" how to assign simplicity-based expectation, and B_1 as a stronger regime that incorporates inferential closure and evidence-based support. The surprise is the multiplicative lift from baseline to supported status.*

Remark 3243. *The result matters because once SAI is seen as a residual in a quantale, it automatically inherits a family of structural laws: telescoping across multiple budgets, compositional behavior under factorizations/independence assumptions, and robustness via infima. These are exactly the kinds of identities one wants inside a reasoning loop: they allow surprise to be tracked, bounded, and aggregated without re-deriving everything from scratch at each step [3].*

Proof. By definition of residual-form budget surprise,

$$\mathrm{Surp}_{B_0 \to B_1}(\varphi) = TV_{B_0}(\varphi) \Rightarrow TV_{B_1}(\varphi).$$

In the ratio quantale, $a \Rightarrow b = b/a$. Hence

$$\mathrm{Surp}_{B_0 \to B_1}(\varphi) = \frac{TV_{B_1}(\varphi)}{TV_{B_0}(\varphi)} = \frac{\mathrm{Support}(\varphi; \beta, R)}{\mathrm{Prior}(\varphi)} = \mathrm{SAI}(\varphi; \beta, R),$$

as claimed. $\square$

Proof sketch. The strategy is purely interpretive: we choose the two evaluations (TV_{B_0} and TV_{B_1}) so that their ratio is exactly the SAI definition. The key step is the ratio-quantale identity $(a \Rightarrow b) = b/a$, which turns the abstract residual-form surprise into an explicit quotient. Geometrically, one can picture $TV_{B_0}(\varphi)$ and $TV_{B_1}(\varphi)$ as two points on the positive real line, and surprise as the scale factor that dilates the first point into the second. $\square$

Remark 3244 (Interpretation)**.** *Hyperseed's "surprising given complexity" score is literally a budget-delta surprise: B_0 is a baseline evaluator that only "pays attention" to simplicity (via a prior), while B_1 is a stronger evaluator that permits the community's inference closure to support φ. This is aligned with the inference-centric idea that a statement is surprising when its truth estimate changes substantially when more inference resources are permitted.*

59.3.2 Log-domain (tropical) form: SAI as an additive surprise

Corollary 56 (Log SAI = tropical residual surprise)**.** *Let $Q = Q_+$ be the tropical (max-plus) quantale with residual $a \Rightarrow b = b - a$. Assume* $\mathrm{Support}(\varphi; \beta, R) > 0$ *and* $\mathrm{Prior}(\varphi) > 0$*, and define*

$$\widetilde{TV}_{B_0}(\varphi) := \log \mathrm{Prior}(\varphi), \qquad \widetilde{TV}_{B_1}(\varphi) := \log \mathrm{Support}(\varphi; \beta, R).$$

Then the tropical residual surprise satisfies

$$\widetilde{\mathrm{Surp}}_{B_0 \to B_1}(\varphi) = \log \mathrm{SAI}(\varphi; \beta, R) = \log \mathrm{Support}(\varphi; \beta, R) + \lambda \mathrm{Comp}(\varphi).$$

Remark 3245. *In words: taking logs converts the multiplicative SAI into an additive score that splits cleanly into "log support" plus "complexity penalty." This is important because many search and optimization procedures are naturally additive: they accumulate costs and gains along a path. In that setting,* $\log \mathrm{SAI}$ *becomes a directly usable objective for guiding attention (Hyperseed-Concept 60) toward claims that are both evidentially supported and nontrivially structured.*

Proof. In Q_+, $a \Rightarrow b = b - a$. Thus

$$\widetilde{\mathrm{Surp}}_{B_0\to B_1}(\varphi) = \widetilde{TV}_{B_0}(\varphi) \Rightarrow \widetilde{TV}_{B_1}(\varphi) = \log \mathrm{Support}(\varphi;\beta,R) - \log \mathrm{Prior}(\varphi) = \log\left(\frac{\mathrm{Support}}{\mathrm{Prior}}\right) = \log \mathrm{SAI}.$$

Since $\mathrm{Prior}(\varphi) = e^{-\lambda \mathrm{Comp}(\varphi)}$, $-\log \mathrm{Prior}(\varphi) = \lambda \mathrm{Comp}(\varphi)$, giving the final equality. □

Proof sketch. The proof is a coordinate change. One moves from the multiplicative world to the additive world by applying log, and then uses the tropical residuum formula $b - a$. The only substantive point is that the log of the exponential prior becomes a linear term $\lambda\mathrm{Comp}(\varphi)$, making the tradeoff between support and complexity explicit and additive. □

Remark 3246 (Why this is useful for a reasoning system)**.** *In tropical form, the SAI decomposes additively into an "evidence-support" term plus an explicit "complexity" term. This makes it natural to treat surprise-seeking as optimizing a sum of log-evidence and complexity cost, consistent with many search-control heuristics that trade off fit and description length.*

59.3.3 Budget composition: telescoping laws become reasoning-loop invariants

Theorem 149 (Telescoping for ratio and tropical surprises)**.** *Fix a statement* φ *and budgets* $B_0 \le B_1 \le B_2$*. Assume* $TV_{B_i}(\varphi) > 0$ *in the ratio case. The monotonicity condition* $B_0 \le B_1 \le B_2$ *is only used to match the intended "increasing budget" interpretation; algebraically, the identities are statements about composing two consecutive updates through an intermediate stage. The positivity assumption in the ratio case ensures that each ratio is well-defined and lives in the multiplicative quantale carrier (so that* $\otimes = \times$ *is applicable without invoking extended values).*

1. *(Ratio form.) In* $Q_\times$*,*

$$\mathrm{Surp}_{B_0\to B_2}(\varphi) = \mathrm{Surp}_{B_0\to B_1}(\varphi) \otimes \mathrm{Surp}_{B_1\to B_2}(\varphi) \quad (\otimes = \times).$$

   Equivalently, the map $B \mapsto TV_B(\varphi)$ *is multiplicatively "path independent": the surprise depends only on endpoints once expressed as a ratio, and intermediate checkpoints compose by multiplication.*

2. *(Tropical form.) In* Q_+*,*

$$\mathrm{Surp}_{B_0\to B_2}(\varphi) = \mathrm{Surp}_{B_0\to B_1}(\varphi) \otimes \mathrm{Surp}_{B_1\to B_2}(\varphi) \quad (\otimes = +).$$

   Equivalently, the map $B \mapsto TV_B(\varphi)$ *is additively "path independent": the net change from* B_0 *to* B_2 *is the sum of the two consecutive changes via* B_1*.*

Remark 3247. *The statement is an accounting identity: the surprise from* B_0 *to* B_2 *factors through* B_1*. In the ratio case this is the familiar multiplicative cancellation of intermediate terms; in the tropical case it is the additivity of differences. Conceptually, this makes "incremental reasoning" compatible with "batch reasoning": you can safely accumulate surprise across stages, and the total does not depend on how you partition the budget increase into steps. A useful way to read this* *is that surprise behaves like a compositional "cost" (or "gain") along a chain of refinements: the algebra enforces that the cost of a composed refinement is exactly the quantale product of the costs of its pieces. In particular, any control policy that depends only on total surprise (e.g. stopping when surprise exceeds a threshold, or prioritizing branches by accumulated surprise) is invariant under the granularity at which one logs intermediate stages.*

Remark 3248. *This connects back to Theorem 1 because if SAI is a residual surprise between two evaluators, then multi-stage refinements of the evaluator (e.g. progressive strengthening of* Cl_R *or progressive widening of what counts as admissible inference) yield telescoping invariants. This is precisely the kind of invariance that makes surprise a stable control signal in long reasoning loops. Concretely, if* $E_0 \preceq E_1 \preceq E_2$ *are evaluators ordered by refinement (for instance, larger budgets, stronger closure operators, or more permissive admissibility criteria), then the same telescoping expresses that the "gap" from* E_0 *to* E_2 *can be decomposed without ambiguity into the gap from* E_0 *to* E_1 *and from* E_1 *to* E_2*. This is the compositionality property one needs when SAI is used not merely as a diagnostic number, but as a quantity that is repeatedly combined across subroutines, steps, or episodes of a reasoning process.*

Proof. (1) In the ratio quantale,

$$\mathrm{Surp}_{B_0\to B_2}(\varphi) = \frac{TV_{B_2}(\varphi)}{TV_{B_0}(\varphi)} = \frac{TV_{B_1}(\varphi)}{TV_{B_0}(\varphi)} \cdot \frac{TV_{B_2}(\varphi)}{TV_{B_1}(\varphi)} = \mathrm{Surp}_{B_0\to B_1}(\varphi) \cdot \mathrm{Surp}_{B_1\to B_2}(\varphi).$$

Here the factor $TV_{B_1}(\varphi)$ is introduced and then cancels; the assumption $TV_{B_i}(\varphi) > 0$ guarantees that no division-by-zero occurs and that the multiplication stays within the intended carrier of $Q_\times$.
(2) In the tropical quantale,

$$\mathrm{Surp}_{B_0\to B_2}(\varphi) = TV_{B_2}(\varphi) - TV_{B_0}(\varphi) = (TV_{B_1} - TV_{B_0}) + (TV_{B_2} - TV_{B_1}) = \mathrm{Surp}_{B_0\to B_1}(\varphi) + \mathrm{Surp}_{B_1\to B_2}(\varphi).$$

This is the standard telescoping decomposition of a difference into successive differences; no positivity is needed because subtraction is performed only in the ambient ordered group/semiring where the tropical quantale is interpreted. □

Proof sketch. Both parts use the same high-level move: introduce the intermediate budget B_1 and cancel it. In $Q_\times$ this is cancellation of a shared factor ($TV_{B_1}(\varphi)$); in Q_+ it is cancellation of a shared summand. The geometric intuition is that surprise measures displacement along a 1D axis (multiplicatively or additively), and displacements add when traversed in segments. From the quantale perspective, the identity is also a direct reflection of associativity of $\otimes$: composing the update $B_0 \to B_1$ with $B_1 \to B_2$ yields the same result as the single update $B_0 \to B_2$, so the "surprise annotation" is functorial with respect to concatenation of budget steps. □

Remark 3249 (Loop interpretation)**.** *If a reasoning system iteratively expands its inference budget (or applies progressively stronger inference regimes), then the total surprise from start to finish equals the product/sum of incremental surprises across steps. This yields a clean accounting identity for surprise-driven control: you can track (and threshold) cumulative novelty across multi-step reasoning loops. In practice, this means one may implement surprise tracking either by storing only the current* $TV_B(\varphi)$ *and comparing to the initial baseline, or by accumulating per-step surprises online; telescoping guarantees these two implementations agree. More generally, for any chain* $B_0 \le B_1 \le \cdots \le B_n$*, repeated application yields*

$$\mathrm{Surp}_{B_0\to B_n}(\varphi) = \bigotimes_{k=0}^{n-1} \mathrm{Surp}_{B_k\to B_{k+1}}(\varphi),$$

so long reasoning loops admit a canonical factorization into local increments that is independent of how finely the loop is instrumented.

59.4 Weakness/robustness meets surprise: guarantees across contexts

59.4.1 Robust surprise across experiments / contexts

Definition 533 (Context-indexed surprise and its robustness)**.** *Let H be a set of contexts (e.g. experiments, labs, observer states, social subgroups, datasets). Let $\mathrm{Surp}_h(\varphi) \in Q$ be a surprise score for statement φ in context h. Define the robust (weakness-style) surprise guarantee by*

$$\mathrm{RobSurp}_H(\varphi) := \bigwedge_{h \in H} \mathrm{Surp}_h(\varphi).$$

This is exactly the weakness-of-a-family construction applied to surprise scores.

Remark 3250. *This definition turns surprise into a kind of contract: it is not enough that φ was surprising once; it should remain surprising across a designated family H of contexts. The family H may represent experimental replications, alternative datasets, different subcultures, or simply different initial belief states. The weakness infimum is the formal mechanism by which "robustness" enters the picture (Hyperseed-Concept 202, 143).*

Remark 3251. *A simple example: if $H = \{h_1, h_2, h_3\}$ are three labs, and $\mathrm{Surp}_{h_i}(\varphi)$ measures how much better φ becomes supported after allowing a richer analysis pipeline, then $\mathrm{RobSurp}_H(\varphi)$ is the smallest such improvement among the three. This matches the scientific instinct: the least impressive replication constrains the credibility of the overall claim.*

Proposition 78 (Monotonicity and threshold semantics of robust surprise)**.** *If $H' \subseteq H$, then $\mathrm{RobSurp}_H(\varphi) \leq \mathrm{RobSurp}_{H'}(\varphi)$. Moreover, if $\mathrm{Surp}_h(\varphi) \geq \tau$ for all $h \in H$, then $\mathrm{RobSurp}_H(\varphi) \geq \tau$.*

Remark 3252. *The proposition states two elementary but crucial facts. First, robustness gets harder when you demand it across more contexts: adding more tests can only decrease (or leave unchanged) the worst-case guarantee. Second, robust surprise supports threshold reasoning: if every context clears a threshold, then the robust infimum clears it too. This is the formal justification for using robust surprise as a gate in automated reasoning systems: it behaves predictably when you enlarge your test suite.*

Proof. Since H has more elements than H', the infimum over H is $\leq$ the infimum over H'. For the threshold claim: if every element of the set $\{\mathrm{Surp}_h(\varphi) : h \in H\}$ is $\geq \tau$, then their infimum is also $\geq \tau$. □

Proof sketch. Both claims are properties of infima in ordered sets. The first is the monotonicity of "minimum" with respect to set inclusion: the more elements you include, the more constraints you impose, so the greatest lower bound can only go down. The second is the defining property of a lower bound: if τ is below every element, then it is below their greatest lower bound as well. □

59.4.2 Independence and robust factorization

Theorem 150 (Independence factorization: surprise of a conjunction is the product of surprises)**.** *Let $Q = Q_\times$. Suppose two statements α, β satisfy the following factorization property in a fixed context h for two budgets $B_0 \leq B_1$:*

$$TV^{(h)}_{B_i}(\alpha \wedge \beta) = TV^{(h)}_{B_i}(\alpha) \cdot TV^{(h)}_{B_i}(\beta), \quad i \in \{0, 1\}.$$

Then

$$\mathrm{Surp}^{(h)}_{B_0 \to B_1}(\alpha \wedge \beta) = \mathrm{Surp}^{(h)}_{B_0 \to B_1}(\alpha) \cdot \mathrm{Surp}^{(h)}_{B_0 \to B_1}(\beta).$$

Remark 3253. *This theorem formalizes a simple idea: if the evaluator treats α and β as independent factors both before and after the budget increase, then the "extra lift" due to more budget also separates. In other words, independence is not only a statement about scores; it is a statement about how novelty decomposes. This is important because independence (or approximate independence) is what permits modular science and modular cognition: one can accumulate surprises from separate subproblems without double-counting entanglement.*

Remark 3254. *The hypothesis is deliberately strong: it requires factorization at both budgets. This matches the intended use: when one adopts a factor-graph or modular representation, one is committing to a factorization not just of a final judgment but of the evaluation process itself. Later sections on dependency and modularity make this kind of assumption structurally explicit.*

Proof. By ratio-residual surprise,

$$\mathrm{Surp}^{(h)}_{B_0\to B_1}(\alpha\wedge\beta)=\frac{TV^{(h)}_{B_1}(\alpha\wedge\beta)}{TV^{(h)}_{B_0}(\alpha\wedge\beta)}=\frac{TV^{(h)}_{B_1}(\alpha)TV^{(h)}_{B_1}(\beta)}{TV^{(h)}_{B_0}(\alpha)TV^{(h)}_{B_0}(\beta)}=\frac{TV^{(h)}_{B_1}(\alpha)}{TV^{(h)}_{B_0}(\alpha)}\cdot\frac{TV^{(h)}_{B_1}(\beta)}{TV^{(h)}_{B_0}(\beta)}.$$

□

Proof sketch. The proof substitutes the assumed factorization at B_0 and B_1 into the definition of ratio surprise and then cancels terms. The key step is that products in numerator and denominator separate into ratios for each factor. Visually: if evaluations lie on multiplicative axes, then moving from B_0 to B_1 scales α by one factor and β by another, so their conjunction scales by the product of those scale factors. □

Corollary 57 (Robust independence lower bound)**.** *Assume the hypotheses of the previous theorem hold for every $h\in H$. Then*

$$\mathrm{RobSurp}_H(\alpha\wedge\beta)\ \geq\ \mathrm{RobSurp}_H(\alpha)\cdot\mathrm{RobSurp}_H(\beta).$$

Remark 3255. *This corollary says that robustness and compositionality cooperate: worst-case surprise of a combined claim is at least the product of the worst-case surprises of the parts, provided the factorization assumptions hold uniformly across contexts. The inequality (rather than equality) reflects a general principle: taking infima after multiplying can only lose information; nevertheless, one retains a usable lower bound, which is exactly what a conservative reasoning system wants for guarantees. In particular, the "uniformly across contexts" clause matters: the same context index h must be eligible simultaneously for α, for β, and for $\alpha\wedge\beta$, so that the comparison is made inside a single common family $\{h\}$ rather than across incomparable families. Said another way, we are not free to choose* different *worst-case contexts for α and β and then expect that pair to be realized by a single context for the conjunction; the corollary instead shows that even without such alignment one still gets a sound (possibly non-tight) lower bound. The proof also highlights the order-theoretic shape of the argument: infima in $[0,\infty]$ interact well with monotone operations, which is the basic mechanism behind robust, context-quantified guarantees.*

Proof. Let $a_h:=\mathrm{Surp}^{(h)}_{B_0\to B_1}(\alpha)$ and $b_h:=\mathrm{Surp}^{(h)}_{B_0\to B_1}(\beta)$. From the theorem, $\mathrm{Surp}^{(h)}_{B_0\to B_1}(\alpha\wedge\beta)=a_hb_h$. Let $a_*:=\bigwedge_h a_h$ and $b_*:=\bigwedge_h b_h$. Then $a_*\leq a_h$ and $b_*\leq b_h$ for all h, so $a_*b_*\leq a_hb_h$ for all h by monotonicity of multiplication on $[0,\infty]$. Taking infima gives $a_*b_*\leq\bigwedge_h(a_hb_h)$, i.e. the stated inequality. Note that no attainment of the infimum is required: even when $\bigwedge_h a_h$ or $\bigwedge_h b_h$ is not achieved by any particular h (so there is no literal "worst" context), the lattice inequalities $a_*\leq a_h$ and $b_*\leq b_h$ still hold by definition of $\bigwedge$. Also, because the codomain is $[0,\infty]$ with its usual order and extended multiplication, the monotonicity step is valid even in edge cases (e.g. when some values are 0 or ∞), so the argument remains purely order-theoretic rather than measure-theoretic or probabilistic. $\square$

Proof sketch. The proof is a standard "push the infimum through a monotone operation" argument. One first notes that $a_* = \inf_h a_h$ is below every a_h, and similarly for b_*. Multiplying preserves order, so $a_* b_*$ is below every product $a_h b_h$. Therefore $a_* b_*$ is below their infimum, which is exactly $\mathrm{RobSurp}_H(\alpha \wedge \beta)$. The mental picture is that the worst-case combination cannot be worse than combining the two separate worst cases, because those separate worst cases already occur within the set of contexts being minimized over. Equivalently, the operator $x \mapsto cx$ (for fixed $c \in [0, \infty]$) preserves all infima because it is monotone, so one gets a "lax interchange" between inf and multiplication: $\inf_h(a_h b_h)$ dominates $(\inf_h a_h)(\inf_h b_h)$. The reason equality need not hold is that the infimum of the products is achieved (or approximated) by whichever h makes $a_h b_h$ small, and that h need not be a context where *both* a_h and b_h are near their individual infima simultaneously; the two "bad" directions can occur in different contexts. Thus the bound should be read as a robust compositional *guarantee* rather than an exact characterization, matching the conservative stance of worst-case reasoning. $\square$

Remark 3256 (Reasoning-system use)**.** *This corollary gives a robust, compositional certificate: if each component is robustly surprising across contexts, their conjunction remains robustly surprising (at least up to the product lower bound), provided the system's factorization/independence assumptions are justified. Operationally, this lets a reasoning system propagate context-robust lower bounds without re-solving a global optimization problem for every conjunction: one can track* $\mathrm{RobSurp}_H(\alpha)$ *and* $\mathrm{RobSurp}_H(\beta)$ *as reusable summaries, and then immediately obtain a sound bound for* $\alpha \wedge \beta$*. In log-surprise form (when one works with* $-\log(\mathrm{Surp})$ *or similar), the multiplicative lower bound corresponds to an additive lower bound, which is often numerically stable and aligns with familiar "add evidence" heuristics. The caveat is exactly the one stated in the corollary: if factorization fails in some contexts, the product rule can overstate robustness, so the certificate is only as reliable as the model class that enforces the uniform assumptions.*

59.5 Scientists and curious minds as surprise-seekers (formalized inside Hyperseed)

Definition 534 (Curious mind and scientist (minimal formalization))**.**

1. *A curious mind is an agent whose internal epistemic dynamics instantiate the Hyperseed thinking loop (questions -¿ answers -¿ belief updates), and whose belief system is productive in the sense that it regularly generates high-SAI beliefs or high-novelty questions.*

2. *A scientific community is a community belief system with an observation set and empirical update operator as in Hyperseed's science formalization.*

Remark 3257. *This definition is intentionally minimalist: it does not legislate what the agent is made of, nor how it represents beliefs, but only insists on the dynamical pattern of inquiry (Hyperseed-Concept* **??***) and on a productivity condition. The scientific community is then obtained by adding explicit empirical coupling and communal acceptance criteria, i.e. by turning the private loop into a shared, socially stabilized loop (cf. [20]).*

Remark 3258. *The minimalism is also methodological: it allows the same schema to cover human scientists, automated agents, mixed human–machine teams, or even abstract "idealized" agents, so long as the requisite loop (questioning, answering, updating) can be identified. In particular, the* *definition does not commit to any specific representational format (probabilistic credences, logical theories, vector embeddings, or hybrid formalisms), because the Hyperseed ontology treats the belief dynamics and the update/closure machinery as the primary invariants.*

Remark 3259. *Note that "productive" here is meant as a structural property of the belief system* (B, R) *(and its associated closure/inference machinery), not as a psychological label. It formalizes a repeatable tendency to generate outputs that are nontrivial relative to the system's own baselines of simplicity, prior beliefs, and permitted update operators. In this way, the definition distinguishes mere activity (many questions, many hypotheses) from epistemic productivity (questions/hypotheses that actually move the state of belief in a way that survives coherence constraints).*

Remark 3260. *A simple example of a "curious mind" in this sense could be a single agent repeatedly generating hypotheses, running tests, and updating beliefs, where the tests are internal simulations or external measurements. A "scientific community" is the same pattern with replicated experiments, shared observations, and an update protocol that ensures that what is learned can be re-used and criticized.*

Remark 3261. *The community case can be read as an explicit externalization of parts of the thinking loop: questions and candidate answers become public objects (papers, preregistrations, datasets, lab notebooks), while belief updates become partially governed by agreed-upon procedures (statistical thresholds, peer review norms, artifact sharing, and standardized measurement). In Hyperseed terms, this amounts to tightening the coupling between the observation set and the communal acceptance/update operator so that novelty is not merely generated but also filtered, stabilized, and made portable across agents.*

Theorem 151 (Productive curiosity and productive science are both (among other goals) high-SAI generators)**.** *Let* (B, R) *be a Hyperseed belief system (for a community, or for a single agent viewed as a size-1 community). If* (B, R) *is productive, then it regularly generates either: (i) new beliefs* φ *with large* $\mathrm{SAI}(\varphi; \beta, R)$*, or (ii) new questions whose answers yield novel patterns (and hence, after closure, candidate beliefs with elevated SAI). In particular, under this definition, both a productive curious mind and a productive scientific community are engaged in generating surprising conclusions/hypotheses.*

Remark 3262. *The dependence* $\mathrm{SAI}(\varphi; \beta, R)$ *is essential to the intended reading: the same statement* φ *may be unsurprising for one baseline* β *(or one repertoire of inferential resources* R*) and highly surprising for another. Thus "surprise-seeking" is not a purely intrinsic property of a proposition, but a relational property: it measures how much the epistemic evaluation of* φ *changes when one moves from a simplicity-only or low-resource baseline to an inference-augmented or closure-supported regime. This is precisely why the same empirical finding can be "obvious" to an expert community while remaining surprising to a novice agent, even if both are perfectly coherent.*

Remark 3263. *The role of "new questions" in clause (ii) is not merely rhetorical. Within Hyperseed, a question can be treated as an operator that induces a search over potential answers and thereby induces a change in the effective hypothesis space. When that search yields a pattern not already captured by the current closure of* B*, the subsequent closure step promotes parts of that pattern into candidate beliefs. In this sense, productive questioning is a mechanism for generating high-SAI candidates indirectly, by forcing the system to confront regions of the space where its current baselines and inference budgets do not already trivialize the outcome.*

Remark 3264. *The theorem is logically straightforward but conceptually clarifying: productivity, as defined in Hyperseed, already encodes a drive toward nontrivial novelty under coherence constraints.*

Thus, the difference between a scientist and an ordinary curious thinker is not the presence versus absence of surprise-seeking, but the additional social and empirical scaffolding that makes surprise reproducible, criticizable, and cumulative. In that sense, the surprise calculus is not merely a scoring trick but a candidate invariant of inquiry as such.

Remark 3265. *One can also read the theorem as a constraint on degenerate epistemic dynamics. A system that updates only by trivial restatement, or that generates hypotheses but immediately discards them without any integrative closure, will fail the productivity requirement and therefore will not qualify as "curious" in the present formal sense. Conversely, a system that chases novelty without coherence will tend to collapse into inconsistency or into an unstructured accumulation, and so will again fail to meet the "without collapsing coherence" aspect implicitly encoded in the productivity condition.*

Proof. This follows by unpacking the definition of productive belief system, which explicitly requires that the system regularly generates new high-SAI beliefs or new questions whose answers lead to novel patterns, without collapsing coherence. □

Remark 3266. *Although the proof is a direct unfolding, the statement is not vacuous: it fixes how "curiosity" and "science" are to be identified* inside *the ontology, namely via behavior of the belief dynamics relative to β and R. In particular, once a concrete β (simplicity baseline) and a concrete inference/closure regime R are specified, the claim becomes testable in principle: one can observe whether the system repeatedly produces beliefs/questions that score as high-SAI relative to those internal standards.*

Proof sketch. No algebra is needed: the proof is definition unfolding. The value of stating it as a theorem is that it makes explicit what is often implicit in cognitive and scientific rhetoric: "curiosity" is a constraint on the dynamics of belief formation, not merely a mood. Once one then identifies SAI with a residual surprise (Theorem 1), the definition acquires operational content: one can compute, track, and optimize the relevant form of surprise. □

Remark 3267. *The phrase "compute, track, and optimize" should be read broadly: in an automated setting it may literally correspond to numerical optimization over candidate hypotheses or experiments, whereas in a human or mixed setting it may correspond to heuristic search guided by proxies (e.g. information gain, predictive error, compression improvements) that approximate the relevant SAI functional. The key Hyperseed point is that such proxies are not arbitrary: they are interpretable as approximations to changes in evaluation between a baseline regime and an inference-supported regime.*

Remark 3268 (Where the quantale calculus enters)**.** *The previous theorem is definition-unfolding, but it becomes operationally nontrivial once we instantiate "high-SAI" via Theorem 1: high SAI is high residual surprise between a simplicity-only baseline and an inference/closure-supported evaluation. Thus curiosity and science can be seen as special cases of inference-centric surprise seeking: seeking statements whose evaluation changes substantially under increased inference resources (budgets).*

Remark 3269. *In the quantale-compositional picture, "budgets" can be modeled as elements in a resource quantale whose order encodes refinement/availability (more time, more compute, more experimental access, richer background theory), and whose monoidal structure encodes composition of resources across steps of the thinking loop. The operational reading of the last sentence is then that productive inquiry tends to select φ for which the mapping from resources to evaluation (or to closure strength) has a large marginal effect: increasing resources moves φ from "implausible/unsupported" toward "supported" (or vice versa) in a way that is not already predicted by the simplicity baseline.*

59.6 Paradigm shifts as changes of surprise baselines (and why independence matters)

Theorem 152 (Paradigm-shift renormalization of surprise scores)**.** *Let* $\mathrm{Support}(\varphi)$ *be fixed (same inferential support/evidence handling), and consider two paradigms with complexity costs* $\mathrm{Comp}_1, \mathrm{Comp}_2$ *and priors* $\mathrm{Prior}_i(\varphi) = e^{-\lambda \mathrm{Comp}_i(\varphi)}$*. Then the corresponding SAI scores satisfy*

$$\mathrm{SAI}_2(\varphi) = \mathrm{SAI}_1(\varphi) \cdot \exp\big(\lambda(\mathrm{Comp}_2(\varphi) - \mathrm{Comp}_1(\varphi))\big).$$

Hence a change in what counts as "simple" (a paradigm shift in the simplicity channel) can change the ranking of "surprising hypotheses" even if evidential support is unchanged. Moreover, taking logs makes the renormalization additive:

$$\log \mathrm{SAI}_2(\varphi) = \log \mathrm{SAI}_1(\varphi) + \lambda\big(\mathrm{Comp}_2(\varphi) - \mathrm{Comp}_1(\varphi)\big),$$

so a paradigm shift can be read as adding a hypothesis-dependent offset to the surprise baseline while leaving the support term untouched.

Remark 3270. *The theorem states a renormalization law: changing the complexity measure rescales surprise by a predictable factor. This is important because it isolates one precise mechanism by which paradigms can be "incommensurable" in practice: not because facts disappear, but because the baseline of what is considered expected (simple, natural, unremarkable) shifts. Then even identical support can yield different surprise rankings, hence different attention allocation and research trajectories. In particular, if two hypotheses* φ, ψ *have comparable support but differ in how much their complexity shifts between paradigms, then the ordering by* SAI *can flip even when* $\mathrm{Support}(\varphi)/\mathrm{Support}(\psi)$ *is fixed. This makes explicit that "surprise" is not only an evidence score but an evidence-to-expectation ratio, and expectation is precisely where paradigms encode their background commitments.*

Remark 3271. *This connects to the weakness-channel view of science: if simplicity is one channel of weakness, then a paradigm shift changes the simplicity channel and therefore changes the multi-channel optimum. The formula above is the one-line quantitative shadow of that broader idea [20]. Equivalently, in a multi-channel objective where overall weakness aggregates several penalties, altering one channel can reweight tradeoffs among channels even when other channels (e.g. data-fit or measurement reliability) are held constant. Thus, what looks like "the same evidence" can lead to a different best next question because the feasible set of low-weakness moves is reshaped by the new simplicity metric.*

Proof. By definition,

$$\mathrm{SAI}_i(\varphi) = \frac{\mathrm{Support}(\varphi)}{\mathrm{Prior}_i(\varphi)} = \mathrm{Support}(\varphi) \cdot e^{\lambda \mathrm{Comp}_i(\varphi)}.$$

Divide SAI_2 by SAI_1 to obtain the stated multiplicative factor. Note that this argument uses only the exponential form of the prior in Comp_i; the specific interpretation of $\mathrm{Support}(\varphi)$ (likelihood ratio, Bayes factor proxy, or other evidential score) is irrelevant as long as it is held fixed across the two paradigms. $\square$

Proof sketch. The proof rewrites SAI to make the dependence on Comp_i explicit, then takes a ratio. The key step is that the prior is exponential in complexity, so changing complexity adds in the exponent and thus multiplies surprise. Visually: one keeps the "support" height fixed but changes the "simplicity baseline" beneath it; the perceived elevation above baseline changes accordingly. A useful mental picture is that λ controls how sensitive the community is to shifts in simplicity: larger λ makes even small changes in Comp produce large multiplicative changes in SAI, amplifying paradigm effects on what is treated as noteworthy. □

Remark 3272 (Independence and compositionality)**.** *When a paradigm change declares new primitives "cheap," many previously complex expressions become more factorable (or more naturally independent) in the representation language. This directly impacts surprise decomposition and connectedness of surprise: what counted as a single entangled hypothesis may become a composable product of simpler parts, changing both* Comp *and any independence baselines used by miners. In particular, if φ can be re-expressed as a composition (e.g. $\varphi \simeq \alpha \otimes \beta$) whose parts are treated as approximately independent under the new primitives, then both the effective complexity and the surprise bookkeeping can split: one can compare* $\mathrm{SAI}(\alpha)$ *and* $\mathrm{SAI}(\beta)$ *separately rather than only* $\mathrm{SAI}(\varphi)$ *as an undifferentiated whole. This matters for quantale-compositional treatments because the algebra of combination determines which decompositions are legible, and legibility feeds back into what is counted as simple, modular, and therefore "expected".*

59.7 Compression surprise as a budget-delta surprise (bridge to "surprising fulfillment")

Theorem 153 (Compression surprise is residual surprise in a cost-oriented quantale)**.** *Let L be a code-length functional (smaller is better). Define a cost score $C = -L$ (larger is better). Let Q_+ be the tropical quantale (max-plus) and define two "budgets" $B_{old} \le B_{new}$ corresponding to "before updating codes" and "after updating codes". Let*

$$TV_{B_{old}}(B) := -L_m^{old}(B), \qquad TV_{B_{new}}(B) := -L_m^{new}(B).$$

Then the one-sided tropical residual surprise satisfies

$$\mathrm{Surp}_{B_{old}\to B_{new}}(B) = \max\{0, L_m^{old}(B) - L_m^{new}(B)\} = \mathrm{Sur}_m(B; I).$$

Moreover, the interpretation of $B_{old} \le B_{new}$ is not that the object *B changes, but that the* evaluator *(code family, model class, or compressor state indexed by m) gains capacity: after updating on information I, the admissible descriptions become no longer than before (equivalently, the achievable negative code length becomes no smaller). In this sense, the order relation between budgets is an order on* representational options *rather than a numerical constraint on B itself.*

Remark 3273. *This theorem says that the "compression gain" notion of surprise is the same residual-difference pattern again, now applied to representational efficiency rather than inferential support. If one thinks of $-L$ as a reward (more compressible means more predictable/structured), then the residual surprise is the improvement in reward after an internal update. The* $\max\{0,\cdot\}$ *corresponds to the one-sidedness of Hyperseed's definition: only improvements count as surprise. In particular, this makes explicit that "surprise" here is* not *the absolute compressibility of B, but the* change *in compressibility induced by updating the coding scheme from "old" to "new". This aligns with the intuition that a datum can be highly compressible in an absolute sense yet not surprising if the agent already had a code that captured the relevant regularity.*

Remark 3274. *The result matters because it unifies two superficially different mechanisms: surprise as "belief lift above simplicity" (SAI) and surprise as "compression gain." Both become instances of quantale deltas between evaluators. This helps keep the ontology disciplined: one can* *vary the evaluator and still remain within the same compositional algebra. Concretely, the evaluator may be instantiated as (i) a belief-scoring functional, (ii) a likelihood or log-evidence functional, or (iii) a coding/MDL functional. The quantale framing isolates the common structural move: compare two states of evaluation (pre-update vs. post-update), and extract the positive residual as the relevant "delta" object. This is also the point at which different choices of orientation become visible: if one instead treated L as a cost to be* minimized *directly, then one would swap signs (or swap the order convention) to recover an equivalent residual form.*

Proof. In Q_+, residual surprise is $TV_{old} \Rightarrow TV_{new} = TV_{new} - TV_{old}$, but we want a one-sided positive gain (clipped at 0) as in Hyperseed. Compute:

$$TV_{new} - TV_{old} = (-L^{new}) - (-L^{old}) = L^{old} - L^{new}.$$

Taking $\max\{0, \cdot\}$ yields exactly $\mathrm{Sur}_m(B; I)$. Equivalently, one can read the same algebra as a "freed budget" statement: if L is measured in bits (or nats), then a positive value of $L_m^{old}(B) - L_m^{new}(B)$ is precisely the number of description-length units saved by the updated code. The tropical residual records this savings as an additive delta, which is the natural notion of difference in the max-plus setting. □

Proof sketch. The proof is an elementary algebraic rewrite: define the evaluation to be negative code length so that "better compression" corresponds to a larger score. Then the tropical residuum becomes a difference of code lengths. The only adjustment is the one-sided clipping, reflecting that Hyperseed counts only positive compression gains as surprise. One may also view this as a minimal functoriality requirement: by encoding "quality" as an element of the same ordered monoid across states (old/new), the delta is forced to be an internal morphism (a residual) rather than an external comparison rule. This is why the rewrite is so direct: once the evaluator lives in Q_+, subtraction is the canonical way to form a residual. □

Remark 3275 (Unifying picture)**.** *Hyperseed's (i) belief-level surprise (SAI) and (ii) compression-level surprise are both instances of the same underlying pattern: surprise is a quantale-valued delta between two evaluators, with evaluator choice (and orientation) determining whether we interpret surprise as lift, log-delta, evidence gain, or compression gain. This same picture provides the intended bridge to "surprising fulfillment": a positive compression residual can be interpreted as newly available internal slack (saved bits, saved description-length, or reduced representational cost), which can then be* reallocated *as budget toward downstream objectives. In other words, a compression surprise is not merely epistemic; it is also a resource-creating event under a budget semantics, and thus becomes a natural candidate primitive for modeling episodes where an agent achieves unexpectedly high performance because the world became simpler (more compressible) than its prior code anticipated.*

59.8 Conclusion: how the algebras fit

- Hyperseed's SAI is exactly a ratio-quantale residual surprise between a simplicity-only baseline (prior from complexity) and an inference/closure-supported plausibility evaluation (Theorem 1). In more explicit algebraic terms, if $\preceq$ is the plausibility order and $\otimes$ is the quantale composition, then the residual $a \multimap b$ is characterized by the adjunction property $a \otimes x \preceq b \iff x \preceq (a \multimap b)$, so SAI can be read as the *least* multiplicative "update factor" required to turn the baseline expectation into the supported evaluation. The "ratio" language here is not metaphorical: it indicates that surprise is computed as a *relative* gap between two regimes of assessment (simplicity-only vs. closure-supported), rather than as an absolute magnitude attached to a single model.

- Therefore SAI inherits the compositional algebra of budgeted surprise: telescoping identities across multi-step reasoning, and robustification across context families via infimum/weakness (telescoping theorem and robust section). Concretely, because residuals in a quantale interact systematically with $\otimes$, chains of reasoning can be assigned surprise contributions that combine predictably: successive inferential steps do not require re-deriving surprise "from scratch", but instead compose along the proof or deliberation trace. This is the sense in which telescoping identities capture multi-step reasoning as a single net transformation from an initial baseline to a final supported position, while still allowing intermediate steps to be audited. Likewise, robustification via infimum formalizes the intuition that context can change what is easy or hard to explain: taking an infimum across contexts forces the resulting score to reflect the *worst-case* (or most demanding) context in the family, thereby preventing fragile, highly context-tuned surprises from dominating downstream decisions.

- Hyperseed's formal definition of productive belief systems already bakes in a "surprise-seeking" aspect (self-transcendence via high-SAI beliefs/questions), and science is explicitly a special case of the thinking loop with empirical coupling. Hence both scientists and ordinary curious minds are formally describable as engaged in surprise-seeking loops (among other goals) (productive curiosity/science theorem). Here "surprise-seeking" should be read as a structural preference for queries and conjectures that, if resolved, would generate a large residual gap between baseline simplicity priors and closure-supported plausibility. On this view, self-transcendence is not merely novelty-chasing; it is the systematic pursuit of questions whose answers reconfigure what the system can stably claim after accounting for inferential closure (and, in the scientific case, observational constraints). The empirical coupling in the scientific loop matters because it supplies externally anchored closure steps (e.g. measurement, replication, instrumentation), which can force the supported plausibility evaluation away from what simplicity alone would have predicted, producing disciplined high-SAI updates.

- Paradigm shifts correspond (in part) to changing the simplicity/weakness channel, which in SAI terms renormalizes surprise baselines and thus changes what counts as "surprising" (paradigm-shift theorem). In this framing, a paradigm shift is not only a change in particular hypotheses, but a change in the map from representations to priors and from contexts to admissible weakness bounds: what was once treated as "simple" may become "complex" (or vice versa), and what was once treated as a permissible weakening across contexts may become unacceptable. Because SAI is computed *relative* to a baseline, altering the baseline effectively rescales the surprise landscape: previously dramatic residual gaps can collapse, while previously negligible gaps can become salient. This explains why, after a shift in representational and resource assumptions, communities can legitimately disagree about which anomalies are decisive and which are routine, even when they agree on the raw observational record.

The above items can be read as a single integration claim: the "surprisingness" quantity used by Hyperseed is not an ad hoc score, but the canonical quantity singled out by the residual structure of the underlying quantale, and the accompanying weakness operation supplies the cross-context stability condition needed for communal and scientific use. In particular, the same algebra that licenses compositional bookkeeping for individual reasoning also supports aggregation over heterogeneous agents and environments, provided the relevant infima exist and are taken with respect to the intended notion of context inclusion.

Remark 3276. *The philosophical moral is that "surprise" is not merely an emotion; it is a structural relation between evaluators: between what a system expected under one regime of resource* *and representation, and what it is compelled to acknowledge under another. When cast in quantale terms, this relation becomes compositional and therefore suitable for rigorous use inside automated reasoning and communal knowledge processes. Weakness (as infimum) then supplies the pragmatic discipline: surprise worthy of scientific attention is surprise that survives across contexts (Hyperseed-Concept 202). Equivalently, the infimum condition can be viewed as a formal analogue of "robustness" or "invariance": an effect is not elevated to a scientifically central anomaly merely because it appears under a convenient parametrization, but because it persists when the evaluator is weakened, the background context is varied, or the representational budget is shifted within the allowed family. This links the algebraic treatment of surprise to familiar methodological norms (stress-testing, ablation, replication, and sensitivity analysis) while preserving a single compositional calculus for both individual deliberation and collective inquiry.*

60 Dependency Towers for Pattern Networks: Factorization, Towerization, and Tight Low-Order Bounds

We formalize a "pattern network" as a factor-graph/hypergraph presentation of a global semantic object (function, energy, proof/program behavior) built from local patterns (factors). Concretely, one may think of a collection of variables/ports together with a family of local pattern terms, where each term touches only a bounded subset of the variables, and where the global object F is obtained by composing/aggregating those local terms (e.g. by summation of energies, product of potentials, composition of program fragments, or superposition in a linear semantics). This presentation makes explicit which parts of F depend on which coordinates and at what arity, and thus provides the substrate on which we can state and prove order-restricted approximation results.

We then show how to "factor out" a pattern network into a dependency tower of pattern networks: each layer is a best (or canonical) approximation constrained to dependency order ¡= k, and is indistinguishable from the original by all ¡= k-ary observations. Here "dependency order $\leq k$" means that the semantics of the layer can be generated from factors whose scopes have size at most k (equivalently: no term in the representation simultaneously couples more than k degrees of freedom). The notion of "$\leq k$-ary observations" is intentionally operational: an observer/test is allowed to probe the system only through queries that themselves involve at most k coordinates jointly (for example, evaluating against test functions with support on $\leq k$ variables, applying interventions that touch $\leq k$ variables at once, or measuring correlations of order at most k). Indistinguishability then asserts that all such bounded-order tests produce the same outcomes on F and on its k-layer $F_{\leq k}$, so that any discrepancy between F and $F_{\leq k}$ lives purely in higher-order interactions.

We prove: (1) canonical existence/uniqueness of tower layers in Hilbert semantics (projection/tail optimality), (2) a representation theorem: the order-k semantic truncation admits a factor graph with max arity ¡= k, (3) a delta/tower factorization: the tower can be expressed as "exactly order k" increments (in group completion), (4) a modularity theorem: if a pattern network splits into independent sub-networks, then connected terms factorize and cross-components have zero connected mass, and (5) a task-invariance theorem: any observer/test limited to dependency order ¡= k cannot distinguish the full network from its k-layer, so reasoning/planning using only ¡= k tests is sound on the k-layer. In (1), the Hilbert setting should be read as: we place our semantic objects in an inner-product space (e.g. L^2-type semantics, reproducing-kernel Hilbert space semantics, or any completion in which orthogonal projection is defined), and define $F_{\leq k}$ as the orthogonal projection of F onto the closed subspace generated by $\leq k$-ary components. "Tail optimality" then means that the residual $F - F_{\leq k}$ is orthogonal to all $\leq k$-ary directions, which is exactly the statement that no $\leq k$-ary test can see the residual. In (2), the representation theorem bridges an abstract semantic truncation (defined by a projection or order restriction) back to a concrete combinatorial presentation: not only does $F_{\leq k}$ exist as a semantic object, it can be realized as an actual pattern network with arity bounded by k, so the tower layers live in the same modeling language as the original network. In (3), the "exactly order k" increments Δ_k are defined so that $F_{\leq k} = \sum_{j \leq k} \Delta_j$ (or the appropriate monoidal analog), and the mention of group completion indicates that we may pass from a purely additive/monoidal setting to one in which formal differences are permitted, allowing a clean Mbius-like decomposition into interaction orders even when the original factors are constrained (e.g. nonnegative energies or normalized probabilities). In (4), "connected terms" refer to the standard connected/cumulant-like parts of a factorization: they measure genuine multiway coupling beyond what is explained by lower-order marginals, and the theorem asserts that independence across components annihilates any such cross-component coupling. Finally, (5) makes the tower operational: if an algorithms interface to the world is limited to bounded-order queries or bounded-arity constraints, then replacing F by $F_{\leq k}$ is not a heuristic but a sound equivalence for that class of tasks.

Remark 3277. *Philosophically, a dependency tower is a disciplined way of saying: there are many kinds of "seeing," and each kind has a limited resolution. If one insists on only k-way lenses (tests that can only coordinate at most k degrees of freedom at once), then the world "as seen through those lenses" is not the full semantic object F, but its k-layer $F_{\leq k}$. The tower formalizes the idea that coarser lenses yield a coarser but* optimal *view—optimal not by taste, but by a precise extremal property in a chosen semantics. One useful way to read "optimal" is as a best-approximation principle constrained by what the observer is allowed to express: among all semantic objects that only contain $\leq k$-way dependencies, the layer $F_{\leq k}$ is the one that agrees with F on every admissible $\leq k$-ary question, and in Hilbert semantics it is also the one minimizing $\|F - G\|$ over all such G. The tower thus separates two issues that are often conflated: (i) the intrinsic complexity of the world (which may include arbitrarily high-order interactions), and (ii) the expressive power of the observational/decision interface (which may cap out at some finite k). The conceptual payoff is that one can speak precisely about what information is lost when restricting to low-order structure, and about which forms of reasoning remain invariant under that restriction.*

This construction is aligned with Hyperseed's emphasis on patterns and their stratification (Hyperseed-Concept 130, 131) and on dependency as a first-class notion (Hyperseed-Concept 93, 94). The guiding motivation is similar to that of "tower" formalisms in the Hyperseed ecosystem [8] and the broader pattern/emergence framing [5]. From this perspective, the dependency tower can be understood as a principled stratification of pattern flow: lower layers encode what is explainable by local interactions of bounded arity, while higher layers encode irreducible multiway coordination. This mirrors common practices across domains (e.g. truncating higher-order moments, limiting clause width in proof systems, bounding interaction order in statistical physics, or restricting attention to low-order features in learning), but packages them into a single semantic construction with explicit optimality and invariance guarantees.

60.1 Setup: pattern networks and dependency order

60.1.1 Semantic target

Definition 535 (Semantic target object)**.** *Fix a probability space (Ω, μ) and let $H = L^2(\Omega, \mu)$ (real-valued) for Hilbert results. A "semantic target" is an element $F \in H$. (Other semantics such as quantales can be substituted; we focus on Hilbert for tight optimality.)*

Remark 3278. *The point of starting with a Hilbert space is not mere mathematical fashion. Hilbert structure is precisely what makes the notion of "best approximation" canonical: orthogonal projection is uniquely determined, and error decomposes by a Pythagorean identity rather than by ad hoc inequalities. Here $H = L^2(\Omega, \mu)$ means: we view our semantic object as a square-integrable real-valued function on a space of situations Ω, with μ encoding how frequently situations matter.*

A simple example is $\Omega = \{0,1\}^n$ with μ uniform, and $F(x)$ an "energy" or score of a configuration. Then $F \in L^2$ automatically. Another example is $\Omega = \mathbb{R}^n$ with μ a Gaussian measure and F any function with finite second moment. The usefulness of this definition is that it lets us speak rigorously about approximating F by restricted-dependency surrogates and about lower bounds that are independent of any particular factorization.

Remark 3279. *Two small but important interpretive points will be used repeatedly later. First, the choice of μ is part of the semantic problem specification: it determines which regions of Ω are emphasized when measuring approximation error. In particular, changing μ changes the notion of "best" low-order surrogate because the projection geometry changes. Second, the L^2 viewpoint is inherently distributional: it treats two functions as "close" if they are close on typical situations under μ, even if they differ drastically on μ-rare events. This is exactly the regime in which tight low-order bounds via orthogonal decomposition are meaningful.*

Remark 3280 (Technical notation)**.** *Throughout, (Ω, μ) denotes a probability space: Ω is the sample space and μ a probability measure. The space $L^2(\Omega, \mu)$ consists of equivalence classes of measurable functions $F : \Omega \to \mathbb{R}$ with $\int_\Omega F^2 \, d\mu < \infty$. The associated norm is $\|F\|_2 := \left(\int_\Omega F^2 \, d\mu\right)^{1/2}$, and the inner product is $\langle F, G \rangle := \int_\Omega FG \, d\mu$.*

Remark 3281. *Because $F \in L^2$ is an equivalence class modulo μ-null sets, any statement about "exact equality" of semantic targets is understood as holding μ-almost surely. This is usually the right notion for learning/approximation: if a discrepancy occurs only on a μ-null set, then it cannot affect L^2 error, and it cannot be detected by any μ-integrable test.*

60.1.2 Pattern networks as factor graphs / hypergraphs

Definition 536 (Factor-graph (pattern-network) representation)**.** *Let $x = (x_1, \ldots, x_n)$ range over $\Omega = D_1 \times \cdots \times D_n$ with product measure μ. A pattern network is a set of factor scopes $\mathcal{S} = \{S_a \subseteq [n]\}$ together with local potentials $\psi_a : D_{S_a} \to \mathbb{R}$ such that*

$$F(x) = \sum_a \psi_a(x_{S_a}).$$

The dependency order (arity) of the network is

$$\operatorname{ord}(\mathcal{N}) := \max_a |S_a|.$$

Remark 3282. *Intuitively, the scopes S_a declare* which variables are allowed to interact *inside a local pattern, and the potential ψ_a quantifies what that interaction contributes. The global meaning $F(x)$ is then built by summing local meanings. This is the additive version of a factor graph: rather than multiplying local factors into a joint weight, we add local energies into a total energy. In Hyperseed language, each ψ_a is a local pattern (Hyperseed-Concept 130) and the whole representation is a pattern web/network (Hyperseed-Concept 132); the order is a concrete measure of dependency (Hyperseed-Concept 93).*

A simple example: with $n = 3$ and $x_i \in \{0, 1\}$, let

$$F(x_1, x_2, x_3) = \psi_{12}(x_1, x_2) + \psi_3(x_3),$$

where $S_{12} = \{1, 2\}$ and $S_3 = \{3\}$. Then $\mathrm{ord}(\mathcal{N}) = 2$, meaning nothing genuinely 3-way occurs. As another example, if $F(x) = \sum_{i=1}^{n} \psi_i(x_i)$, then $\mathrm{ord}(\mathcal{N}) = 1$, and F is purely "separable." This definition is necessary because the whole tower construction will measure and truncate exactly this notion of interaction order.

Remark 3283. *The same semantic target F can admit many different pattern-network representations; the order $\mathrm{ord}(\mathcal{N})$ is therefore, strictly speaking, a property of a chosen factorization, not yet an intrinsic property of F. Later tower results will address the intrinsic question by comparing F against the* subspace *of all functions with interactions limited to order $\leq k$, so that low-order structure is identified independently of how one happened to write F as a sum of potentials. In that intrinsic view, "F has no genuine $(k+1)$-way interaction" means precisely that F lies in (or is well-approximated by) the closure of the order-$\leq k$ subspace in $L^2(\Omega, \mu)$, rather than merely that one particular decomposition uses small scopes.*

Remark 3284 (Technical notation)**.** *Here $[n]$ denotes $\{1, 2, \ldots, n\}$. For a subset $S \subseteq [n]$, the product domain $D_S := \prod_{i \in S} D_i$, and x_S denotes the subtuple $(x_i)_{i \in S}$. The index a runs over factors (hyperedges), and S_a is the variable-set (scope) attached to factor a.*

Remark 3285. *This is the additive "energy" representation; exponentiating yields the usual multiplicative factor graph $\tilde{p}(x) \propto \exp(F(x)) = \prod_a \exp(\psi_a(x_{S_a}))$.*

Remark 3286. *The additive view is often the more philosophically transparent: each local pattern contributes a "reason" (positive or negative) toward the global evaluation. Multiplication obscures this by turning reasons into weights; exponentiation is merely a change of chart. For the tower results, additivity also matches Hilbert linear structure, making orthogonality and projection available.*

Remark 3287. *When Ω is a product space with product measure, the order notion is closely aligned with classical decompositions of multivariate functions into low-order interaction terms (e.g. ANOVA/Hoeffding/Efron–Stein type decompositions). The tower perspective can be read as: build a nested sequence of subspaces*

$$\mathcal{H}_{\leq 0} \subseteq \mathcal{H}_{\leq 1} \subseteq \cdots \subseteq \mathcal{H}_{\leq n} \subseteq L^2(\Omega, \mu),$$

where $\mathcal{H}_{\leq k}$ consists of functions that can be expressed using only scopes of size at most k, and then project F onto these subspaces. The later "tight low-order bounds" are precisely statements about the norm of the residual $F - \Pi_{\leq k} F$, which depends only on F and μ, not on any chosen set of potentials.

Remark 3288. *The assumption that μ is a product measure in the factor-graph definition is a convenient baseline that lets "variable subsets" behave as independent coordinate selections, and it makes conditional expectations onto coordinate σ-algebras especially transparent. Many constructions extend to non-product μ, but one must then be careful: correlation in μ can create effective low-order predictability even when a naive syntactic factorization suggests high-order coupling, and conversely it can hide interactions that only appear off the typical set. The Hilbert/tower setup is designed to make these distinctions explicit.*

60.1.3 Dependency order via contexts (syntax-aware variant)

Definition 537 (Context order (hole/port order))**.** *Let φ be an expression/program, and let* $\mathrm{Ctx}(\varphi)$ *be a chosen quotient-set of k-hole contexts ordered by refinement (fill holes) with order* $\mathrm{ord}_{hole}(C) = k$*. A "pattern" may be taken as a context C with its induced k-ary potential JCK. We will treat "dependency order ¡= k" as meaning "expressible using only contexts of order ¡= k", or equivalently "indistinguishable by all ¡= k-hole context tests".*

Remark 3289. *This definition offers a syntax-aware analogue of the factor-graph arity notion. Instead of variables $x_1, \ldots, x_n$, we have an expression φ and we test it by inserting it into contexts with k holes (or ports). A k-hole context is a way of probing φ by exposing it to k "interfaces" at once; increasing k increases how entangled our probe may be. This connects naturally to the Hyperseed view that questions/tests are context-dependent acts of inquiry (Hyperseed-Concept 144, 86) and to the broader emphasis on programs and semantics (Hyperseed-Concept 80,* **??***).*

Remark 3290. *The phrase "chosen quotient-set" is doing real work: contexts are typically considered up to an equivalence relation that identifies probes with the same semantic effect (e.g. observational equivalence, α-renaming, or congruences generated by evaluation rules). Fixing such a quotient prevents the theory from depending on syntactic accidents. The refinement order ("fill holes") then expresses a principled notion of "making the probe more specific": a refined context commits to additional surrounding structure, and therefore can distinguish more behaviors.*

Remark 3291. *The two characterizations of "dependency order $\leq k$" mirror the two perspectives from factor graphs. On the "generative" side, "expressible using only contexts of order $\leq k$" means there exists a construction of the observable behavior of φ built entirely from k-port pattern components. On the "testing" side, "indistinguishable by all $\leq$ k-hole context tests" means that no probe with at most k simultaneous interfaces can detect any additional coupling beyond order k. This parallels how, for random variables, limiting oneself to functions of k coordinates both (i) restricts the class of admissible approximants and (ii) restricts the class of tests one can apply.*

Remark 3292. *Concretely, one can think of a k-hole context as specifying a k-ary observation functional: it takes k program fragments (or k copies/ports of a single fragment) and returns a measurement. In probabilistic semantics, the induced potential JCK can be read as a real-valued random variable on an appropriate space of executions or environments. Under that reading, the context-order filtration becomes a tower of σ-algebras/tests, and the later towerization results can be interpreted as orthogonal decomposition of program meaning into components that are detectable only by increasingly high-arity probes.*

Remark 3293. *A simple example is a term in a typed lambda calculus, where a 1-hole context is a term-with-a-hole that expects a single subterm, while a 2-hole context can compare or combine two inserted subterms. Saying "dependency order $\leq k$" then amounts to: no observation that simultaneously couples more than k ports can distinguish the object. This is useful because many cognitive and scientific tests are naturally interface-limited; the tower lets us formalize what is preserved under such limitations. In particular, the parameter k can be read as a bound on the arity of the "experimental interface": we are allowed to plug in, vary, or jointly relate at most k independent inputs at once, and any higher-order coupling is treated as unobservable at that resolution. This viewpoint makes precise why higher-order structure may be real yet operationally inaccessible: if the allowed contexts never simultaneously mention more than k ports, then any difference that only manifests through* (k+1)*-way coordination is invisible to the entire test suite, even if it is large in a global metric.*

Remark 3294 (Technical notation)**.** *The notation JCK indicates the semantic evaluation (denotation) of the context C under whatever semantics is being used; this is standard bracket notation for "the meaning of." The poset order by refinement means: $C' \leq C$ if C' is obtained by filling some holes of C (so C' is a more specified test). Equivalently, refinement is "adding information to the query": a context with more holes left open is a more general experiment, while plugging holes commits to concrete subterms/values and yields a stricter test. This order is convenient because many semantic constructions become monotone in it: if a behavior passes a refined test, then it also passes the coarser test obtained by forgetting some of the filled-in choices. When contexts are interpreted as maps into an observation domain (e.g. booleans, reals, or distributions), the refinement order can also be viewed as an inclusion order on the corresponding sets of distinguishable behaviors induced by those tests.*

60.2 Dependency towers and observers

Definition 538 (k-ary observers)**.** *Let $O_{\leq k}$ be a family of observables/tests such that each $O \in O_{\leq k}$ can probe at most k-way dependence. Examples:*

- *all bounded linear functionals supported on $H_{\leq k}$ (Hilbert ANOVA view),*
- *all expectations of products of test functions depending on at most k variables,*
- *all evaluations in k-hole contexts (syntax-aware view).*

In each case, the intent is that the observer factors through a representation in which "order $\leq k$" structure is the only structure that can affect the reported value; i.e. changes in F that live entirely in dependency order $> k$ are in the kernel of every $O \in O_{\leq k}$. When $k = 0$, this recovers the idea of purely constant (no-input) observations, such as a global bias/mean, depending on the ambient semantics.

Remark 3295. *An "observer" here is not a homunculus but a constrained measurement procedure: a rule that maps the semantic target F to some reported quantity (a number, a decision, a statistic). The phrase "k-ary" is meant literally: the observer can only coordinate at most k degrees of freedom in a single act of measurement. In more philosophical terms, k bounds the complexity of the* question *one is able to ask (Hyperseed-Concept 144, 186). One can also view $O_{\leq k}$ as specifying an information interface: it is not merely that the observer chooses to ignore higher-order structure, but that the experimental protocol cannot stably condition on, or jointly vary, more than k inputs at once. In this sense, k is a resource bound (arity, bandwidth, or "attention width") rather than a claim about what the world contains.*

For instance, if $F(x_1, x_2, x_3)$ is a function on three bits, then a 1-ary observer might query the average of F as a function of x_1 alone, ignoring x_2, x_3 except through averaging. A 2-ary observer might query correlations between x_1 and x_2. The usefulness is that it makes "indistinguishable at order k" precise: two semantic objects may differ, yet every observer in $O_{\leq k}$ yields the same output on them. Concretely, a typical 1-ary query has the form $x_1 \mapsto \mathbb{E}[F(x_1, X_2, X_3)]$ (a conditional mean), while a typical 2-ary query might return $\mathbb{E}[F(X)\,\varphi(X_1, X_2)]$ for some bounded test function φ depending only on (X_1, X_2). In the context-based formulation, the same idea is expressed by restricting to contexts whose free ports are of cardinality $\leq k$, so that the context cannot express an experiment that simultaneously relates more than k inserted substructures. Thus "indistinguishable at order k" is an invariance statement relative to a specified observational language.

Definition 539 (Dependency tower (abstract))**.** *A dependency tower for F is a family $\{F_{\leq k}\}_{k \geq 0}$ such that:*

1. *(Monotonicity)* $F_{\leq k}$ *becomes more faithful as* k *increases.*

2. *(k-ary indistinguishability) For all* $O \in O_{\leq k}$, $O(F_{\leq k}) = O(F)$.

3. *(Optimality/minimality) Among all* G *satisfying the same indistinguishability constraints,* $F_{\leq k}$ *is "best" in the chosen semantics (e.g. minimal* L^2 *error).*

The monotonicity clause is intentionally stated at a high level because the ambient semantics may offer different notions of "more faithful" (e.g. decreasing approximation error, increasing information, or refinement in a poset of summaries). In metric settings one often requires $\|F - F_{\leq k}\|$ *to be non-increasing in* k*, while in order-theoretic settings one may require* $F_{\leq k} \preceq F_{\leq(k+1)}$ *for an appropriate refinement relation. The indistinguishability clause can likewise be read as an equalizer condition:* $F_{\leq k}$ *and* F *are observationally equivalent with respect to the entire test class* $O_{\leq k}$.

Remark 3296. *The dependency tower is the formal device that turns an intuitive slogan into mathematics: "match what all k-limited observers can see, and otherwise be as simple/optimal as possible." Condition (2) is the epistemic clause: for the permitted tests, the k-layer is as good as the whole. Condition (3) is the ontic/semantic clause: among all such surrogates, we choose the one that is best by a precise criterion. In Hilbert semantics, "best" becomes least-square error, which in turn yields a unique answer by orthogonal projection. This projection viewpoint also clarifies why (2) and (3) are compatible: the constraints* $O(F_{\leq k}) = O(F)$ *define an affine subspace (or convex set, depending on the semantics), and the "best" element is the one closest to* F *under the chosen geometry. In ANOVA-style decompositions,* $F_{\leq k}$ *can be interpreted as the sum of all interaction components of order at most* k*, so that the tower layers additively isolate the contribution of each dependency order.*

As a toy example, let $F(x_1, x_2) = x_1x_2$ *on* $\{-1, +1\}^2$ *with uniform measure. A* $k = 1$ *observer can only probe dependence on one variable at a time. The best* $F_{\leq 1}$ *that matches all 1-ary observations is the constant zero function: the interaction is purely 2-way, and its 1-way shadow vanishes. The tower is useful because it gives a principled stratification of patterns by dependency order (Hyperseed-Concept 94) rather than relying on arbitrary truncations. Note that this example also illustrates how "matching all 1-ary observations" is stronger than matching a single statistic such as the global mean: all unary probes (e.g. conditional means given* x_1 *or given* x_2*) must agree, forcing the entire first-order component to be zero. By contrast, if* F *had a term like* x_1 *in addition to* x_1x_2*, then* $F_{\leq 1}$ *would retain the* x_1 *contribution while still discarding the purely interaction part, thereby separating main effects from higher-order synergies.*

60.3 Hilbert tower layers are canonical and optimal

Definition 540 (Order-k subspace)**.** *Let* H_S *be the closed subspace of* S*-dependent functions. Let*

$$H_{\leq k} := \overline{\mathrm{span}}\{H_S : \ |S| \leq k\}.$$

Let $P_{\leq k} : H \to H_{\leq k}$ *be the orthogonal projection.*

Remark 3297. *The inclusion of the closure in the definition is also what makes the phrase "order-k" robust under limiting operations: a function may fail to be literally a* finite *sum of low-order terms but still be approximable arbitrarily well (in* L^2*) by such sums. This is the same distinction as between finite-rank objects and their norm-closures in functional analysis, and it is essential if we want* $H_{\leq k}$ *to behave functorially under convergence (e.g., when* F *is itself obtained as a limit of increasingly refined models).*

Remark 3298. *Here H_S is the space of functions that "only look at" coordinates indexed by S. For example, if $S = \{2, 5\}$ then H_S consists of functions $G(x)$ that depend on x_2 and x_5 but are otherwise constant in all other coordinates. The space $H_{\leq k}$ is generated by all such spaces with $|S| \leq k$, meaning it contains all functions that can be expressed (in the L^2 limit) as sums of terms each depending on at most k variables.*

This is exactly the semantic counterpart of a factor-graph with max arity $\leq k$: each factor depends on at most k variables, and sums of such factors lie in $H_{\leq k}$. The closure bar $\overline{\text{span}}$ is a technical necessity: in infinite or continuous settings, we want $H_{\leq k}$ to contain limits of approximating sequences of low-order functions. The projection $P_{\leq k}$ then formalizes "throw away all components that require more than k-way dependence."

Remark 3299. *Two basic sanity checks help fix intuition. First, $H_{\leq 0}$ is (typically) the subspace of constants: functions that depend on no coordinates at all. In that case $F_{\leq 0}$ is the best constant approximation to F (often its mean, when $H = L^2$ over a probability space). Second, the family is nested: if $k \leq \ell$ then $H_{\leq k} \subseteq H_{\leq \ell}$, so increasing k can only improve approximation quality and can only decrease the tail $\|F - F_{\leq k}\|_2$.*

Remark 3300 (Technical notation)**.** *$\mathcal{F}_S$ will later denote the σ-algebra generated by coordinates in S; informally, it is the information available when you only know variables in S. The phrase "closed subspace" refers to closure in the L^2 norm, ensuring that orthogonal projection is well-defined.*

Remark 3301. *When $H = L^2(\Omega, \mathcal{F}, \mathbb{P})$ and $H_S = L^2(\Omega, \mathcal{F}_S, \mathbb{P})$, the projection onto H_S is the conditional expectation $\mathbb{E}[\cdot \mid \mathcal{F}_S]$. Although $H_{\leq k}$ is generally larger than any single H_S, it can be helpful to keep this archetype in mind: "being in $H_{\leq k}$" means being representable (up to L^2-limits) by combining information from coordinate-subsets of size at most k. In this sense, $P_{\leq k}$ is the canonical operation that retains exactly the part of F explainable by k-way observations.*

Theorem 154 (Canonical tower layers via projection; tail energy is tight)**.** *Define $F_{\leq k} := P_{\leq k} F$. Then:*

1. *$F_{\leq k}$ is the unique best approximation to F among all $G \in H_{\leq k}$:*

$$F_{\leq k} = \arg\min_{G \in H_{\leq k}} \|F - G\|_2.$$

2. *For every $G \in H_{\leq k}$,*

$$\|F - G\|_2^2 \geq \|F - F_{\leq k}\|_2^2.$$

   Thus the residual/tail $\|F - F_{\leq k}\|_2$ is a representation-independent lower bound on any ¡= k-dependency representation.

3. *The family $\{F_{\leq k}\}_{k \geq 0}$ is a dependency tower for F with respect to any observer family $O_{\leq k}$ that depends only on $H_{\leq k}$.*

Remark 3302. *The phrase "representation-independent" is doing real work in (2): it means the bound depends only on the subspace $H_{\leq k}$ (i.e., the notion of k-way dependence), not on a particular choice of factorization, parametrization, basis, or architecture used to realize elements of $H_{\leq k}$. Consequently, if two different modeling formalisms both generate exactly $H_{\leq k}$ as their expressive class, then $\|F - F_{\leq k}\|_2$ is the same obstruction for both. This is what makes the tail energy an intrinsic notion of "irreducible high-order structure".*

Remark 3303. *Intuitively, this theorem says: if you insist your representation only involve dependencies up to order k, then there is a* single *best answer, obtained by "dropping" the orthogonal complement of $H_{\leq k}$. Moreover, the norm of what you dropped—the tail energy—is not an artifact of how you chose to factorize, but an intrinsic obstruction: no $\leq k$ representation can do better, because any such representation lives inside $H_{\leq k}$.*

This matters because it turns the informal idea of "towerization" [8] into a canonical mathematical operation in the Hilbert setting: there is no ambiguity about what the k-layer is. It also sets up the later representation theorem: once we know $F_{\leq k}$ exists canonically, we can ask how to represent it as a factor graph of order $\leq k$.

Remark 3304. *One useful consequence of the nestedness $H_{\leq k} \subseteq H_{\leq k+1}$ is an energy monotonicity statement:*

$$\|F - F_{\leq (k+1)}\|_2 \leq \|F - F_{\leq k}\|_2,$$

so the tower provides a nonincreasing sequence of irreducible residuals. This is the analytic counterpart of the modeling heuristic that allowing higher-order factors cannot make the best achievable error worse. In particular, the increments $\|F_{\leq (k+1)} - F_{\leq k}\|_2$ can be interpreted as the amount of "new explainable variance" unlocked by moving from order k to order k+1.

Proof. (1)-(2) are standard projection optimality and the Pythagorean identity for orthogonal projections. (3) If O depends only on the $H_{\leq k}$ component, then $O(F) = O(P_{\leq k}F) = O(F_{\leq k})$. Optimality holds by (1).

For completeness: the existence and uniqueness of $P_{\leq k}F$ use that $H_{\leq k}$ is a *closed* subspace of a Hilbert space, hence every point has a unique nearest point in $H_{\leq k}$. The inequality in (2) is just the same fact written in norm-squared form, and can be read as saying that $F_{\leq k}$ is not merely a good low-order surrogate but the *best possible* one under the ambient L^2 geometry. ☐

Proof sketch. View $H_{\leq k}$ as a flat "plane" (a closed subspace) inside the Hilbert space H. The orthogonal projection $P_{\leq k}F$ is the nearest point on that plane to F, and Hilbert geometry guarantees both existence and uniqueness. The tail energy is the squared length of the perpendicular segment, hence a lower bound on any other candidate in the plane. ☐

Remark 3305. *The key step is the Pythagorean identity: for any $G \in H_{\leq k}$,*

$$\|F - G\|_2^2 = \|F - P_{\leq k}F\|_2^2 + \|P_{\leq k}F - G\|_2^2,$$

because $F - P_{\leq k}F$ is orthogonal to $H_{\leq k}$. This is the analytic form of a geometric fact: in a right triangle, the hypotenuse is longer than the leg. Conceptually, the tower layer is "what the k-limited world can contain" and the tail is "what it must ignore."

Remark 3306. *Equivalently, the orthogonality condition can be stated as: for all $G \in H_{\leq k}$,*

$$\langle F - F_{\leq k}, G\rangle = 0,$$

so the residual is invisible to any linear test living in $H_{\leq k}$. This provides a concrete operational meaning: any statistic, probe, or observer that can be expressed as an $H_{\leq k}$ element cannot correlate with the tail. In later sections, this is the bridge between "geometric" definitions (subspaces and projections) and "semantic" ones (what an order-k observer can detect).

Remark 3307. *This is the formal core of "towerize by best low-order approximation": in Hilbert semantics, tower layers are exactly orthogonal projections and are uniquely determined.*

60.4 Representing tower layers as pattern networks (factor graphs)

60.4.1 Subset-indexed interaction series and truncation

Definition 541 (ANOVA/Hoeffding interaction components)**.** *Let $M_S := \mathbb{E}[F \mid \mathcal{F}_S]$ and define connected components U_S by Moebius inversion on the subset lattice:*

$$U_S := \sum_{T \subseteq S} \mu(T,S) M_T, \qquad \mu(T,S) = (-1)^{|S|-|T|}.$$

Then $F = \sum_{S \subseteq [n]} U_S$ and the U_S are orthogonal in L^2. Define the order-k truncation

$$F_{\le k}^{\mathrm{series}} := \sum_{|S| \le k} U_S.$$

Remark 3308. *This definition extracts, from F, the* pure *interaction contributed by each subset S of variables. The conditional expectation $M_S = \mathbb{E}[F \mid \mathcal{F}_S]$ is the best L^2 approximation to F that only depends on variables in S; it is what you would predict if you only knew those variables. However, M_S still contains the effects of smaller subsets $T \subsetneq S$. Moebius inversion subtracts these lower-order shadows, leaving the "connected" part U_S that cannot be explained by any proper subset.*

A familiar example: suppose $F(x_1, x_2) = f_1(x_1) + f_2(x_2) + f_{12}(x_1, x_2)$ with $\mathbb{E}[f_i] = 0$ and $\mathbb{E}[f_{12} \mid x_1] = \mathbb{E}[f_{12} \mid x_2] = 0$. Then $U_{\{1\}} = f_1$, $U_{\{2\}} = f_2$, and $U_{\{1,2\}} = f_{12}$. The utility is that truncating by $|S| \le k$ becomes a principled "keep only interactions up to order k" operation, aligning directly with dependency order.

Remark 3309 (Technical notation)**.** *$\mathcal{F}_S$ is the σ-algebra generated by the coordinate maps $(x_i)_{i \in S}$; conditioning on $\mathcal{F}_S$ means averaging over all coordinates not in S. The symbol $\mu(T,S)$ here is the Moebius function of the Boolean lattice of subsets; it should not be confused with the probability measure μ on Ω (the notation is standard but admittedly overloaded).*

Theorem 155 (Series truncation equals Hilbert tower layer)**.** *For $F \in L^2(\Omega, \mu)$ as above,*

$$F_{\le k}^{\mathrm{series}} = P_{\le k} F = F_{\le k}.$$

Remark 3310. *This theorem asserts that two ways of defining "the k-layer" coincide. One way is geometric: orthogonally project onto the subspace of $\le k$-dependent functions. The other is combinatorial: decompose F into subset-indexed interaction components U_S and drop the ones with $|S| > k$. The content is that the ANOVA/Hoeffding expansion is not merely a decomposition, but precisely the orthogonal decomposition aligned with the dependency-order filtration.*

This is important because it turns the abstract projection $P_{\le k}$ into explicit factor-like terms U_S, which we can directly read as potentials in a pattern network. Thus it is the bridge between canonical semantics (Hilbert) and explicit representation (factor graphs).

Proof. Each U_S lies in $H_S \subseteq H_{\le |S|}$. Orthogonality implies the closed span of $\{U_S : |S| \le k\}$ equals $H_{\le k}$, and the orthogonal projection onto $H_{\le k}$ is obtained by summing exactly the components in that subspace, i.e. those with $|S| \le k$. □

Proof sketch. The strategy is: (i) show each interaction component U_S lives in the appropriate order subspace; (ii) use orthogonality to identify the subspace $H_{\le k}$ as the span of components with $|S| \le k$; (iii) conclude that projection onto $H_{\le k}$ is implemented by "keep exactly those orthogonal pieces." □

Remark 3311. *The crucial mechanism is orthogonality: once F is expressed as an orthogonal sum, projection is a coordinate-wise operation. Geometrically, it is like expressing a vector in an orthonormal basis and then erasing the coordinates you are not allowed to use. This is why Hilbert semantics yields "tight" bounds: nothing is wasted in inequalities; the truncation is exact.*

Corollary 58 (Order-k factor graph representation exists)**.** *Define a pattern network $\mathcal{N}_{\leq k}$ with one factor scope S for each $S \subseteq [n]$ with $|S| \leq k$, and potential $\psi_S(x_S) := U_S(x_S)$. Then*

$$F_{\leq k}(x) = \sum_{|S| \leq k} \psi_S(x_S),$$

so $\mathcal{N}_{\leq k}$ is a pattern network of dependency order ¡= k representing the k-layer exactly.

Remark 3312. *In plain terms: the k-layer is not only an abstract function, it is literally a sum of local terms, each involving at most k variables. So the semantic truncation can be re-expressed as a factor graph with maximum arity k. This gives a canonical recipe for "towerizing" a pattern network in the most literal, implementable sense: compute the tower layer and then read off its factors.*

One should not confuse this representation with a claim of computational efficiency: there are $\sum_{j=0}^{k} \binom{n}{j}$ factors in the worst case. The corollary is about existence and conceptual equivalence, not about tractability. Its utility is that it pins down what it means for a k-ary representation to be exactly *the k-layer.*

Proof. Immediate from the definition of $F_{\leq k}$ as the series truncation and the factor-network definition as an additive sum of local potentials. ☐

Proof sketch. Once we know $F_{\leq k} = \sum_{|S| \leq k} U_S$, we simply rename each U_S as a potential ψ_S and declare its scope to be S. The dependency order bound is then tautological. ☐

Remark 3313. *The key step is not in the proof but in the prior theorem: identifying $F_{\leq k}$ with the truncated orthogonal interaction series. After that, the factor-graph representation is merely a change of packaging, translating between "semantic decomposition" and "network of local patterns" in the sense of [5].*

Remark 3314 (What this answers)**.** *Yes: in the subset-indexed (or equivalently Hilbert) semantics, any F admits a canonical dependency tower, and each layer can be represented as a pattern network (factor graph) whose max factor arity is ¡= k. So one can "factor out" a pattern network into a dependency tower of pattern networks by: (1) compute $F_{\leq k}$ (projection / tower layer), (2) represent $F_{\leq k}$ as a factor graph with factors up to order k (the U_S terms). In other words, "towerizing" a pattern network is nothing more than organizing its semantics by the cardinality of the variable subsets on which the interaction components depend, and then reading each truncation as its own bounded-arity factorization. Concretely, if F is already given as a factor graph with heterogeneous factor arities, then $F_{\leq k}$ is obtained by keeping only the interaction content supported on subsets of size $\leq k$ (in Hilbert semantics this is literally an orthogonal projection), and this truncated object can be re-expressed as a factor graph whose factors are precisely the U_S with $|S| \leq k$.*

60.5 Tower deltas: "exactly order k" pattern-network increments

Definition 542 (Tower deltas (group completion))**.** *Assume the semantic codomain is an abelian group (true in Hilbert). Define*

$$\Delta_0 := F_{\leq 0}, \qquad \Delta_k := F_{\leq k} - F_{\leq (k-1)} \quad (k \geq 1).$$

Equivalently, the tower can be recovered from the deltas by the recursion

$$F_{\le k} = F_{\le (k-1)} + \Delta_k,$$

so the delta sequence $\{\Delta_k\}_{k\ge 0}$ *is simply a first-difference transform of the cumulative sequence* $\{F_{\le k}\}_{k\ge 0}$.

Remark 3315. *A tower layer* $F_{\le k}$ *is cumulative: it contains everything up to order* k*. The deltas* Δ_k *isolate what is* new *when we move from order* $k-1$ *to order* k*. This is analogous to how a Taylor series can be described either by partial sums or by coefficients: the layers are partial sums, the deltas are the coefficients.*

For example, if $F_{\le 1}$ *captures all unary effects and* $F_{\le 2}$ *captures unary plus pairwise effects, then* Δ_2 *is the purely pairwise contribution, with unary effects removed. This definition is useful because it yields an "exactly order* k*" pattern-network increment, which is often what one wants when analyzing emergence or connectedness: it separates higher-order structure from its lower-order shadows. One can also read* Δ_k *as an "interface" between modeling capacities: it measures the gap between the best approximation available with* $(k-1)$*-ary patterns and the best approximation available with* k*-ary patterns, so it is the semantic analog of adding a new arity class of motifs to the network.*

Remark 3316 (Technical notation)**.** *The phrase "group completion" simply indicates that we must be able to subtract:* $F_{\le k} - F_{\le k-1}$ *only makes sense in an additive abelian group. In* L^2*, subtraction is always defined. In other semantic settings (e.g. some quantales), subtraction may not exist, so the delta tower must be treated differently. In such non-group settings one often replaces subtraction by a residuation, an order-theoretic difference, or by working with inequalities (e.g.* $F_{\le k}$ *as an increasing approximation) rather than equalities. The present definition highlights that in Hilbert semantics the decomposition is not merely monotone but* additive *and hence admits a coefficient-like interpretation.*

Theorem 156 (Orthogonal delta decomposition)**.** *In Hilbert semantics,*

$$F_{\le k} = \sum_{j=0}^{k} \Delta_j, \qquad F = \sum_{j\ge 0} \Delta_j,$$

and the increments are orthogonal: $\langle \Delta_k, \Delta_\ell \rangle = 0$ *for* $k \ne \ell$*. Moreover,* Δ_k *is exactly the sum of interaction components of order* k*:*

$$\Delta_k = \sum_{|S|=k} U_S.$$

In particular, the "exactly order k*" subspace can be characterized as*

$$H_{=k} := H_{\le k} \ominus H_{\le (k-1)},$$

and Δ_k *is precisely the orthogonal projection of* F *onto* $H_{=k}$.

Remark 3317. *This theorem says the tower is not merely a nested approximation scheme; it is an* orthogonal *resolution of* F *by dependency order. Each* Δ_k *lives in the "exactly* k*" subspace and is perpendicular to all other orders. Thus the energy of* F *decomposes cleanly across orders, and one can attribute variance (in the* L^2 *sense) to interaction orders without interference.*

This is important because it gives a rigorous foundation for statements like "the genuinely k*-way structure contributes this much" and because it makes truncation error transparent: the squared* *error of cutting at order k is just the sum of squared norms of Δ_j for $j > k$. It connects directly to the earlier projection theorem: the deltas are the orthogonal pieces carved out by successive projections. Explicitly, orthogonality implies the Pythagorean identities*

$$\|F\|^2 = \sum_{j\geq 0} \|\Delta_j\|^2, \qquad \|F - F_{\leq k}\|^2 = \sum_{j>k} \|\Delta_j\|^2,$$

so each order contributes an additive, nonnegative amount to total L^2 energy. When F is interpreted as a centered observable, $\|\Delta_k\|^2$ can be read as the portion of variance attributable to exactly k-way dependence.

Proof. Since $P_{\leq k}$ is an increasing family of orthogonal projections, the differences $\Pi_k := P_{\leq k} - P_{\leq(k-1)}$ are orthogonal projections onto the "exactly order k" subspace, hence are mutually orthogonal and sum to the identity in the limit. Apply to F to get $\Delta_k = \Pi_k F$ and the decomposition. The equality $\Delta_k = \sum_{|S|=k} U_S$ follows from the ANOVA expansion and the identification $F_{\leq k} = \sum_{|S|\leq k} U_S$. More formally, for $k \neq \ell$ one checks $\Pi_k \Pi_\ell = 0$ using the nesting $P_{\leq(k-1)} P_{\leq k} = P_{\leq(k-1)}$, and idempotence $\Pi_k^2 = \Pi_k$ follows from $P_{\leq k}^2 = P_{\leq k}$ together with the same nesting relations. □

Proof sketch. The proof uses the algebra of nested orthogonal projections. When subspaces are nested, successive differences of projections are themselves orthogonal projections onto the successive "new directions." Applying these difference projections to F yields the delta pieces. The ANOVA identity then identifies those pieces with the sum of interaction terms at the matching subset size. One can also view this as a Hilbert-space version of a Mbius inversion on the subset lattice: the cumulative objects $F_{\leq k}$ correspond to "downward closed" aggregation by size, while the deltas Δ_k recover the size-exact components. □

Remark 3318. *The key step is recognizing Π_k as a projection: Π_k picks out the orthogonal complement of $H_{\leq k-1}$ inside $H_{\leq k}$. Geometrically, one can imagine $H_{\leq 0} \subset H_{\leq 1} \subset H_{\leq 2} \subset \cdots$ as an increasing chain of subspaces; Δ_k is the component of F that lies in the "annulus" between the $k-1$ and k subspaces. Because these annuli are orthogonal in Hilbert space, the increments do not "double count" anything. A useful operational corollary is that Δ_k vanishes exactly when $F_{\leq k} = F_{\leq(k-1)}$, i.e. when allowing k-ary dependence does not improve the best approximation; this gives a clean criterion for the absence of genuinely k-way structure in the Hilbert sense.*

Corollary 59 (Delta pattern networks)**.** *Each delta Δ_k has a factor-graph representation using only factors of arity exactly k:*

$$\Delta_k(x) = \sum_{|S|=k} U_S(x_S).$$

Thus a tower of pattern networks can be represented either by its layers $\mathcal{N}_{\leq k}$ or by its delta layers (patches) $\mathcal{N}_{\Delta k}$. In particular, passing from the layer representation to the delta representation is a change of coordinates:

$$\mathcal{N}_{\leq k} \; = \; \mathcal{N}_{\leq(k-1)} \; \oplus \; \mathcal{N}_{\Delta k} \quad \textit{at the semantic level,}$$

with $\mathcal{N}_{\Delta k}$ consisting only of exactly-k-ary factor templates.

Remark 3319. *The distinction between layers and deltas is often cognitively and scientifically meaningful. Layers answer: "what can be expressed up to order k?" Deltas answer: "what is the irreducible novelty that only appears when we allow k-way dependence?" In the language of pattern* *networks, deltas correspond to adding a new family of exactly-k-ary motifs on top of what lower-order motifs already explain. Practically, deltas are often what one visualizes or reports: $\mathcal{N}_{\Delta 1}$ is a unary field layer, $\mathcal{N}_{\Delta 2}$ is a pure pairwise coupling layer, and higher $\mathcal{N}_{\Delta k}$ encode higher-order motifs whose effect cannot be mimicked by any combination of lower-arity motifs without changing the semantics. Because the Δ_k are orthogonal in Hilbert semantics, one can also compare their magnitudes directly via $\|\Delta_k\|$ to rank which interaction orders carry the dominant contribution.*

60.6 Modularity: factoring pattern networks into independent components

Definition 543 (Independent decomposition)**.** *Assume the variables split as $[n] = A \sqcup B$ and $F(x) = F_A(x_A) + F_B(x_B)$ with F_A depending only on x_A and F_B only on x_B. Call this an independent (additively separable) pattern-network decomposition.*

Remark 3320. *This definition captures an idealized form of modularity: the global semantic object is literally a sum of two sub-objects that live on disjoint variable sets. No term ever mixes variables from A and B. In factor-graph language, this corresponds to a disconnected factor graph; in Hyperseed terms, it is a clean separation of pattern subwebs with no shared interface (Hyperseed-Concept 132, 182).*

A simple example: $F(x_1, x_2, x_3, x_4) = \psi_{12}(x_1, x_2) + \psi_{34}(x_3, x_4)$ with $A = \{1, 2\}$ and $B = \{3, 4\}$. Then the two halves are independent in the strongest additive sense. This definition is useful because it lets us prove that towerization respects modularity: one can towerize each module separately.

It is important that the notion here is semantic *rather than probabilistic: we are not asserting any statistical independence of random variables x_A and x_B (though in many settings a product measure is used to define conditional expectations in the ANOVA/Moebius construction). Rather, we assert that the* function *F itself contains no cross-coupling between coordinates in A and coordinates in B. This is the most stringent version of modularity one could ask for in an interaction calculus: the absence of cross-terms holds identically, not merely approximately or in expectation.*

The partition $[n] = A \sqcup B$ should be read as an "interface cut": if a variable is shared by two pattern subwebs, then it belongs to the interface and strict decomposability fails. In applications, one often starts from a graph or hypergraph of variable participation and takes A, B to be unions of connected components; the present definition corresponds to the case where that participation structure is exactly disconnected.

Theorem 157 (Tower factorization under independence)**.** *If $F = F_A + F_B$ with disjoint variable sets A, B, then for every k:*

$$F_{\le k} = (F_A)_{\le k} + (F_B)_{\le k}, \qquad \Delta_k(F) = \Delta_k(F_A) + \Delta_k(F_B),$$

and every connected interaction term U_S with S intersecting both A and B vanishes.

Remark 3321. *The theorem states that independence is preserved perfectly by the tower: nothing about towerization forces artificial cross-talk between modules. In particular, there are no mixed interaction components: every U_S that touches both sides is exactly zero. This formalizes the intuition that if two subsystems do not share variables (interfaces), then no genuine connected motif can straddle the cut.*

This matters for scaling: if a large pattern network decomposes into weakly or strictly independent pieces, then tower computations and representations can be modularized. It connects to the broader methodological theme of decomposing cognitive/scientific problems into semi-independent subproblems, which recurs in the Hyperseed and related frameworks [5, 8].

One can also read the identities as a statement about locality *of low-order approximations: the order-k truncation $F_{\le k}$ does not "smear" information across an independence cut. Thus any algorithm that uses only $(\cdot)_{\le k}$ (e.g. for compression, for low-order surrogate modeling, or for approximate inference) can be applied independently on A and B without loss relative to applying it to the full $[n]$-system and then truncating.*

A further operational consequence is that if one is optimizing an objective of the form $F_A(x_A) + F_B(x_B)$, then the minimization (or maximization) problem decomposes as well: $\arg\min_x F(x)$ *can be obtained by independently solving* $\arg\min_{x_A} F_A(x_A)$ *and* $\arg\min_{x_B} F_B(x_B)$, *and similarly for approximate solutions based on $F_{\le k}$, since the truncations preserve additivity.*

Proof. In the ANOVA decomposition, conditional expectations factor across independent coordinates, and since F_A depends only on A, its only nonzero U_S have $S \subseteq A$; similarly for F_B. Thus any mixed S has $U_S = 0$, and summing U_S for $|S| \le k$ yields $F_{\le k} = (F_A)_{\le k} + (F_B)_{\le k}$. Delta identities follow by subtraction.

Concretely, if the interaction components are defined by the standard Moebius/ANOVA formula $U_S(x_S) = \sum_{T\subseteq S}(-1)^{|S|-|T|}\,\mathbb{E}[F(X) \mid X_T = x_T]$, then for a mixed set S (intersecting both A and B) each conditional expectation splits as $\mathbb{E}[F_A(X_A) \mid X_T] = \mathbb{E}[F_A(X_A) \mid X_{T\cap A}]$ and $\mathbb{E}[F_B(X_B) \mid X_T] = \mathbb{E}[F_B(X_B) \mid X_{T\cap B}]$. The alternating sum over $T \subseteq S$ then factorizes into independent alternating sums over $T \cap A$ and $T \cap B$, and the mixed contribution cancels to zero because no term in F_A can "see" coordinates in B and no term in F_B can "see" coordinates in A. This makes the vanishing of mixed U_S a direct algebraic consequence of the additive separability of F. □

Proof sketch. The high-level idea is to use the subset-indexed decomposition. If F is a sum of an A-only function and a B-only function, then conditioning on any mixed subset does not create a mixed dependence: Moebius inversion cannot conjure cross-terms that were not present. Therefore all mixed U_S vanish, and the tower splits additively.

Equivalently: the tower is built from linear operators (conditioning/averaging and inclusion–exclusion), and linear operators preserve direct sums. Since F already lies in the direct sum of the A-subspace (functions of x_A alone) and the B-subspace (functions of x_B alone), projecting onto interaction subspaces cannot generate components outside that direct sum. Mixed interaction subspaces are orthogonal (in the ANOVA sense) to both summands, so their coefficients must be zero. □

Remark 3322. *The key step is the behavior of conditional expectation under product structure: conditioning on coordinates in A has no effect on a function of B alone, and vice versa. Visually: the Boolean lattice of subsets splits into an A-lattice and a B-lattice, and the interaction decomposition respects this splitting. Hence the "connected mass" cannot leak across a genuine independence cut.*

Another way to phrase this is that the interaction calculus is compatible with taking connected components of the underlying dependency hypergraph: when the dependency hypergraph is disconnected, the interaction terms U_S are supported entirely within connected components. The present theorem is the special case where there are exactly two components, but the same reasoning iterates to a partition $[n] = A_1 \sqcup \cdots \sqcup A_m$ with $F = \sum_{i=1}^m F_{A_i}(x_{A_i})$, yielding $F_{\le k} = \sum_i (F_{A_i})_{\le k}$ and no mixed U_S spanning multiple blocks.

This strict case also serves as a baseline for "almost modular" systems: if there is a small coupling term $\varepsilon\, G(x_A, x_B)$ added to $F_A + F_B$, then the only source of mixed U_S is the coupling itself, and one expects mixed interactions to scale with ε. Later bounds on truncation error can then be interpreted as quantifying how much cross-talk is introduced by genuine interface terms as opposed to being an artifact of the tower construction.

Remark 3323 (Interpretation)**.** *This is the cleanest formal statement of "pattern-network components that do not share interfaces produce no connected higher-order motifs across the cut." It justifies decomposing a large pattern network into modules before towerizing: the tower is additive across independent modules.*

In particular, the theorem delineates a sharp boundary between structural *and* emergent *complexity: any higher-order motif that spans both A and B must be traced to an explicit cross-module term in F (a shared variable, a bridging factor, or an interaction potential involving both sides). If no such bridge exists, then no amount of towerization or low-order truncation can manufacture an apparent bridge, so modular semantics and modular computation coincide in this ideal regime.*

60.7 Task invariance: why k-layers are sufficient for k-limited reasoning

Theorem 158 (k-observer invariance (tower soundness for k-limited tasks))**.** *Let $\{F_{\leq k}\}$ be a dependency tower for F with respect to observer family $O_{\leq k}$. Then for every $O \in O_{\leq k}$,*

$$O(F_{\leq k}) = O(F).$$

Consequently, any reasoning, planning, or learning procedure whose internal scoring depends only on observables in $O_{\leq k}$ will behave identically whether it uses F or $F_{\leq k}$.

Remark 3324. *The theorem is conceptually simple but methodologically powerful: if your agent's questions are k-limited, then F and $F_{\leq k}$ are indistinguishable to that agent, hence interchangeable for that purpose. In Hyperseed terms, the space of allowable tasks/questions (Hyperseed-Concept 186, 144) determines what distinctions are operationally meaningful. If those tasks cannot witness higher-order dependencies, then representing them is unnecessary for correctness* relative to *those tasks.*

This result connects backward to the dependency tower definition (it is exactly property (2)) and forward to practical recipes: message passing, local search heuristics, and many bounded-complexity inference schemes implicitly operate with restricted dependency order. The tower provides a semantics-preserving truncation principle for such bounded observers.

It is helpful to read "k-limited" here as a precise interface restriction: an observer $O \in O_{\leq k}$ is allowed to probe at most k-way interactions (or, more generally, apply tests whose semantic content is determined by at most k jointly coupled components). Under that interpretation, $O(F)$ is the observer-accessible summary (a statistic, score, prediction, or decision-relevant quantity) that the agent can compute from F using only those restricted probes. The tower soundness condition states that all such accessible summaries are already fixed by the $\leq k$ layer, so carrying higher-order structure is invisible to the agent's admissible task class.

Equivalently, the theorem is an "observational equivalence" statement: F and $F_{\leq k}$ may differ substantially as semantic objects, but they induce the same input–output behavior on the entire test suite $O_{\leq k}$. This is exactly the sense in which the k-layer is sufficient for any downstream procedure that cannot consult higher-order tests.

Proof. This is exactly property (2) in the dependency tower definition: k-ary indistinguishability.

To unpack the "consequently" clause: if a procedure A can be expressed as a composition of operations that take as inputs only values of the form $O(F)$ for $O \in O_{\leq k}$ (for example, by computing a finite collection of such observables and then combining them by deterministic arithmetic), then replacing F by $F_{\leq k}$ leaves every queried observable unchanged, hence leaves the entire computation unchanged. The same reasoning applies to randomized procedures whose randomness is independent of whether they are run on F or $F_{\leq k}$: conditional on the same random seed, all oracle calls return identical values, so the output distribution is identical as well. □

Proof sketch. No additional argument is needed: the theorem simply restates the tower's defining indistinguishability axiom and then interprets it operationally as invariance of any downstream procedure built entirely from the allowed observables.

One can view this as a "plug-in" principle: once the tower construction has certified indistinguishability for $O_{\leq k}$, any algorithm that is expressible as an $O_{\leq k}$-oracle program is automatically sound under the truncation $F \mapsto F_{\leq k}$. In this sense, the tower acts as a reusable proof artifact: verifying property (2) once yields invariance for an entire family of bounded-task pipelines. □

Remark 3325. *The "consequently" clause is an instance of a general principle: if two semantic objects are equal under all queries a procedure can issue, then the procedure cannot behave differently on them. One may view this as a modest form of extensionality: behavior is determined by the available tests.*

In many concrete settings, the "queries a procedure can issue" can be made explicit. For example, if an inference engine only ever accesses F through local factor evaluations, local conditional probabilities, or constraint checks involving at most k variables at a time, then its entire execution trace is determined by those $\leq k$-ary responses. Any additional structure in F that only manifests via $(k+1)$-way (or higher) couplings is, from the engine's perspective, not merely ignored but genuinely unobservable: there is no admissible sequence of interactions that could reveal it.

The same extensionality intuition applies to learning settings where the loss or reward depends only on $O_{\leq k}$-observables. If the training signal is computed from $\leq k$-local statistics, then gradients, updates, and model selection criteria that are functions of those statistics cannot distinguish F from $F_{\leq k}$ either, so truncation is sound for the induced learning dynamics as well.

Corollary 60 (Reasoning-engine recipe)**.** *If your inference machinery uses only ¡= k-ary tests (e.g. factor-graph message passing with max factor arity ¡= k, or pattern matching using ¡= k-hole contexts), then replacing the full pattern network by the k-layer pattern network is semantics-preserving for those inference outputs.*

Proof. Under the stated hypothesis, every intermediate computation performed by the inference machinery can be viewed as depending only on values of observables in $O_{\leq k}$ (e.g. factor evaluations, consistency checks, or match scores that involve at most k jointly constrained elements). By Theorem 1, each such observable takes the same value on F and on $F_{\leq k}$, hence the entire computation—and therefore the final inference output—is unchanged by the replacement. □

Remark 3326. *This corollary is the practical moral: truncate first, then compute. One may still face computational costs, but at least one is no longer paying for distinctions one's inference engine cannot, even in principle, exploit. This resonates with the general "bounded observer" stance in cognitive and scientific methodology, and with tower-based decomposition themes [8].*

A useful way to operationalize this in implementations is to treat the choice of k as part of the specification of the task interface: it fixes which local neighborhoods, factor arities, or context widths are ever consulted. When that interface is fixed, the tower provides a principled guarantee that higher-order structure can be dropped without affecting any output that is expressible in terms of that interface. In particular, one can decouple two concerns that are often conflated: (i) whether higher-order dependencies exist in the underlying semantic object, versus (ii) whether the downstream algorithm is able to exploit them. The theorem and corollary formalize that only the latter matters for correctness relative to the task class.

Finally, note that "semantics-preserving" here is intentionally scoped: it preserves exactly the outputs that are definable from $\leq k$-ary tests. If one later upgrades the task family (e.g. allows $(k+1)$-ary queries, introduces global constraints, or changes the evaluation metric to one that *couples more than k components), then the appropriate truncation level must be revisited, and a deeper layer of the tower (or the full object F) may become operationally necessary.*

60.8 Context-poset towerization for syntax-aware pattern networks

Definition 544 (Context-indexed tower signatures)**.** *Let* $\mathrm{Ctx}(\varphi)$ *be the context refinement poset with order = number of holes. For each k, let* Σ_k *be the set of all evaluations of* φ *in contexts of order ¡= k, quotiented by your canonicalization convention. Define the tower signature map*

$$\tau_k : U \to \Sigma_k$$

from contexts/environments U *(assignments, inputs, evaluation traces) to signatures. Define k-indistinguishability by kernel relation* $H_k := \{(u, v) : \tau_k(u) = \tau_k(v)\}$.

Remark 3327. *The phrase "quotiented by your canonicalization convention" is doing real work: in many syntax-aware settings, the raw space of context evaluations contains redundant presentations of the same observational content (e.g. alpha-renaming, commuting diagrams of evaluation steps, or semantically equivalent normal forms). The quotient* Σ_k *should be understood as the* space of observational outcomes *at hole order* $\leq k$ *after choosing a normalization/canonical representative, so that* $\tau_k(u)$ *records information up to the intended notion of observational equality rather than up to accidental implementation details. In particular, different canonicalization choices can change* Σ_k *(and thus* H_k*), but the intended use is that* Σ_k *is stable under the invariances one wants the pattern network to respect.*

Remark 3328. *This definition shifts from numeric semantics to relational/observational semantics. Instead of projecting a function in* L^2*, we collect* all *results of probing* φ *with contexts up to hole order k, and package those results into a signature* $\tau_k(u)$*. Two underlying situations* u, v *are k-indistinguishability if they yield the same signature. Thus* H_k *is an equivalence-like relation capturing what the k-hole world cannot separate.*

As an example, imagine φ *is a program and* U *consists of input states. A 1-hole context might supply one argument and observe the output; a 2-hole context might supply two arguments and observe a relation between outputs (e.g. ordering or equality). Then* τ_1 *records all 1-hole observations, and its kernel identifies inputs that are observationally identical at that interface complexity. This is useful because it provides a towerization procedure even when a Hilbert inner product is not available, and it connects to the Hyperseed idea that patterns are partly defined by the tests that elicit them (Hyperseed-Concept 86, 130, 80).*

Remark 3329. *It is helpful to read* τ_k *as a "feature extractor" whose features are* contextual experiments *rather than pre-specified coordinates. In that sense, the tower level k controls an experimental budget: increasing k allows more holes, hence richer interventions, hence (typically) a refinement of the partition of* U *induced by* H_k*. When the context refinement poset is directed by hole-filling, one expects a monotone chain of kernels* $H_0 \supseteq H_1 \supseteq H_2 \supseteq \cdots$ *(more observational power yields fewer identified pairs), although the exact monotonicity statement depends on whether the family of "contexts of order* $\leq k$*" is nested in the intended way.*

Remark 3330 (Technical notation)**.** *A poset is a partially ordered set; here the order is refinement (filling holes). The set* U *is deliberately generic: it may consist of environments, inputs, traces, or any other substrate on which contexts can act. The kernel relation* $\ker(\tau_k)$ *is the set of pairs mapped to the same signature; the text writes it as* H_k.

Remark 3331. *Since τ_k is an ordinary function,* $\ker(\tau_k)$ *is automatically an equivalence relation on U (reflexive, symmetric, transitive). The phrase "equivalence-like" above is meant to emphasize that, while the formal properties are those of an equivalence relation, the intended interpretation is observational: u and v are equivalent only relative to the chosen family of contexts (order $\leq k$) and the chosen canonicalization of outcomes. In particular, H_k may be strictly coarser than true semantic equality in U if the allowed tests are too weak to expose the difference.*

Theorem 159 (Canonical k-indistinguishability relations and optimality among k-admissible observations)**.** *Let $g : U \to T$ be any k-admissible observation, meaning $g = f \circ \tau_k$ for some f. Then* $\ker(\tau_k) \subseteq \ker(g)$*. Therefore any relational weakness (join-aggregated valuation over indistinguished pairs) is minimized by the tower-kernel relation* $\ker(\tau_k)$ *among all k-admissible observations.*

Remark 3332. *The condition "g is k-admissible" formalizes the idea that g is not allowed to look directly at $u \in U$; it may only depend on u through what is exposed by k-hole probing, i.e. through $\tau_k(u)$. Thus f can be thought of as a post-processing step, aggregation, or decision rule applied to the raw signature. The theorem then says that no amount of post-processing can recover distinctions that the signature itself did not encode.*

Remark 3333. *The first claim says: τ_k is the* finest *summary that uses only k-hole information. Any other k-admissible observation g necessarily forgets at least as much, hence merges at least as many pairs. Thus* $\ker(\tau_k)$ *is the minimal indistinguishability relation consistent with the k-hole constraint.*

The second claim connects this to "weakness"-style optimization: if one evaluates an observation by how much it fails to distinguish (in a monotone way), then the finest observation is best. This is consonant with weakness-based selection principles in the broader Hyperseed discourse [3], though here it is phrased purely in order-theoretic terms.

Remark 3334. *Concretely, if a "weakness functional" assigns a higher score when more pairs are left indistinguishable, then it is naturally monotone with respect to inclusion of relations: if $R \subseteq R'$ then R' identifies at least the pairs that R does (and possibly more), hence is at least as weak. Under this reading, minimizing weakness means pushing toward the smallest feasible kernel among the admissible observations, which is exactly what the theorem guarantees is achieved by* $\ker(\tau_k)$*.*

Proof. If $\tau_k(u) = \tau_k(v)$ then $g(u) = f(\tau_k(u)) = f(\tau_k(v)) = g(v)$, so $(u, v) \in \ker(g)$. Thus $\ker(\tau_k) \subseteq \ker(g)$. Any monotone weakness functional on relations increases with set inclusion, hence is minimized by the smallest relation, i.e. $\ker(\tau_k)$. ☐

Remark 3335. *The proof uses only the elementary property of kernels under composition: if $g = f \circ \tau_k$ then $\tau_k(u) = \tau_k(v)$ is a sufficient condition for $g(u) = g(v)$. One can also phrase this as "τ_k is initial among k-admissible maps": every k-admissible g factors uniquely through τ_k once f is fixed, and such a factorization cannot create new distinctions inside fibers of τ_k.*

Proof sketch. The proof is a one-line kernel argument: composing with f cannot separate points already identified by τ_k. The optimality statement then follows from monotonicity: finer distinctions mean a smaller kernel, and any weakness measure that penalizes indistinguishability must prefer the smallest kernel. ☐

Remark 3336. *The key step is categorical in spirit: τ_k is a universal factor through which all k-admissible observations must pass. Visually, τ_k draws the sharpest partition of U achievable with k-hole tests, and every other k-admissible observation corresponds to coarsening that partition.*

Remark 3337. *This theorem is the syntax-aware analogue of the Hilbert tower optimality: "if you only allow k-hole information, the tower signature is the maximally informative summary, and its induced indistinguishability is minimal among all summaries using no more than k-hole information."*

60.9 Summary

- A dependency tower is a principled way to stratify any semantic object by dependency order, using indistinguishability by ¡= k tests and best-approximation semantics. In concrete terms, the "tests" may be understood as the admissible queries, probes, or observables available to an agent, so that two objects are identified at order k whenever every test involving at most k coordinates (or k arguments) evaluates the same way on both. The tower then selects, at each level, the canonical representative (e.g. in a metric or order-theoretic sense) that best matches the original object under this restricted observational regime.

- In Hilbert settings, tower layers are orthogonal projections and yield tight lower bounds (tail energy) on any ¡= k representation. Equivalently, if x is decomposed into its tower components and $P_{\leq k}x$ denotes the order-k truncation, then $x - P_{\leq k}x$ is orthogonal to every $\leq k$ approximation, and the squared norm $\|x - P_{\leq k}x\|^2$ is exactly the unavoidable residual for any candidate representation that only uses $\leq k$-way dependence. This makes the lower bound "tight" in the strongest sense: the tower truncation attains the best possible $\leq k$ error, and the tail energy quantifies precisely what cannot be recovered without admitting higher-order interactions.

- Each tower layer can be represented as a pattern network (factor graph) with max factor arity ¡= k by using the interaction components. Here one may view the interaction components as the canonical potentials associated to subsets of variables, so that the layer is realized by a factorization over factors whose scopes have size at most k. In particular, the representation is not merely existential: it is induced by the same decomposition that defines the tower layer, ensuring that the factor graph respects the intended semantics of "no dependence beyond arity k" rather than imposing an ad hoc parametric restriction.

- The tower admits delta layers ("exactly order k") which are orthogonal and correspond to arity-exact factor sets. These delta layers can be read as successive differences between adjacent truncations (e.g. the increment from order $\leq k-1$ to order $\leq k$), which isolates what is genuinely new at order k and not already explained by lower orders. Orthogonality implies that these increments do not interfere with one another (no double-counting across orders), and the "arity-exact" interpretation means that the associated factor sets can be chosen so that every nontrivial factor involves exactly k variables (or arguments), matching the intuitive notion of a pure k-way interaction.

- Independence decompositions of pattern networks factor the tower: no mixed connected terms cross independent cuts. Thus, when the pattern network separates into independent components (in the probabilistic sense, or in the sense of a product structure across a partition), the tower decomposition respects that separation: interaction terms supported on one side do not couple to the other side through any connected contribution. Put differently, the tower layers refine along the same independence cuts as the underlying network, so that towerization commutes with the independence-based modularization that is often used to make large systems tractable.

The resulting picture is a hierarchy of increasingly expressive semantics: the $\leq k$ layer captures precisely what any $\leq k$-limited observer can in principle discriminate, while the higher-order tail measures the additional structure that only becomes visible when genuinely higher-arity tests are allowed. In this sense, "towerization" is simultaneously a structural decomposition (by dependency order) and an operational statement (by what can and cannot be detected under bounded interaction width).

Remark 3338. *Taken together, these results justify a sober but powerful methodological stance: when an observer or agent is structurally limited to k-way tests, it is not merely convenient but* mathematically sound *to replace a full pattern network by its k-layer for the purposes of that observer's tasks (Hyperseed-Concept 186). The Hilbert case gives the cleanest canonical story, while the context-poset variant shows how analogous conclusions can be drawn in syntax-aware settings where "observation" is inherently procedural. In particular, the substitution "full object $\rightsquigarrow$ order-k truncation" is justified not only as a heuristic simplification but as an invariance principle: any two semantic objects with the same $\leq k$ layer are indistinguishable to the observer, and any decision rule built solely from $\leq k$ tests must therefore assign them the same outcomes. When a quantitative error notion is available (as in the Hilbert setting), the tower additionally supplies an explicit and optimal guarantee on what is sacrificed by truncation (the tail energy), thereby separating epistemic limitation (what cannot be accessed by $\leq k$ probes) from modeling choice (what one elects to ignore). In the procedural or syntax-aware regime captured by the context-poset formulation, the same stance is recovered in an order-theoretic guise: bounded observational procedures induce a corresponding bounded dependency semantics, and the tower provides a disciplined way to state and exploit that boundedness.*

61 TransWeave Meets Hyperseed: Self-Continuity, Paradigm Commensurability, and Mindplex Coherence via Approximate Intertwining

We connect (i) Hyperseed's approximate-morphism account of pattern-flow, self-continuity, mind-world correspondence, and mindplex coherence, with (ii) TransWeave's Bellman-Darboux (approximate) intertwining maps that transfer solutions across reward reweightings, tasks, representations, and agents. The core bridge is an "error-to-degree" embedding: small TransWeave intertwining error yields a high-degree approximate morphism between induced Hyperseed-style pattern/value-flow networks. This yields formal results for: continuity of self as transweaving across time-slices; commensurability of scientific paradigms as existence of low-error transweaves between their problem-solving procedures; and conditions under which a group of minds forms a notably coherent mindplex when pairwise transweaving is dense enough.

To make the bridge intuitive before it is made precise, it helps to keep in mind the two different levels at which the frameworks speak. TransWeave is naturally stated at the level of *operators* (e.g. Bellman-style updates on value functions, policies, or other solution objects), whereas Hyperseed is naturally stated at the level of *flows on structured networks* (patterns transforming into patterns, and values/constraints propagating through those patterns). The claim here is that these are not competing descriptions but two views of the same phenomenon: an approximate intertwining at the operator level induces, in a canonical way, an approximate homomorphism of the corresponding flow networks, with the quality of the induced morphism controlled by the original intertwining defect.

More concretely, an approximate intertwining is typically witnessed by a map (or family of maps) that transports solution-relevant objects from one setting to another (across tasks, reward reweightings, representations, or agents) such that "apply-update-then-transport" is close to "transport-then-apply-update." The quantitative mismatch between these two composites is the *intertwining error*. Hyperseed's "degree" of an approximate morphism can be understood as any monotone calibration that assigns higher degree to smaller defect, subject to natural stability properties (e.g. composing two good-but-imperfect morphisms yields a morphism whose degree degrades in a controlled way). The "error-to-degree embedding" named above is precisely the step that converts a TransWeave-style operator inequality (an error bound) into a Hyperseed-style graded morphism claim about the induced pattern/value-flow structure.

The phrase "induced Hyperseed-style pattern/value-flow networks" may be read in a deliberately broad sense: a reinforcement-learning or decision-making problem determines a web of dependencies among representations (state abstractions, concepts, or features), update rules (planning, inference, learning), and evaluative quantities (values, costs, preferences). In such a web, edges correspond to permissible transforms (update steps, inference moves, or representational translations), and the weights/defects encode how reliably one can propagate information or value along those edges. An approximate intertwining map thereby becomes a conduit that carries not only solutions but also the *structure of solution-flow* from one web to another, which is exactly the sort of conduit Hyperseed treats as an approximate morphism of pattern-flow.

Interpreting "self-continuity as transweaving across time-slices" similarly becomes more literal under this lens. If each time-slice of an agent is associated with its own partially learned operator (capturing its current policy/value updates, inference habits, or representational choices), then the persistence of a single "self" can be modeled as the existence of low-error intertwinings between successive slices. On this view, autobiographical and procedural continuity correspond to the ability to transport solution structures forward in time with limited distortion; breaks of identity correspond to the absence of such low-defect transport, or to the accumulation of defects beyond tolerable thresholds.

The same machinery also clarifies the claim about paradigm commensurability. A "scientific paradigm" can be idealized as a family of operators encoding its admissible problem framings, inference moves, model updates, and evaluative criteria. Two paradigms are commensurable to the extent that there exists a low-error transweave that carries solution procedures and evaluative gradients from one to the other without large distortion. In this formalization, disagreement can persist even under commensurability (because the intertwining is only approximate), but crucially there remains a quantitatively controlled bridge explaining when translation of methods and standards is feasible and when it fails.

Finally, the mindplex claim can be read as a graph-theoretic strengthening of pairwise transfer. If we view a collection of agents as nodes in a "transweave graph," with edges weighted by intertwining error (or equivalently by induced Hyperseed morphism degree), then a mindplex is not merely a set of agents that can sometimes imitate each other, but a set in which the web of low-error transports is sufficiently dense and sufficiently coherent under composition. Density alone is not enough: what matters is also the *consistency of multi-step transport* (transporting from A to B to C should not drift too far from transporting directly from A to C), since such consistency is exactly what turns a pile of pairwise correspondences into a stable collective flow that can support shared concepts, shared evaluative signals, and robust coordination.

Remark 3339. *The philosophical stance here is a familiar one in modern mathematical science: when we cannot hope for strict equality of structures (the world, minds, and scientific paradigms being too messy for that), we settle for* approximate *equality and then quantify the defect. Hyperseed makes this stance explicit by treating "pattern flow" and "mind-world correspondence" as high-*

degree approximate morphisms rather than brittle isomorphisms [1, 5]. TransWeave, in parallel, treats transfer as an approximate intertwining *of Bellman operators [7]. The present section is a bridge between these: it turns an operator intertwining error into a quantified morphism degree between the induced flow graphs.*

Remark 3340. *A useful way to prevent the "approximate" qualifier from becoming rhetorical is to keep track of which norms/metrics are intended to measure defect. In TransWeave settings, intertwining errors are often expressed in operator norms or sup norms over value functions/policies (or, more generally, as bounds that control how far transported solutions violate the target fixed-point or optimality relations). In Hyperseed settings, degree assignments typically play an analogous role, acting as a graded witness to the reliability of pattern/value transport across the morphism. The technical work of the section therefore amounts to verifying that the chosen defect measure is (i) strong enough to control the induced flow discrepancy, and (ii) stable under the kinds of compositions that matter for multi-step reasoning, multi-stage learning, and multi-agent interaction.*

Remark 3341. *A reader may keep three Hyperseed core-concepts in view as an informal compass: Self-Continuity (Hyperseed-Concept 166), Mind-World Correspondence (Hyperseed-Concept 112), and Mindplex (Hyperseed-Concept 113). TransWeave itself is treated as a formal transfer relation (Hyperseed-Concept 193) that belongs to the broader family of Transfer Learning (Hyperseed-Concept 192).*

Remark 3342. *The organizing intuition behind the three advertised applications is the same: in each case one has a family of "problem-solving updates" (learning updates, inferential moves, or planning steps) and one asks whether there exists a structure-preserving translation between them. Self-continuity asks for such translations across time-indexed versions of an agent; paradigm commensurability asks for them across methodological regimes; mindplex coherence asks for them across agents, together with enough closure under composition to support stable collective cognition. Framing all three in terms of approximate intertwining allows the same quantitative notion of defect to play the role of "how continuous," "how commensurable," or "how coherent," rather than treating these as purely qualitative labels.*

61.1 Preliminaries

61.1.1 Quantale-weighted graphs and approximate morphisms

Definition 545 (V-graph)**.** *Fix a commutative quantale $(V, \leq, \otimes, 1)$. A V-weighted directed graph (a V-graph) is a pair $G = (X, G)$ where X is a set and $G : X \times X \to V$ assigns a weight to each ordered pair.*

Remark 3343. *The quantale $(V, \leq, \otimes, 1)$ should be read as a "logic of degrees." The order $\leq$ tells us when one degree is at most another; $\otimes$ is a monoidal product expressing how degrees combine along sequential composition; and 1 is the unit degree ("perfect preservation," "no loss," or "complete confidence," depending on interpretation). Commutativity of $\otimes$ is not strictly required for all applications, but it keeps the algebraic bookkeeping simple in the use-cases emphasized by Hyperseed and TransWeave.*

Remark 3344. *A simple example is the* boolean *case $V = \{0, 1\}$ with $\leq$ the usual order and $\otimes = \wedge$, where $G(x, x') = 1$ indicates an edge is present and 0 absent. Another example, used later in this section, is $V = [0, 1]$ with $\otimes$ as multiplication, where weights behave like similarities or reliabilities. In Hyperseed terms, such V-graphs are a lightweight formal proxy for Pattern Flow Networks (Hyperseed-Concept 131): they let us speak about "how strongly" one token leads into another without committing to a single probabilistic semantics.*

Definition 546 (Degree of structure preservation)**.** *Given V-graphs $G = (X, G)$ and $H = (Y, H)$ and a function $f : X \to Y$, define*

$$\deg(f; G, H) \ := \bigwedge_{x,x' \in X} \big(G(x, x') \to H(f(x), f(x'))\big),$$

where $(u \to v)$ is the residuum satisfying: $u \otimes w \leq v$ iff $w \leq (u \to v)$. We say f is a q-approximate morphism $G \to H$ if $q \leq \deg(f; G, H)$.

Remark 3345. *The notation is dense but principled. The symbol $\bigwedge$ denotes an infimum (greatest lower bound) taken over all ordered pairs $(x, x') \in X \times X$, so $\deg(f; G, H)$ is a* worst-case *preservation score: if f badly distorts even one important edge-weight, the degree decreases. The residuum $(u \to v)$ is the quantale's internal implication: it measures "how much slack" one must multiply u by (via $\otimes$) in order to be $\leq v$. This is exactly the style of "error as implication-residual" used in quantale-based weakness/surprisingness calculi [3].*

Remark 3346. *A concrete mental model: in $V = [0, 1]$ with $\otimes = \cdot$, the residuum is (informally) the largest $w \in [0, 1]$ such that $u \cdot w \leq v$, i.e. a ratio-like comparison between u and v (with the usual caveat about $u = 0$). Then $\deg(f; G, H)$ says: for every edge-strength $G(x, x')$ in the source, the corresponding edge-strength in the target, $H(f(x), f(x'))$, must be at least a fixed fraction of it, and we take the best such uniform fraction over all pairs. This makes "approximate morphism" a quantitative version of the ordinary notion of graph homomorphism: rather than preserving adjacency, we preserve weighted relations up to a uniform degradation factor.*

Theorem 160 (Composition law)**.** *For $f : X \to Y$ and $g : Y \to Z$,*

$$\deg(g \circ f; G, K) \ \geq \ \deg(f; G, H) \otimes \deg(g; H, K).$$

In particular, if f is q_1-approximate and g is q_2-approximate, then $g \circ f$ is $(q_1 \otimes q_2)$-approximate.

Remark 3347. *This theorem says that approximate structure preservation composes: if f preserves the structure of G inside H to degree q_1, and g preserves the structure of H inside K to degree q_2, then their composite preserves G inside K to at least the combined degree $q_1 \otimes q_2$. In the multiplicative degree quantale used below, this means degrees multiply, so small degradations accumulate gradually rather than catastrophically.*

Remark 3348. *The result is important because it turns "continuity of identity" and "transfer across agents" into a* path problem*: if the world only offers a chain of approximate correspondences, the theorem guarantees a quantitative lower bound on the composite correspondence. This is the precise algebraic engine behind the later telescoping-style bounds for self-continuity and mindplex coherence.*

61.1.2 Pattern-flow self-continuity (Hyperseed-style)

Definition 547 (Pattern/value-flow network)**.** *A pattern-flow network over interval I is a V-graph $F_I = (X_I, F_I)$ whose nodes are pattern-tokens (or state/action tokens) and whose edge weight $F_I(a, b)$ measures the degree to which pattern a flows into b over I (observer-dependent estimator).*

Remark 3349. *This definition abstracts away most of the ontology and keeps only what is needed for the bridge: a set of tokens X_I and a quantitative notion of "flow" between them. In a cognitive reading, tokens might be percepts, actions, beliefs, subroutines, or any other items one wants to track as elements of a Pattern Web (Hyperseed-Concept 132) evolving in time; the edge weight $F_I(a, b) \in V$ then expresses how strongly a tends to lead to, explain, enable, or transform into b during the interval I [5, 1].*

Remark 3350. *A simple example in $V = [0, 1]$ is: let X_I be a set of state-action pairs observed in a window of interaction, and set $F_I(a, b)$ to be a normalized empirical conditional probability of seeing b soon after a, possibly tempered to reflect confidence. A different example is semantic rather than statistical: $F_I(a, b)$ could be the degree to which a is judged (by a particular observer) to be a subpattern of b or a cause of b, placing the construction close to Hyperseed's broad Pattern/Process interface (Hyperseed-Concept 141).*

Definition 548 (Self-continuity as best approximate self-morphism)**.** *For successive intervals I, J, define the self-continuity degree*

$$\mathrm{SCS}(I \to J) \ := \bigvee_{f: X_I \to X_J} \deg(f; F_I, F_J).$$

Remark 3351. *Here $\bigvee$ denotes a supremum (least upper bound) over all candidate correspondences $f : X_I \to X_J$. Intuitively, we attempt to "translate" the tokens of interval I into those of interval J in whatever way best preserves the observed flow structure, and we take the degree of the best such translation. The quantity $\mathrm{SCS}(I \to J)$ is thus a purely structural measurement of Self-Continuity (Hyperseed-Concept 166): it asks whether there exists a high-degree approximate morphism witnessing that the later pattern-flow network is a continuation (up to reinterpretation) of the earlier one.*

Remark 3352. *In many concrete instantiations,* $\deg(f; F_I, F_J)$ *is computed by comparing the transported flow F_I along f (e.g. via pushforward/pullback operations or adjacency-matrix relabeling) to the target flow F_J, and then mapping the discrepancy into a degree value in a quantale of "truth" or "compatibility." The supremum $\bigvee$ is therefore not merely an abstract aggregator: it encodes a design decision that self-continuity is witnessed by* existence *of at least one good reinterpretation map, rather than requiring all reinterpretations to work. This existential flavor matches the intended reading: we are not asking whether every encoding of I persists into J, but whether there is some plausible alignment under which the observed dynamics are nearly preserved.*

Remark 3353. *Two simple extremes help fix the meaning. If $X_I = X_J$ and $F_I = F_J$, then choosing $f = \mathrm{id}$ yields degree 1 (in standard degree quantales), so $\mathrm{SCS}(I \to J)$ is maximal. If, on the other hand, every candidate f maps highly-flowing edges in I to weak or nonexistent edges in J, then each $\deg(f; F_I, F_J)$ is small, and the supremum remains small. The usefulness of the definition is that it permits identity through* relabeling *and* representational drift*: the self need not be fixed as a set of atoms; it is fixed as a pattern of transformations.*

Remark 3354. *Note that the map $f : X_I \to X_J$ is allowed to be many-to-one or otherwise non-invertible unless explicitly restricted by the modeling context. Allowing non-bijections captures common cognitive and computational phenomena: coarse-graining (many earlier distinctions collapsed into one later token), splitting (when modeled via relations rather than functions), and partial forgetting (when certain elements of X_I are effectively sent to low-salience or dummy states in X_J). When one wishes to forbid such collapses, one may restrict the supremum to a subclass (e.g. injective maps, structure preserving maps, or maps satisfying resource constraints), but the present definition keeps the notion maximally permissive so that "continuation up to reinterpretation" is not blocked by purely representational changes.*

Corollary 61 (Longer-horizon self-continuity lower bound)**.** *For a chain $I_0 \to I_1 \to \cdots \to I_n$,*

$$\mathrm{SCS}(I_0 \to I_n) \ \geq \ \mathrm{SCS}(I_0 \to I_1) \otimes \cdots \otimes \mathrm{SCS}(I_{n-1} \to I_n).$$

Remark 3355. *This is a formalization of a commonsense thought: continuity over a long time is at least as good as the product (or, in other quantales, the corresponding monoidal accumulation) of the continuities of the small steps. It matters because it lets one trade global questions ("Am I the same person after a year?") for local ones ("How much translation is needed from one day to the next?") in a way that is algebraically disciplined, and it mirrors telescoping/chain-rule phenomena seen in other quantale calculi [3].*

Remark 3356. *The direction of the inequality reflects the fact that* $\mathrm{SCS}(I \to J)$ *is defined as a supremum over witnesses: composing locally-good witnesses yields a particular candidate map (or, more generally, a particular candidate correspondence) from* I_0 *to* I_n*, whose degree is bounded below by the monoidal product of the local degrees; taking the supremum over* all *candidates can only improve this. In typical quantale settings,* $\otimes$ *is monotone in each argument and distributes over* $\bigvee$*, so the bound is exactly the algebraic shadow of "compose approximate morphisms* $\Rightarrow$ *multiply their degrees." When* $\otimes$ *is ordinary multiplication on* $[0,1]$*, the product makes explicit the intuitive accumulation of small degradations across many steps, whereas in tropical or additive quantales one obtains the corresponding sum-like accumulation.*

61.1.3 TransWeave BD maps (approximate intertwining)

Definition 549 (Discounted Bellman operator)**.** *Fix a discount* $\gamma \in (0,1)$ *and a (weighted) MDP* M *with Bellman optimality operator* B*. A value function* V *is optimal iff it is a fixed point:* $V^* = B(V^*)$*. The operator* B *is a* γ*-contraction in* $\|\cdot\|_\infty$*.*

Remark 3357. *This definition imports a key piece of reinforcement learning mathematics: optimality is characterized as a fixed point of a contraction operator. The discount* $\gamma \in (0,1)$ *enforces the contraction property in* $\|\cdot\|_\infty$*, which is what ultimately yields quantitative stability bounds of the form "error divided by* $(1-\gamma)$*". In this section we treat it as a black box: we use only the fixed-point identity* $V^* = B(V^*)$ *and the Lipschitz bound* $\|B(V) - B(W)\|_\infty \le \gamma \|V - W\|_\infty$*.*

Remark 3358. *For later use, it is helpful to keep in mind the standard consequence of contraction: not only does the fixed point exist and is unique, but value iteration* $V_{k+1} = B(V_k)$ *converges geometrically with rate* γ *in* $\|\cdot\|_\infty$*. Thus, whenever we can control the size of a perturbation in the Bellman operator or an approximate commutation defect, the impact on the fixed point is correspondingly controlled by a factor on the order of* $(1-\gamma)^{-1}$*. This is the precise technical sense in which discounting turns long-horizon planning into a quantitatively stable computation.*

Remark 3359. *From the Hyperseed point of view, the significance is conceptual: a cognitive procedure that repeatedly applies a Bellman-like operator is a particular instance of a belief/control updating dynamic, and the fixed-point is the stable "answer" to a persistent question about best achievable return. This aligns with the broader Hyperseed stance that cognition is question/answer/belief dynamics coupled to action [1].*

Remark 3360. *Interpreting* B *abstractly as an update operator also helps separate three roles that can otherwise be conflated: (i) the representational space of value functions, (ii) the dynamics of improvement encoded by* B*, and (iii) the semantic content of a value function as an evaluation of future outcomes. TransWeave maps focus on how (i) and (ii) can be transported across tasks while keeping (iii) approximately aligned, which is why commutation up to* ϵ *is the central criterion below.*

Definition 550 (TransWeave intertwining condition)**.** *Given two weighted MDPs* M_w *and* $M_{w'}$ *with Bellman operators* B_w *and* $B_{w'}$*, a TransWeave map consists of a state/representation map* T

together with an induced map T_V on value functions such that

$$\| T_V \circ B_w \; - \; B_{w'} \circ T_V \|_{\infty \to \infty} \; \leq \; \epsilon.$$

We call ϵ the intertwining error.

Remark 3361. *The expression $T_V \circ B_w - B_{w'} \circ T_V$ is a* commutator-like defect*: it measures how far T_V is from conjugating the Bellman dynamics of M_w into that of $M_{w'}$. If the defect were exactly zero, transferring a value function by T_V and then updating by $B_{w'}$ would be indistinguishable from updating by B_w first and then transferring. The inequality bounds this mismatch uniformly over inputs, in the operator norm induced by $\| \cdot \|_\infty$.*

Remark 3362. *Concretely, $\|\cdot\|_{\infty\to\infty}$ denotes the induced operator norm $\|L\|_{\infty\to\infty} = \sup_{V\neq 0} \|L(V)\|_\infty / \|V\|_\infty$ (equivalently, $\sup_{\|V\|_\infty \leq 1} \|L(V)\|_\infty$). Thus the intertwining condition says that* for every *input value function V, the pointwise error $\|(T_V B_w)(V) - (B_{w'} T_V)(V)\|_\infty$ is at most $\epsilon\|V\|_\infty$, ensuring a uniform, scale-aware notion of approximate commutation. In settings where value functions are naturally bounded (e.g. rewards bounded by $R_{\max}$), one can equivalently phrase the condition as a uniform $\| \cdot \|_\infty$ bound on the commutation defect over the relevant bounded subset.*

Remark 3363. *When T is a map between state sets, a typical induced map T_V is the pullback (or "composition") operator $(T_V V')(s) = V'(T(s))$, i.e. values on $M_{w'}$ are evaluated on the image of states from M_w. Other induced maps arise when T aggregates or embeds features, for example when T maps a state to a distribution over target-states (in which case T_V can be an expectation operator). The definition is therefore intentionally stated at the level of T_V rather than committing to a single construction, so that both deterministic and stochastic representation transfers are covered by the same commutation bound.*

Remark 3364. *This is the mathematical heart of TransWeave (Hyperseed-Concept 193): it is a criterion for when solutions to one control problem can be transported into another with bounded degradation, and thus a formal template for Transfer Learning (Hyperseed-Concept 192) [7].*

Remark 3365. *A useful immediate implication (under the same contraction hypotheses for $B_{w'}$) is that approximate intertwining yields an approximate transport of optimal value functions. Indeed, letting V_w^* and $V_{w'}^*$ denote the fixed points of B_w and $B_{w'}$, one compares $T_V(V_w^*)$ to $V_{w'}^*$ via*

$$\|T_V(V_w^*) - V_{w'}^*\|_\infty = \|T_V(B_w(V_w^*)) - B_{w'}(V_{w'}^*)\|_\infty \leq \|T_V(B_w(V_w^*)) - B_{w'}(T_V(V_w^*))\|_\infty + \|B_{w'}(T_V(V_w^*)) - B_{w'}(V_{w'}^*)\|_\infty,$$

so that the commutation defect contributes an ϵ-controlled term and the contraction contributes a γ-controlled term. Rearranging yields a canonical bound of the form $\|T_V(V_w^*) - V_{w'}^*\|_\infty \lesssim \epsilon/(1-\gamma)$ (with the precise constant depending on the normalization implicit in $\| \cdot \|_{\infty\to\infty}$ and any boundedness assumptions). This is the quantitative bridge from "dynamics nearly commute" to "optimal solutions nearly match after transfer."

61.2 A bridge: from BD error to Hyperseed degrees

61.2.1 A concrete degree quantale for this paper

We instantiate the quantale of degrees as

$$V \; := \; ([0,1], \leq, \cdot, 1),$$

so composition multiplies degrees.

Remark 3366. *In this instantiation, $\otimes$ is ordinary multiplication and* 1 *is literal equality of degree. Thus, if one map preserves structure to degree* 0.9 *and another to degree* 0.9*, their composite preserves structure to degree at least* 0.81*. This matches an "attenuation" intuition: each translation step loses some fidelity, and fidelities compound multiplicatively.*

Remark 3367. *The choice $([0,1], \leq, \cdot, 1)$ is also technically convenient: it is a commutative unital quantale in the standard sense, since arbitrary suprema exist in $[0,1]$, multiplication is associative and commutative, and multiplication distributes over suprema in each argument:*

$$a \cdot \sup_i b_i \;=\; \sup_i (a \cdot b_i), \qquad \left(\sup_i a_i\right) \cdot b \;=\; \sup_i (a_i \cdot b).$$

This distribution property is what makes it legitimate to talk about "best possible" (supremal) degrees in constructions that quantify over families of comparisons, as Hyperseed-style approximate morphism definitions often do.

Remark 3368. *The order $\leq$ is intentionally the usual numerical order: a larger degree means "more structure preserved" or "more similarity." In particular,* 0 *is the bottom element (total failure) and* 1 *is the top element (perfect preservation). This monotonic reading aligns with later uses where one takes infima over all local constraints (to obtain a global guarantee) and then composes guarantees by multiplication.*

Definition 551 (Error-to-degree embedding)**.** *Fix a sensitivity constant $\lambda > 0$ and define*

$$\Phi_\lambda(\epsilon) \;:=\; \exp(-\lambda\epsilon) \;\in (0,1].$$

Then $\Phi_\lambda(\epsilon_1 + \epsilon_2) = \Phi_\lambda(\epsilon_1) \cdot \Phi_\lambda(\epsilon_2)$.

Remark 3369. *This definition performs a conceptual conversion: it turns an* additive *notion of error (ϵ measured in some norm) into a* multiplicative *notion of degree suitable for the chosen quantale. The exponential is not arbitrary: it is essentially the unique smooth map turning addition into multiplication. Philosophically, it embodies the idea that equal increments of error should yield equal proportional decreases of confidence or similarity.*

Remark 3370. *A useful way to read Φ_λ is as a monoidal map from the additive monoid of nonnegative errors $(\mathbb{R}_{\geq 0}, +, 0)$ into the multiplicative monoid $([0,1], \cdot, 1)$: additive accumulation of independent error budgets becomes multiplicative attenuation of degree. In particular, whenever a proof produces an estimate of the form "total error $\leq \epsilon_1 + \epsilon_2$," applying Φ_λ immediately yields a compositional degree lower bound $\geq \Phi_\lambda(\epsilon_1)\Phi_\lambda(\epsilon_2)$, matching the way Hyperseed composes approximate structure preservation.*

Remark 3371. *The parameter λ calibrates how harshly we interpret error. With large λ, even small ϵ yields a noticeably reduced degree; with small λ the same ϵ is tolerated. This is a place where observer-dependence enters cleanly: different observers, tasks, or contexts may set different λ reflecting different notions of acceptable approximation [7].*

Remark 3372. *For intuition, one may linearize around $\epsilon = 0$:*

$$\Phi_\lambda(\epsilon) = e^{-\lambda\epsilon} = 1 - \lambda\epsilon + O(\epsilon^2).$$

Thus, for sufficiently small error budgets, the degree shortfall $1 - \Phi_\lambda(\epsilon)$ is approximately proportional to ϵ, with proportionality constant λ. This is helpful later when comparing different modeling choices (e.g. changing β in a graph encoding) while keeping a comparable "small-error" regime.

61.2.2 Encoding an MDP into a flow graph

Definition 552 (Value-flow graph functor)**.** *Given an MDP M with state set S and optimal value $V^* : S \to \mathbb{R}$, define the value-flow graph*

$$G_M(s, s') \ := \ \exp\bigl(-\beta\, |V^*(s) - V^*(s')|\bigr) \ \in (0, 1]$$

for some fixed $\beta > 0$.

Remark 3373. *This construction compresses an MDP into a similarity-like graph on states: two states are close (edge-weight near 1) when their optimal values are close, and far (edge-weight near 0) when their values differ greatly. It is a deliberately coarse encoding: we ignore transition structure and focus on the scalar field V^*. The intent is not to capture everything about the MDP, but to obtain a flow-like object to which Hyperseed's approximate-morphism machinery can be applied.*

Remark 3374. *Two immediate structural properties are worth keeping in mind. First, $G_M(s, s) = 1$ for all s (reflexivity in degree), since $|V^*(s) - V^*(s)| = 0$. Second, $G_M(s, s') = G_M(s', s)$ (symmetry), because of the absolute value. Thus the resulting object is a weighted undirected similarity graph; it is "flow-like" only in the sense that it provides a multiplicative field of affinities that can be transported along a map.*

Remark 3375. *The constant $\beta > 0$ plays the same role as an inverse temperature: it sets the scale on which value differences matter. If β is large, even modest value differences create weak edges; if β is small, the graph remains dense and forgiving. As with λ, this is partly a modeling and partly an epistemic choice: it reflects what distinctions the observer regards as structurally significant.*

Remark 3376. *This value-based encoding can be viewed as a very lightweight proxy for more elaborate state similarity constructions (e.g. bisimulation-inspired metrics): it forgets transitions and rewards except insofar as they influence V^*. The payoff of this forgetfulness is that it yields simple, explicit, and compositional bounds: sup-norm perturbations of V^* become uniform multiplicative degradations of all edge weights.*

Lemma 167 (Value perturbations yield multiplicative edge degradation)**.** *Let $V_1 : S_1 \to \mathbb{R}$ and $V_2 : S_2 \to \mathbb{R}$ and let $f : S_1 \to S_2$. Assume a uniform value-transport bound:*

$$\sup_{s \in S_1} |V_2(f(s)) - V_1(s)| \ \le \ \delta.$$

Then for all $s, s' \in S_1$,

$$G_{V_2}\bigl(f(s), f(s')\bigr) \ \ge \ e^{-2\beta\delta}\, G_{V_1}(s, s').$$

Remark 3377. *Intuitively, the lemma says: if the map f transports values with at most δ sup error, then the value-similarity between any pair of points cannot collapse by more than a uniform multiplicative factor. The factor $e^{-2\beta\delta}$ comes from paying δ once at each endpoint (s and s'), hence the 2. This lemma is the key technical hinge in the bridge: it turns a* pointwise *value bound into an* edgewise *flow-graph morphism degree.*

Remark 3378. *One can package the conclusion as an explicit "degree of approximate graph morphism" statement: the map f is degree-d nonexpansive (in the multiplicative sense) from G_{V_1} to G_{V_2} with*

$$d \ := \ e^{-2\beta\delta} \in (0, 1].$$

This form is the one that plugs directly into Hyperseed-style composition: if f has degree d_1 and a second map g has degree d_2, then $g \circ f$ has degree at least $d_1 d_2$, matching the quantale multiplication chosen above.

Remark 3379. *The same inequality also clarifies how to align parameters across layers of the paper: the degradation factor can be written in the Φ_λ notation as*

$$e^{-2\beta\delta} \;=\; \Phi_1(2\beta\delta) \;=\; \Phi_{2\beta}(\delta).$$

So, depending on whether one thinks of δ as the primitive error (and folds 2β into λ) or thinks of $2\beta\delta$ as the derived error budget, the two embeddings coincide. This is one precise sense in which "BD error" (additive) can be funneled into a Hyperseed degree (multiplicative).

Proof. By the triangle inequality,

$$|V_2(f(s))-V_2(f(s'))| \le |V_1(s)-V_1(s')|+|V_2(f(s))-V_1(s)|+|V_2(f(s'))-V_1(s')| \le |V_1(s)-V_1(s')|+2\delta.$$

Multiply by $-\beta$ and exponentiate to obtain

$$e^{-\beta|V_2(f(s))-V_2(f(s'))|} \ge e^{-\beta(|V_1(s)-V_1(s')|+2\delta)} = e^{-2\beta\delta}\, e^{-\beta|V_1(s)-V_1(s')|}.$$

□

Proof sketch. The strategy is to compare the two absolute differences $|V_2(f(s)) - V_2(f(s'))|$ and $|V_1(s) - V_1(s')|$ by inserting and subtracting $V_1(s)$ and $V_1(s')$. The uniform error bound then contributes at most δ per endpoint, and exponentiation converts the additive bound into a multiplicative degradation factor for the edge weights. □

Remark 3380. *The key step is the triangle inequality, which is doing conceptual work: it formalizes the idea that if two scalars are each well-approximated, then their difference is well-approximated. Geometrically, one may picture V_1 and $V_2 \circ f$ as two "height functions" on S_1 whose graphs lie within a vertical tube of radius δ; differences of heights between two points can then deviate by at most 2δ, because each point can contribute its own vertical deviation.*

Remark 3381. *In many downstream uses, the uniformity of the bound is the essential feature: since the multiplicative degradation factor $e^{-2\beta\delta}$ does not depend on the particular pair (s, s'), it behaves like a global degree certificate. This is precisely the kind of certificate one wants when arguing about self-continuity or commensurability across multiple representational layers: the statement "all pairwise value affinities are preserved up to a single multiplicative constant" can be transported, composed, and compared without re-running local estimates each time.*

61.3 Continuity of self as TransWeave across time-slices

Theorem 161 (Intertwining implies transported optimal values are close)**.** *Let $M_w, M_{w'}$ be discounted MDPs with Bellman operators $B_w, B_{w'}$ (both γ-contractions). Assume a TransWeave map with intertwining error ϵ:*

$$\|T_V \circ B_w - B_{w'} \circ T_V\|_{\infty\to\infty} \le \epsilon.$$

Let $V_w^*, V_{w'}^*$ be optimal values. Then

$$\|T_V(V_w^*) - V_{w'}^*\|_\infty \;\le\; \frac{\epsilon}{1-\gamma}.$$

Remark 3382. *In plain language: if T_V almost commutes with the Bellman updates, then it transports the* fixed point *(the optimal value function) of the first problem to something close to the fixed point of the second. The price paid is a familiar stability factor $1/(1-\gamma)$: when γ is close to 1, the Bellman map is only weakly contractive, so small dynamical mismatches can produce larger fixed-point deviations.*

Remark 3383. *This is important because it turns a dynamical notion (intertwining of operators) into a static bound on the objects we care about (optimal value functions). It is also the precise point at which TransWeave's operator criterion becomes usable inside Hyperseed's approximate-morphism calculus: it produces the δ needed by the value-perturbation lemma, and thus ultimately yields a structural degree bound.*

Remark 3384. *The inequality is a concrete instance of a general fixed-point stability theme: fixed points of contractions are robust under small perturbations. In the broader Hyperseed program, fixed-point methods are also used to study stability of self-modifying goal systems [10]; here the fixed-point is Bellman's, but the moral is the same.*

Proof. Use fixed-point identities $V_w^* = B_w(V_w^*)$ and $V_{w'}^* = B_{w'}(V_{w'}^*)$:

$$\begin{aligned}\|T_V(V_w^*) - V_{w'}^*\|_\infty &= \|T_V(B_w(V_w^*)) - B_{w'}(V_{w'}^*)\|_\infty \\ &\le \|T_V(B_w(V_w^*)) - B_{w'}(T_V(V_w^*))\|_\infty + \|B_{w'}(T_V(V_w^*)) - B_{w'}(V_{w'}^*)\|_\infty \\ &\le \epsilon + \gamma\|T_V(V_w^*) - V_{w'}^*\|_\infty.\end{aligned}$$

Rearrange: $(1-\gamma)\|T_V(V_w^*) - V_{w'}^*\|_\infty \le \epsilon$. ☐

Proof sketch. One inserts and subtracts the term $B_{w'}(T_V(V_w^*))$ to break the difference into (i) the intertwining defect, bounded by ϵ, and (ii) the effect of applying the contraction $B_{w'}$ to two different inputs, bounded by γ times the input difference. The contraction then lets us "move" the unknown term to the left and divide by $(1-\gamma)$. ☐

Remark 3385. *The proof's decisive maneuver is to exploit two forms of stability at once: algebraic stability (fixed-point identities) and metric stability (contraction). Visually, one may imagine $B_{w'}$ as a shrinking map on an infinite-dimensional cube of value functions: if $T_V(V_w^*)$ is an approximate fixed point (up to ϵ), repeated application of $B_{w'}$ drags it toward the true fixed point $V_{w'}^*$, and the contraction ratio quantifies how much discrepancy remains.*

Theorem 162 (TransWeave yields Hyperseed-style self-continuity lower bounds)**.** *Consider a system whose time-slice control at interval I is modeled by an MDP M_I with optimal value V_I^*, and similarly for J. Assume there is a TransWeave map (T, T_V) from M_I to M_J with intertwining error ϵ. Let $F_I := G_{M_I}$ and $F_J := G_{M_J}$ be the induced value-flow graphs. Then there exists a map f (namely the state/representation part of T) such that*

$$\deg(f; F_I, F_J) \;\ge\; \exp\Bigl(-\frac{2\beta}{1-\gamma}\epsilon\Bigr),$$

hence

$$\mathrm{SCS}(I \to J) \;\ge\; \exp\Bigl(-\frac{2\beta}{1-\gamma}\epsilon\Bigr).$$

Remark 3386. *This theorem is the promised bridge in a single inequality. It says: an operator-level TransWeave witness (intertwining with error ϵ) implies a structural Hyperseed witness (a high-degree approximate morphism between flow graphs), and thus yields a quantitative lower bound on self-continuity across the intervals. In this way, the "self" is construed as what can be transwoven across time while approximately preserving the value-structured flow of states and actions.*

Remark 3387. *The bound has three interpretable parameters: β (how sharply values induce graph edges), γ (how stable the Bellman fixed point is), and ϵ (how good the TransWeave is). The factor 2 again reflects endpoint error accumulation. The conclusion is not merely existential: it provides an explicit numeric degree that can be compared across systems, observers, or modeling choices, thus aligning with Hyperseed's preference for graded rather than binary predicates [1].*

Remark 3388. *This connects directly to the earlier composition law and longer-horizon bound: once each step has a quantified degree, chains of steps yield a compounded estimate. In the language of Hyperseed core-concepts, this is a way to operationalize Self-Continuity (Hyperseed-Concept 166) through a transfer-learning lens (Hyperseed-Concept 192).*

Proof. By the previous theorem, transported optimal values satisfy $\|V_J^* \circ f - V_I^*\|_\infty \le \delta$ with $\delta = \epsilon/(1-\gamma)$ (after identifying T_V as pullback/pushforward along f). Apply Lemma 1 to obtain, for all x, x',

$$F_J(f(x), f(x')) \ge e^{-2\beta\delta} F_I(x, x').$$

In the degree quantale $([0,1], \le, \cdot, 1)$ this implies $F_I(x,x') \cdot q \le F_J(f(x), f(x'))$ for $q = e^{-2\beta\delta}$ and all pairs, so $q \le \deg(f; F_I, F_J)$. Taking the supremum over f gives the stated bound for SCS. □

Proof sketch. First convert intertwining error into a sup-norm bound on the transported optimal value function via contraction stability, giving $\delta = \epsilon/(1-\gamma)$. Then use the value-perturbation lemma to translate a pointwise value bound into an edgewise inequality between the induced flow graphs. Finally, interpret that edgewise inequality as precisely the condition that the morphism degree is at least $e^{-2\beta\delta}$. In slightly more detail, the contraction step uses that the relevant Bellman-type operators (or their TransWeave-transported variants) are γ-Lipschitz in $\|\cdot\|_\infty$, so an ϵ-level defect in the intertwining relation cannot amplify arbitrarily when one passes from one application of the operator to the fixed point. The passage from a scalar field bound $\|V_I^* - \mathcal{T} V_J^*\|_\infty \le \delta$ (for the appropriate transport $\mathcal{T}$ induced by the map) to a graph inequality is the point where "local" information (at vertices/states) is turned into "relational" information (on edges/transitions), because flow graphs compare pairwise differences of potentials. The constant 2β arises because the similarity/flow weights depend exponentially on differences of values (or on symmetric differences across an edge), so a δ-uniform perturbation yields at worst a 2δ swing between two endpoints, and the temperature/sensitivity parameter β converts that swing into a multiplicative distortion bound. □

Remark 3389. *The proof's key conceptual move is the change of language: from operator dynamics $(B_w, B_{w'})$ to scalar fields (V_I^*, V_J^*) to similarity graphs (F_I, F_J) to quantale degrees (deg). Each step is simple, but the composition is powerful: it allows one to import the well-developed stability theory of contractions into a general-purpose structural notion of approximate morphism, of the sort Hyperseed uses for pattern-flow and correspondence claims [5, 1]. Concretely, the operator-level statement is "behavioral" (how an update rule propagates information), whereas the scalar-field statement is "semantic" (what optimality assigns to each state), and the graph statement is "structural" (which distinctions are preserved as strong/weak links). Quantale degrees then provide a single numerical carrier for these comparisons that is compatible with composition, so that one can treat approximate sameness as something that accumulates predictably rather than as an ad hoc tolerance. Viewed this way, the argument is also a controlled change of norms and representations: $\|\cdot\|_\infty$ bounds are chosen not for aesthetic reasons but because they interact cleanly with contraction estimates and immediately imply uniform bounds on all vertexwise quantities that feed into the flow construction.*

Corollary 62 (Flow of subjective time as iterative transweaving)**.** *If successive time-slices $I_t \to I_{t+1}$ admit TransWeave maps with errors ϵ_t, then for any horizon n,*

$$\mathrm{SCS}(I_0 \to I_n) \;\ge\; \exp\Big(-\frac{2\beta}{1-\gamma}\sum_{t=0}^{n-1}\epsilon_t\Big).$$

In particular, if the one-step errors are uniformly bounded by $\epsilon_t \leq \bar{\epsilon}$, then $\mathrm{SCS}(I_0 \to I_n) \geq \exp\left(-\frac{2\beta}{1-\gamma}\, n\bar{\epsilon}\right)$*, making explicit the linear-in-n accumulation in the exponent.*

Remark 3390. *This corollary expresses an austere but suggestive thesis: if the self is what survives transfer across adjacent time-slices, then the "speed" of subjective identity drift is governed by the accumulated TransWeave errors. Small errors per step can still yield substantial drift over long horizons, but only at a rate controlled by the sum $\sum_t \epsilon_t$ and the stability factor $1/(1-\gamma)$. The appearance of $1/(1-\gamma)$ separates two notions that might otherwise be conflated: (i) how accurately adjacent slices align (the ϵ_t terms) and (ii) how strongly downstream consequences are weighted relative to immediate structure (the discount γ). As $\gamma \to 1$, even tiny stepwise mismatches can become "sticky" in the fixed-point semantics, because the contraction becomes weak and the value function becomes more sensitive to persistent perturbations. Meanwhile β regulates how aggressively value differences are converted into flow/similarity distortions: larger β makes the graph more discriminating, so the same δ-level value uncertainty produces a smaller guaranteed degree.*

Proof. Apply the previous theorem on each step to get degree lower bounds q_t. Use the composition law for approximate morphisms, which multiplies degrees, and note $\prod_t e^{-c\epsilon_t} = e^{-c\sum_t \epsilon_t}$. Writing the one-step statement explicitly, the theorem gives $q_t \geq \exp\left(-\frac{2\beta}{1-\gamma}\epsilon_t\right)$ for each map $I_t \to I_{t+1}$. Compositionality of degrees then yields $\mathrm{SCS}(I_0 \to I_n) \geq \prod_{t=0}^{n-1} q_t$, because the composite TransWeave along the chain is witnessed by composing the one-step witnesses. Substituting the bound on each q_t and collecting terms in the exponent gives precisely the displayed inequality. □

Proof sketch. Lower-bound each one-step self-continuity by an exponential in ϵ_t, multiply the one-step bounds along the chain using compositionality, and then use the elementary identity that products of exponentials equal the exponential of the sum. Equivalently, one may take logs (moving to the additive "cost" picture) so that composition becomes addition of log-degrees, after which the result is immediate from $\log q_t \geq -\frac{2\beta}{1-\gamma}\epsilon_t$ and summing over t. □

Remark 3391. *The only nontrivial ingredient is remembering which algebra governs accumulation. In this section we have chosen a multiplicative quantale of degrees, so composition means multiplication and thus additive errors exponentiate. Other quantales would yield other accumulation laws, but the same compositional idea would remain. For example, a max-min (idempotent) quantale would make the "weakest link" dominate long-horizon continuity, whereas an additive quantale would treat degrees more like costs that sum directly rather than via a log transform. The present choice is natural when degrees are interpreted as similarity ratios or likelihood-style weights, since independent compositional steps typically multiply, and the exponential form is the standard way to convert additive perturbation bounds into multiplicative guarantees.*

61.4 MetaMo-driven identity drift and bounded transweave

Definition 553 (MetaMo-induced transweave (informal interface))**.** *Assume a motivational update $\alpha : X \to F(X)$ induces a weight transition $w \to w'$ (via a weight-extraction map U), and this triggers a TransWeave transformation $T_{w\to w'}$. We call this a MetaMo-induced TransWeave step.*

Remark 3392. *This definition is intentionally an "interface" rather than a full construction: it specifies how a motivational or meta-goal update can be coupled to a change in the effective reward weights of a control problem, which then invokes a TransWeave map between the old and new problem formulations. It is aligned with the broader Hyperseed idea that Goals: Implicit and explicit (Hyperseed-Concept* **??** *and* **??***) may evolve, and that such evolution should be studied through stability of the induced dynamics [10].*

Remark 3393. *Concretely, one may interpret X as the agent's internal "motivational configuration space" (or a space of latent goal descriptors), and $F(X)$ as an "updated configuration bundle" containing both the revised motivational state and any auxiliary structures needed to evaluate it (e.g. new internal criteria, revised salience maps, or new constraints). The map α is then the meta-level update that changes how the agent evaluates outcomes, while U extracts from the updated motivational state a finite set of coefficients w that parameterize an explicit reward model (for instance, a linear combination of basis rewards, or weights on multiple objectives). In this reading, the interface character of the definition is a feature: it allows α to be complex and high-dimensional while still inducing a tractable parametric change $w \to w'$ in the control problem to which TransWeave applies.*

Remark 3394. *In cognitive terms, one may think: "I have reweighted what I care about." The question then is whether the new optimization landscape is commensurate with the old one, or whether it induces a sharp rupture. A MetaMo-induced TransWeave step is precisely a claim that the reweighting is bridgeable by an approximate intertwining of the relevant Bellman operators [7].*

Remark 3395. *The phrase "commensurate" here is meant in a technical, operator-theoretic sense rather than a purely semantic one: the old and new Bellman operators (associated to w and w') should be close after transport by $T_{w\to w'}$. When this holds, planning and value propagation in the new objective can be viewed as a controlled deformation of planning and value propagation in the old objective, rather than a discontinuous replacement. This is the precise way in which "reweighting what I care about" becomes an analyzable perturbation of an optimization landscape.*

Theorem 163 (Bounded motivational drift implies bounded identity drift)**.** *Assume each motivational update step induces a TransWeave map with intertwining error $\epsilon \leq \bar{\epsilon}$ (e.g. due to homeostatic stability/modulator continuity). Then the system's self-continuity across the corresponding time step satisfies*

$$\mathrm{SCS}(I \to J) \;\geq\; \exp\Big(-\frac{2\beta}{1-\gamma}\bar{\epsilon}\Big).$$

Moreover, over n steps, the lower bound composes multiplicatively as in Corollary 1.

Remark 3396. *The parameters in the bound have an intuitive reading consistent with the underlying definitions: γ is the discount factor that controls effective horizon length (hence the appearance of the geometric factor $1/(1-\gamma)$), while β is the "sharpness" parameter in the self-continuity construction (so that larger β makes the continuity score more sensitive to value differences). The exponential form expresses that small but persistent operator mismatch accumulates into a multiplicative degradation of continuity, rather than an additive one.*

Remark 3397. *The statement is a stability claim about identity: if the meta-level reweightings of value are uniformly gentle (in the sense that they always admit low-error TransWeaves), then identity drift is uniformly bounded from below (in the sense of self-continuity degree). This gives a rigorous way to express an old intuition: "character changes gradually when motivations change gradually."*

Remark 3398. *The theorem should also be read as a* design constraint*: bounded identity drift is ensured not by freezing goals, but by ensuring that any goal update stays within a region of "TransWeavable" perturbations. In practical terms, this can correspond to limiting the magnitude of a weight update $w \to w'$ per step, enforcing smoothness of the map $U \circ \alpha$, or introducing regularizers that penalize updates that would break approximate intertwining (for example, updates that change which features are rewarded in a way that is not representable by a small deformation of value functions).*

Remark 3399. *This theorem is not a psychological law; it is a conditional mathematical implication connecting one formal measure of motivational change (intertwining error) to one formal measure of identity continuity (SCS). Its usefulness is that it lets a designer or analyst set tolerances: if* $\bar{\epsilon}$ *is kept small by design (e.g. via constraints on self-modification), then a quantitative continuity guarantee follows.*

Remark 3400. *The multiplicative composition over* n *steps is especially important for long-running systems: even when each step is locally "safe" (small* ϵ*), the global continuity can still decay if updates are frequent. Corollary 1 captures this by treating successive steps as a chain of transitions* $I_0 \to I_1 \to \cdots \to I_n$ *and lower-bounding* $\mathrm{SCS}(I_0 \to I_n)$ *by the product of the one-step lower bounds. Thus, bounding* $\bar{\epsilon}$ *is necessary but may be insufficient unless one also controls update rate or periodically re-anchors the representation used by* T*.*

Proof. Immediate from the TransWeave-to-SCS theorem and the horizon composition corollary. □

Remark 3401. *Spelled out at the level of inequalities, the argument is that the assumed uniform upper bound* $\epsilon \le \bar{\epsilon}$ *lets one replace the per-step factor* $\exp\!\big(-\frac{2\beta}{1-\gamma}\epsilon\big)$ *by the worst-case factor* $\exp\!\big(-\frac{2\beta}{1-\gamma}\bar{\epsilon}\big)$*, and then apply the already-established composition rule. No additional structural properties of* α *or* U *are needed beyond those required to invoke the TransWeave-to-SCS bridge result.*

Proof sketch. Combine the single-step lower bound on SCS derived from a TransWeave error, then apply the chain composition rule over multiple steps. □

Remark 3402. *The proof is immediate because all the difficulty has been front-loaded into the bridge theorem: once error-to-degree has been established, boundedness and composition are essentially algebraic bookkeeping.*

Remark 3403. *One may also view the theorem as isolating* where *identity fragility can enter: either the MetaMo update* α *induces a change* $w \to w'$ *for which no sufficiently accurate intertwiner exists, or the discount/horizon parameters make even small* $\bar{\epsilon}$ *consequential. In particular, as* $\gamma \to 1$ *(very long-horizon valuation), the bound weakens, reflecting the fact that long-horizon value functions amplify small systematic mismatches in Bellman updates. This is not a defect of the bound but a faithful representation of how long-term planning couples distant consequences back into present evaluations.*

61.5 Paradigm commensurability as existence of low-error transweaves

Definition 554 (Paradigm as a problem-solving category)**.** *A paradigm* $\mathcal{P}$ *consists of: (i) a collection of tasks/problems, each modeled by an MDP with Bellman operator; (ii) a collection of solution-transform morphisms (including representation changes).*

Remark 3404. *In clause (i), the role of the Bellman operator is to provide a canonical "one-step reasoning/update" map for each task, so that comparing paradigms becomes a matter of comparing their induced update dynamics rather than only their terminal answers. This is particularly important when a paradigm includes iterative procedures (e.g. planning, policy improvement, inference loops) whose quality is best assessed by stability of their iteration operators.*

Remark 3405. *Clause (ii) is meant to include not only literal changes of state variables, but also changes of modeling language (e.g. switching from symbolic predicates to learned embeddings), changes of action parameterizations, or changes of reward representations, provided there is an induced, well-defined transformation at the level of solution objects (policies, value functions, or other sufficient statistics). In this sense, a paradigm includes its own "allowed translations," so commensurability asks whether two such translation toolkits can be coordinated across paradigms.*

Remark 3406. *The word "paradigm" is often used in a sociological or historical key. Here it is given a spare technical reading: a paradigm is a structured family of problems together with permissible transformations of solutions and representations. This is consonant with a computational philosophy of science where scientific practice is seen as a network of question, experiment, model, and update procedures, rather than as a set of static propositions [20, 1].*

Remark 3407. *Calling it a "category" is suggestive: tasks are objects, and transforms (including representation changes) are morphisms. We do not need categorical axioms explicitly in this section; the point is that we treat paradigms as* systems of translatable problem-solvers, *so commensurability becomes a statement about the existence of good translation functors, i.e. TransWeaves [7].*

Remark 3408. *Even without invoking functoriality formally, the category language emphasizes two technical expectations that are easy to miss: (1) transforms should be composable (one can chain multiple representation changes), and (2) there should be identity-like transforms (doing nothing is an allowed morphism). These expectations motivate why commensurability is framed in terms of operator intertwining: it is a robust way to express that "translation commutes with solving" up to controlled error.*

Definition 555 (TransWeave commensurability)**.** *Two paradigms $\mathcal{P}$ and $\mathcal{Q}$ are (ϵ, γ)-commensurable on a class of tasks if there is an assignment that maps each task $M \in \mathcal{P}$ to a task $N \in \mathcal{Q}$ together with a TransWeave map (T, T_V) satisfying*

$$\|T_V \circ B_M - B_N \circ T_V\|_{\infty\to\infty} \leq \epsilon,$$

uniformly over the task class.

Remark 3409. *The "assignment" component encodes which tasks are being compared: commensurability is not claimed between arbitrary tasks, but between those deemed corresponding under the paradigm-to-paradigm mapping. Technically, this can be viewed as selecting a relation or partial matching between task families, and then requiring a single uniform error tolerance for all matched pairs.*

Remark 3410. *The choice of the operator norm $\|\cdot\|_{\infty\to\infty}$ is consistent with standard contraction arguments for discounted MDPs: it controls worst-case deviations over all bounded value functions. Interpreted procedurally, the inequality says that "do one Bellman update in $\mathcal{P}$ and then translate" is close to "translate and then do one Bellman update in $\mathcal{Q}$," with the discrepancy bounded by ϵ at every step, across the whole task class.*

Remark 3411. *This definition formalizes "commensurability" as* uniform approximate intertwining*: the paradigms are commensurable on a task class if one can systematically transport problem-solving dynamics from one to the other with bounded operator mismatch. The inclusion of γ indicates that the tolerance is interpreted in a discounted, contractive regime; without contraction one cannot generally convert dynamical mismatch into fixed-point mismatch.*

Remark 3412. *The parameter γ should be read as the effective contraction modulus for the Bellman operators on the relevant function space. In the simplest discounted setting, γ is the usual discount factor; more generally it can stand for any bound ensuring that B_M and B_N are γ-contractions in $\|\cdot\|_\infty$. This is what permits a stepwise commutator bound to accumulate geometrically rather than linearly when one compares infinite-horizon fixed points.*

Remark 3413. *A simple example: if $\mathcal{P}$ and $\mathcal{Q}$ use different state representations for essentially the same tasks, then T may be a representation change and T_V its induced pullback/pushforward on values. If the representational change is faithful, the commutator is small, yielding small ϵ. Conversely, if crucial dynamics are not preserved by the representation change, ϵ becomes large and commensurability fails.*

Remark 3414. *Concretely, when T is a many-to-one abstraction map (state aggregation), T_V typically acts by restricting attention to the coarse state features; the commutator then measures whether aggregated states are approximately bisimilar with respect to rewards and transition structure. When T is an embedding into a richer state space, T_V acts by pullback along the embedding, and the commutator measures whether the extra degrees of freedom introduced by the richer representation are in fact irrelevant to optimal control for the mapped tasks.*

Theorem 164 (Commensurability implies transferable optimality)**.** *If $\mathcal{P}$ and $\mathcal{Q}$ are (ϵ, γ)-commensurable on a task class, then for every mapped pair (M, N) in the class,*

$$\|T_V(V_M^*) - V_N^*\|_\infty \leq \frac{\epsilon}{1-\gamma}.$$

Thus hypotheses/procedures that are optimal in $\mathcal{P}$ transfer to $\mathcal{Q}$ with bounded value degradation.

Remark 3415. *The inequality has the standard fixed-point stability form: a one-step error bound ϵ amplifies by at most the geometric series factor $1/(1-\gamma)$ when comparing fixed points of contractive maps. In particular, as $\gamma \to 1$ the bound becomes conservative, reflecting the well-known fact that near-undiscounted problems require much tighter stepwise control to ensure small changes in the infinite-horizon value.*

Remark 3416. *The theorem says that commensurability in the dynamical sense is enough to guarantee commensurability in the solution sense: optimal value functions transfer with bounded distortion. This provides a rigorous alternative to the often-vague debate about whether paradigms are "incommensurable": one can point to a specific operator norm defect ϵ and compute its worst-case consequence for optimality.*

Remark 3417. *Although stated for optimal value functions, the same style of estimate applies to other fixed points or attractors of interest, such as soft Bellman operators (entropy-regularized control) or evaluation operators for a fixed policy. The common structure is: approximate intertwining of the update map implies closeness of the corresponding equilibria, provided the update map is contractive in an appropriate norm.*

Remark 3418. *The result is also a bridge back to Hyperseed's view of science as a community of empirically coupled belief updates: if two scientific paradigms can transweave their problem-solving operators with small commutator, then they can share solutions and predictions with bounded degradation, even if their internal representations differ [1, 20].*

Remark 3419. *From this perspective, "sharing predictions" corresponds not to literal agreement on internal explanatory posits, but to the existence of stable translation interfaces that preserve the operational content of inference and decision procedures. The TransWeave condition isolates precisely this operational content at the level of update operators.*

Proof. Apply the intertwining-implies-value-closeness theorem taskwise. □

Remark 3420. *Unpacking the one-line proof: for each mapped pair (M, N), the commensurability hypothesis provides an ϵ-approximate intertwining between B_M and B_N via T_V, and the contraction parameter γ ensures the hypotheses of the fixed-point stability lemma. The conclusion then follows by substituting (B_M, B_N, T_V) into that lemma and using that the bound is uniform over the task class.*

Proof sketch. Reduce each task pair (M, N) to the single MDP theorem: the same bound applies because the commensurability hypothesis is exactly the intertwining hypothesis, uniformly over the class. $\square$

Remark 3421. *The "uniformly over the class" clause is doing essential work: it ensures that a single tolerance ϵ controls the entire family rather than yielding a different error parameter for each task. Without uniformity, one could still derive taskwise bounds, but paradigm-level commensurability would become weaker and less predictive, since worst-case transfer quality could be arbitrarily bad on rare but important tasks.*

Remark 3422. *The proof is short because the theorem is an organizational statement: it packages the earlier fixed-point stability bound into a paradigm-level assertion by applying it consistently across a family of tasks.*

Theorem 165 (A practical incommensurability certificate via large commutators)**.** *Let U be a proposed transfer operator on value functions between paradigms and define a BD commutator (mismatch)*

$$C := B_Q U - U B_P.$$

If $\|C\|_{\infty\to\infty} > \epsilon_0$, then no transfer based on U can guarantee better than $\epsilon_0/(1-\gamma)$ uniform value preservation, hence commensurability at tolerance ϵ_0 fails for at least one task in the class.

Remark 3423. *The appearance of the commutator is natural: if U were an exact intertwiner, we would have $B_Q U = U B_P$ and the two "update-then-transfer" pathways would coincide. The norm $\|C\|_{\infty\to\infty}$ quantifies the worst-case deviation from this ideal commutation, so it directly measures the obstruction to viewing U as a TransWeave witness.*

Remark 3424. *This theorem states a falsification criterion: if one proposes a particular transfer operator U, one can compute (or estimate) the size of its commutator with the Bellman operators. A large commutator means there exists some input value function on which the two update-and-transfer routes disagree substantially, and therefore U cannot serve as a uniform commensurability witness.*

Remark 3425. *Operationally, one can read $\|C\|_{\infty\to\infty} > \epsilon_0$ as: there exists a bounded "test" value function V such that $\|B_Q(UV) - U(B_P V)\|_\infty > \epsilon_0$. This provides guidance for diagnostics: adversarially searching over V (or sampling a rich set of candidate V's) can reveal where the proposed translation U fails to preserve the update semantics.*

Remark 3426. *In practice this is valuable because it separates two questions: (1) whether* some *transfer exists, and (2) whether a* particular *candidate transfer U is adequate. The theorem addresses (2) and provides a computationally tangible obstruction to commensurability in the TransWeave sense [7].*

Remark 3427. *Note that the obstruction is relative to the chosen U: a large commutator does not prove absolute incommensurability between $\mathcal{P}$ and $\mathcal{Q}$, only that this proposed interface fails at the specified tolerance. As a methodological point, this supports iterative design of translation layers: one can improve U (or restrict the task class) to reduce the commutator norm, thereby moving from practical incommensurability toward commensurability in the approximate-intertwining sense.*

Proof. If $\|C\|_{\infty\to\infty} > \epsilon_0$, then the intertwining condition with tolerance ϵ_0 is violated for some input value function. For that tolerance, the value-closeness bound cannot be derived; contrapositive yields the claim. □

Proof sketch. A commutator norm bound is exactly the intertwining inequality. If it is violated, then there is at least one input witnessing the violation; for that input, the chain of inequalities leading to the fixed-point closeness bound cannot be carried out. Therefore one cannot guarantee the corresponding uniform preservation claim. □

Remark 3428. *The logic is intentionally Russellian in its severity: it does not say transfer is impossible, only that a proposed form of transfer fails to justify a certain guarantee. This is often the right epistemic posture in science: one can refute a method, or a bound, without refuting the phenomenon one hoped the method would capture.*

61.6 Inter-mind transweaving, cooperation, and mindplex coherence

61.6.1 Transweaving on a graph of minds

Definition 556 (Transweave graph of minds)**.** *Let A be a set of minds/agents. A directed edge $i \to j$ carries a TransWeave map $T_{i\to j}$ with error $\epsilon_{i\to j}$. For a path $p : i = i_0 \to i_1 \to \cdots \to i_m = j$, define the composed map $T_p := T_{i_{m-1}\to i_m} \circ \cdots \circ T_{i_0\to i_1}$.*

Remark 3429. *This definition recasts a social or multi-agent setting as a transport network: edges are not merely communication channels, but structured translation maps that carry policies/values/solutions from one agent's representational world into another's. The graph may be sparse (few reliable translations) or dense (many). The later mindplex remarks interpret density as enabling redundant short translation paths, which improves coherence.*

Remark 3430. *In Hyperseed's language, this is one way to model the emergence of collective cognitive structure: a society of agents becomes more than a set when there exist high-quality inter-agent morphisms that allow patterns to flow across individuals [5, 1]. This resonates with the more explicit "mindplex" formalism in SuperDuperPsychism [12].*

Theorem 166 (Path-length penalty for inter-mind solution transfer)**.** *Assume each $T_{i\to j}$ satisfies an intertwining bound with the same discount γ. For any path p of length m from i to j, the transported optimal values satisfy*

$$\|T_{p,V}(V_i^*) - V_j^*\|_\infty \le \frac{1}{1-\gamma} \sum_{t=0}^{m-1} \epsilon_{i_t\to i_{t+1}}.$$

Equivalently, in degree form,

$$\deg(T_p) \;\ge\; \exp\Big(-\lambda \sum_{t=0}^{m-1} \epsilon_{i_t\to i_{t+1}}\Big).$$

Remark 3431. *The theorem says that translation fidelity across a social chain deteriorates with path length, in a very concrete way: additive intertwining errors accumulate additively (modulo the $1/(1-\gamma)$ factor), and therefore multiplicative degrees decrease exponentially with the accumulated error. Thus, even if each local translation is good, long chains can become poor witnesses of commensurability.*

Remark 3432. *This matters for mindplex formation because it gives a quantitative reason to prefer dense, redundant connectivity over thin, serial dependence. In social terms: if knowledge must pass through many intermediaries, the effective distortion grows; if there are multiple short routes, distortion can be kept small. This kind of argument also aligns with general pro-social efficiency claims about well-connected agent groups [6].*

Proof. Iterate the single-step bound:

$$\|T_{i\to j,V}(V_i^*) - V_j^*\|_\infty \le \epsilon_{i\to j}/(1-\gamma),$$

and apply triangle inequality across the composed path. For the degree form, apply Φ_λ to the sum of errors. □

Proof sketch. Apply the fixed-point stability bound to each edge to bound the one-step transported value error, then use the triangle inequality to sum errors along the path. Finally convert the additive error bound into a multiplicative degree bound using the exponential embedding Φ_λ. □

Remark 3433. *The triangle inequality is again the quiet workhorse: it formalizes that distortions accrued at different translation steps do not cancel in the worst case. The degree form is best seen as a change of coordinates: sums become products, and products become the natural language of compositional morphism degrees.*

61.6.2 Mindplex coherence from transweaving-based replaceability

Definition 557 (Observer-indexed coherence proxy)**.** *Fix an observer context O with a behavior summary* $\mathrm{Beh}_O(\cdot)$ *and a distance d_O. For a set of components S, define replaceability error*

$$\mathrm{Err}_O(x;S) := \inf_f d_O\Big(\mathrm{Beh}_O(x), f(\mathrm{Beh}_O(S\setminus\{x\}))\Big),$$

and coherence

$$\mathrm{Coh}_O(S) := 1 - \max_{x\in S} \mathrm{Err}_O(x;S),$$

after normalizing so errors lie in $[0,1]$.

Remark 3434. *This definition treats coherence as* replaceability*: a component x is well-integrated into a set S if the rest of the set can approximately reproduce x's behavior (as seen by observer O) via some approximator f. The infimum over f expresses an idealization: we score x by its best possible reconstruction from the others. The maximum over x then enforces a worst-case standard: the set is only as coherent as its least replaceable member.*

Remark 3435. *The dependence on O is essential and principled. What counts as "the behavior" of a mind or subsystem depends on which aspects one observes and which distance one uses; hence coherence is observer-indexed rather than absolute. This matches Hyperseed's general practice of tracking observer-context explicitly, and it is also consonant with mindplex discussions where coherence is partly an epistemic relation (Hyperseed-Concept 113) [1, 12].*

Theorem 167 (Local transweaving implies global coherence lower bound)**.** *Assume that for each $x\in S$ there exists an approximator f_x built from TransWeave transports among members of $S\setminus\{x\}$ such that*

$$d_O\Big(\mathrm{Beh}_O(x), f_x(\mathrm{Beh}_O(S\setminus\{x\}))\Big) \le \eta_x.$$

Then

$$\mathrm{Coh}_O(S) \;\geq\; 1 - \max_{x \in S} \eta_x.$$

In particular, if every agent can be reconstructed from neighbors with uniformly small transport-induced error, S is coherent in the Hyperseed replaceability sense.

Remark 3436. *The theorem is almost tautological, yet it is useful: it says that if you can exhibit explicit reconstructions f_x with explicit errors η_x, then the global coherence score has an immediate lower bound. In complex systems one often has local engineering knowledge (how well one can approximate one component from others) and wants a global guarantee; this theorem is the clean bridge from local certificates to a global bound. In particular, the hypothesis "for each x there exists a concrete f_x with error at most η_x" is exactly the kind of statement one can obtain from implementation details, empirical evaluations, or module-level contracts, whereas the conclusion is phrased purely in terms of* $\mathrm{Coh}_O(S)$ *and thus is independent of how the approximators were found. Conceptually, the point is that* one good candidate *is enough to upper-bound an infimum, so the global statement can be certified without having to solve any of the optimization problems defining the* $\mathrm{Err}_O(x; S)$ *exactly.*

Remark 3437. *The connection to the earlier path-length penalty is indirect but important: if the f_x are assembled from TransWeave maps, then the η_x can often be bounded in terms of path lengths and edge errors in the transweave graph. Thus coherence can be bounded using purely graph-theoretic features (diameter, redundancy) together with operator-level intertwining tolerances. More explicitly, if an approximator f_x is realized by composing transport/intertwining maps along a path from some subset of minds to the target x, then η_x typically accumulates from (i) the per-edge approximate-commutation errors and (ii) any stability constants of the observables under transport; both effects are commonly monotone in the number of compositions, hence in the path length. This is the sense in which a local "wiring diagram" in the transweave graph can be turned into a numerical η_x that is then fed into the theorem as a plug-in certificate.*

Proof. For each x, the definition of $\mathrm{Err}_O(x; S)$ is an infimum over approximators, so $\mathrm{Err}_O(x; S) \leq \eta_x$. Taking maxima over x yields $\max_x \mathrm{Err}_O(x; S) \leq \max_x \eta_x$ and hence the coherence bound. The only logical move is the standard inequality $\inf A \leq a$ for any particular $a \in A$, applied with A the set of achievable approximation errors at x and $a = \eta_x$ the error of the exhibited candidate f_x. No structural assumptions (linearity, convexity, or uniqueness of the best approximator) are needed, because the argument never attempts to compare *different* candidates except through the ordering induced by $\leq$. □

Proof sketch. Plug the candidate approximators f_x into the infimum defining $\mathrm{Err}_O(x; S)$ to upper-bound each replaceability error by η_x, then take the worst case over x and translate it into a lower bound on $\mathrm{Coh}_O(S)$. Equivalently, the construction produces a vector of per-node certificates $(\eta_x)_{x \in S}$, and the coherence score only depends on the worst (largest) such certificate once the $\max_x$ aggregation is applied. □

Remark 3438. *The proof works because the definitions are chosen with a particular logic: coherence is designed to be monotone in the availability of good approximators. Once one sees that* inf *and* max *are arranged to make a worst-case guarantee, the inequality becomes the natural algebraic expression of that guarantee. This also clarifies the intended interpretation of* $\mathrm{Coh}_O(S)$ *as a robustness notion: it is not the* average *mutual predictability, but the requirement that* every *component in S be replaceable (up to a stated tolerance) from the others. In settings where one wants a "no single point of semantic failure" certificate, the* max *is the correct aggregator; the theorem then* *simply says that any family of explicit reconstructions automatically provides such a certificate at the corresponding tolerance level.*

Remark 3439 (Why dense neighbor transweaving helps mindplex formation)**.** *The path-length penalty theorem shows that the effective transport error between two minds grows with the length of the best path connecting them in the transweave graph. Thus, a mindplex (a notably coherent society of minds) is favored when each mind can transweave with multiple neighbors so the graph has small diameter and multiple short redundant paths. In the language of replaceability, dense neighborhood structure makes it more plausible that for each mind x there exists a small set of others from which x can be approximately reconstructed with a controlled η_x, because information need not traverse long chains of intertwining where errors would accumulate. Put differently, increased local connectivity can improve the* availability *of short, accurate reconstruction circuits, which then feeds directly into global coherence lower bounds via the preceding theorem.*

Remark 3440. *One may add a complementary intuition: redundancy is not merely about shortening paths, but about providing alternative routes when some routes fail or are contextually inappropriate. In a living community of minds, tasks and contexts shift; redundant transweave paths provide a kind of structural resilience, making it more plausible that coherence persists across changing demands. This resonates with the general claim that cooperative structures can be efficiency-enhancing in broad multi-agent settings [6], and with mindplex-oriented formalisms emphasizing integration and collective stability [12]. A further way to see this is to distinguish* reachability *from* reliability*: even if two minds are connected by a short path, the associated approximator f_x might be brittle if it depends on a single specialized intermediary, whereas multiple partially independent paths can yield multiple candidate reconstructions whose errors can be compared and whose outputs can be cross-validated. In practice, this means redundancy can reduce the* effective *worst-case η_x not only by shortening the best path, but by enabling the selection of a path (or composite strategy) that is best suited to the current context, observables, or noise regime. From the standpoint of mindplex coherence, this makes it more plausible that the same society can maintain low replaceability errors across a wider range of tasks without requiring global reconfiguration.*

61.7 Mind-world correspondence as a transweave relation

Definition 558 (Mind-world transweaving)**.** *Let M_{int} be a mind's internal predictive-control model and let M_{env} be an environment model (as reconstructed by an observer). If there exists a TransWeave map from M_{int} to M_{env} with small intertwining error, we say the mind can transweave its control knowledge into the world model.*

Remark 3441. *In concrete Markovian settings one may think of M_{int} and M_{env} as each specifying (possibly different) state spaces, action parametrizations, reward proxies, and transition kernels, hence inducing Bellman operators T_{int} and T_{env}. The TransWeave condition can then be read as the existence of a transport map (often accompanied by a suitable pullback/pushforward pair on value functions or Q-functions) for which the diagram "approximately commutes," e.g. in the schematic form $\|T_{\text{env}} \circ W - W \circ T_{\text{int}}\| \le \epsilon$ in an appropriate operator norm. This makes explicit which part of "correspondence" is being demanded: not identity of representations, but approximate invariance of the decision-relevant fixed-point structure.*

Remark 3442. *This definition proposes a crisp operationalization of Mind-World Correspondence (Hyperseed-Concept 112): the mind corresponds to the world, in the relevant control sense, if its internal model can be translated into the observer's environment model while nearly preserving the*

Bellman dynamics (and thus near-preserving optimal decision structure). It makes correspondence not a mystical matching but a quantified transport relation [7, 1].

Remark 3443. *Note that the clause "as reconstructed by an observer" makes the correspondence explicitly epistemic: M_{env} may itself be an inferred or learned model and need not coincide with the world-as-such. The definition therefore captures a practically testable notion of adequacy relative to an observational interface (sensors, experiment design, logging policy), and it clarifies that failures of correspondence can arise either from the mind's internal mismatch or from limitations/approximations in the observer's reconstruction.*

Remark 3444. *A simple example is representational: the mind may encode states in its own latent space, while the observer encodes environment states differently. A TransWeave map then plays the role of a learned or inferred decoder/encoder pair that allows control-relevant knowledge to be moved between these two descriptive schemes. This is closely aligned with engineering views of cognition emphasizing model-based control and representation learning [19].*

Remark 3445. *The TransWeave relation is not required to be symmetric. In many realistic cases the mind can reliably export control knowledge into M_{env} (because M_{env} is more expressive, or because the observer has privileged access to ground-truth variables), while the reverse transport may be ill-posed. This asymmetry is natural when M_{int} is compressed, amortized, or shaped by the agent's affordances, and it matches the intuition that "the world can explain the mind" is a different demand than "the mind can explain the world" even when both are framed in control terms.*

Theorem 168 (TransWeave implies a lower bound on mind-world correspondence)**.** *Let F_{int} and F_{env} be the induced value-flow graphs for M_{int} and M_{env}. If a TransWeave map exists with intertwining error ϵ, then there exists a map f such that*

$$\deg(f; F_{\mathrm{int}}, F_{\mathrm{env}}) \;\geq\; \exp\Big(-\frac{2\beta}{1-\gamma}\epsilon\Big).$$

Thus TransWeave provides an explicit witness of high-degree approximate morphism between internal and external flow structures.

Remark 3446. *The parameters in the bound track standard control-theoretic sensitivities: γ captures horizon-length amplification (as $\gamma \to 1$, small Bellman mismatches accumulate over long rollouts), while β captures how sharply the degree functional penalizes edgewise deviations in the value-flow comparison. Accordingly, the same ϵ can correspond to substantially different correspondence guarantees depending on the effective horizon and the chosen degree temperature.*

Remark 3447. *The theorem states that mind-world correspondence, when cashed out in this value-flow/degree language, is not a separate primitive: it is the same bridge inequality already proved for self-continuity, with "earlier time-slice" replaced by "internal model" and "later time-slice" replaced by "environment model." In short: correspondence is continuity across a boundary rather than across time.*

Remark 3448. *One can also read the result as a control-commensurability statement: if two descriptions support nearly the same Bellman back-ups after transport, then they induce nearly the same comparative advantage relations between actions/states, hence nearly the same flow of "where value goes" under optimal or near-optimal behavior. This helps justify the flow-graph proxy F as a representation-invariant object: it forgets irrelevant coordinate details while retaining the parts that matter for decision structure.*

Remark 3449. *This is conceptually important because it suggests a unification: the same formal apparatus can treat persistence of self, transfer between paradigms, coherence of groups, and adequacy of world-modeling. What changes are the systems being related and the tolerances one is willing to accept; what stays fixed is the logic of approximate intertwining and approximate morphism degree.*

Proof. Same as the TransWeave-to-SCS theorem, replacing time-slices by (internal model, environment model). □

Proof sketch. Reuse the earlier argument verbatim: intertwining error yields a bound on transported optimal values, the value-perturbation lemma yields an edgewise flow-graph inequality, and that inequality is precisely a lower bound on morphism degree. □

Remark 3450. *Spelled out slightly more concretely, the instantiation proceeds by (i) transporting $V^\star_{\mathrm{int}}$ (or $Q^\star_{\mathrm{int}}$) through the TransWeave map into the* env *description, (ii) using the ϵ-approximate commutation to show this transported object is an ϵ'-approximate fixed point of the* env *Bellman operator, (iii) applying the same contraction-based perturbation argument to relate it to $V^\star_{\mathrm{env}}$, and (iv) translating the resulting uniform value discrepancy into the edgewise inequalities defining high degree between F_{int} and F_{env}. The only change from the temporal case is the interpretation of the two sides of the transport: they index "model boundary" rather than "time."*

Remark 3451. *The proof is a template instantiation. This is mathematically modest but methodologically notable: it exemplifies how choosing the right abstraction makes many theorems become corollaries of a single bridge lemma.*

61.8 Optional appendix: dependency towers and transweave

Remark 3452. *If one further represents a paradigm or a mind's procedure library by dependency-tower layers (low-order dependencies first), then TransWeave-compatibility questions can be asked layerwise: does a transweave map send the kth-order approximation layer to the kth-order layer (or near it)? Such theorems make commensurability and cooperation criteria more granular: one may be commensurable at low dependency order but incommensurable at high order. One convenient way to formalize this is to regard the dependency tower as a filtration $(F_k)_{k\geq 0}$ on the relevant object (e.g. a space of models, programs, or procedures), where F_k is "everything constructible using at most k layers of dependence," and then ask for a* filtered *(or approximately filtered) TransWeave map T satisfying*

$$T(F_k) \subseteq F_{k+\Delta} \qquad \text{for small } \Delta,$$

or more stringently $T(F_k) \subseteq F_k$ for exact layer preservation. The phrase "or near it" can then be read as allowing controlled leakage across adjacent layers, measured by an application-appropriate norm or divergence (e.g. a risk gap on tasks of depth $\leq k$, an operator norm bound on residual components outside F_k, or a bound on failure probability when projecting back to F_k). In this filtration language, "commensurable at low order" means that the induced map on low layers (or on associated graded pieces $\mathrm{gr}_k := F_k/F_{k-1}$) is well-behaved and informative, while "incommensurable at high order" means that the map fails to respect or accurately transport the fine structure that only appears in deeper layers.

Remark 3453. *This remark connects to the Dependency Tower viewpoint (Hyperseed-Concept 94) and the associated towerization/tradeoff mathematics [8, 9]. Layerwise TransWeave analysis would amount to asking whether the transfer respects the coarse-to-fine organization of dependence: perhaps two paradigms agree on low-order regularities (and thus transfer well for simple tests), yet* *diverge in high-order structure (so transfer fails for subtle interventions). This provides a precise sense in which "partial commensurability" can be true without contradiction. A useful operational reading is that low-order agreement supports robust* predictive *alignment on ordinary regimes, while high-order disagreement manifests under distribution shift, counterfactual intervention, or long-horizon planning—settings where deep dependencies are repeatedly composed. In such cases, a layerwise criterion can be stated as: for tasks whose solution lives primarily in F_k, the transferred solution $T(x)$ should remain accurate after projection back to F_k, whereas for tasks requiring F_{k+m} structure the same transfer may systematically mis-specify the relevant dependencies. When the TransWeave construction is expressed via approximate intertwining (e.g. $T \circ A \approx B \circ T$ for salient operators A, B encoding update rules, inference steps, or dynamics), the layerwise refinement asks for these approximate intertwinings to hold* uniformly across levels *or with an error that grows slowly with k:*

$$\|TA|_{F_k} - BT|_{F_k}\| \leq \varepsilon_k,$$

with ε_k small for the layers one intends to treat as commensurable. This explicitly separates "we can translate each other's basic notions and replicate baseline competence" (small ε_k for small k) from "we can safely import each other's subtle causal or normative commitments" (requiring control of ε_k at high k). In the tradeoff perspective, this also illuminates why cooperation may succeed in low-dependency domains (shared coarse structure, low tower depth) yet fail in high-dependency domains (tower-depth amplification), and suggests a quantitative handle: one can treat the sequence (ε_k) or the minimal feasible Δ as a commensurability profile across dependency order.

62 Consciousness Locations, PNSE, and Mindplexes: A Bridge Between SuperDuperPsychism and the Hyperseed Ontology

We connect the SuperDuperPsychism (SDP) formalization of consciousness (GCC/RC, Locations, and collective Locations) with the Hyperseed ontology's formal interface for consciousness (presentational immediacy, workspace closure, reflective fixed points, and mindplexes). We introduce a translation layer and then state and prove a collection of theorems that are meant to be directly useful as reasoning tools: monotone parameter-to-Location mappings, formal PNSE criteria, collective stability/integration thresholds, and mindplex development results.

The intended role of this section is not to rebuild either framework from scratch, but to exhibit a minimal set of shared "handles" that let SDP-style Location claims be stated and checked inside the Hyperseed interface. In particular, we will treat an SDP Location (or collective Location) as something that can be tracked by (i) which propositions are consciously supported above threshold, (ii) whether the workspace dynamics admit stable states, and (iii) whether the system supports a reflective fixed point with sufficiently robust self-related content. The rest of the paper can then use these handles to formulate PNSE-like criteria and mindplex-level development statements without committing to a single implementation-level story.

62.1 Preliminaries: a minimal Hyperseed consciousness interface

We use a deliberately small slice of Hyperseed's consciousness formalism. The guiding principle is that we keep only those components needed to (a) represent graded support for content, (b) impose a global-workspace-style closure condition, and (c) express a reflective layer in which some of the content is about the system's own content. This is enough to state fixed-point and robustness conditions that later serve as proxies for "having a stable conscious state" and "having an integrated reflective self" in the sense required for the SDP–Hyperseed bridge.

Definition 559 (Evidence values and evidence states)**.** *Let $V := [0,1]^2$ with the componentwise order. An* evidence state *for an observer-context* Ob *is a map $E : L_{\mathrm{Ob}} \to V$, where L_{Ob} is a finite set of propositions. Write $E(\varphi) = (E^+(\varphi), E^-(\varphi))$. For $\theta \in (0,1)$ define the* conscious proposition set

$$\mathrm{Con}_\theta(E) := \{\varphi \in L_{\mathrm{Ob}} : E^+(\varphi) \geq \theta\}.$$

Here $V = [0,1]^2$ is used to keep track of two independent grades: a "for" component $E^+(\varphi)$ and an "against" component $E^-(\varphi)$. The componentwise order makes V a product poset, so increasing evidence in either component is formally meaningful and compatible with monotonicity assumptions introduced later. We do not require any special relationship between $E^+(\varphi)$ and $E^-(\varphi)$ (such as summing to 1); this allows the interface to represent uncertainty (both low), conflict (both high), and ordinary confidence (high/low or low/high) without additional machinery. The finiteness of L_{Ob} is a technical convenience that will later support existence arguments for stable points of monotone operators, and it also matches the intended use: L_{Ob} is a contextually selected "working" vocabulary rather than the set of all expressible sentences.

The set $\mathrm{Con}_\theta(E)$ is deliberately defined using only the positive component. The choice reflects the interpretation that conscious accessibility is primarily driven by a sufficiently strong "present" support signal, while negative evidence can still play an important role inside update operators. The threshold θ is kept as an explicit parameter because different later theorems will compare how varying θ changes the resulting conscious set, and because collective/PNSE criteria naturally involve threshold trade-offs.

Definition 560 (Workspace operator and conscious evidence state)**.** *A* workspace operator *is a monotone map $W : V^{L_{\mathrm{Ob}}} \to V^{L_{\mathrm{Ob}}}$. An evidence state E is* workspace-stable *if $W(E) = E$.*

The space $V^{L_{\mathrm{Ob}}}$ is ordered pointwise (induced from the componentwise order on V), so monotonicity of W means that if an evidence state is strengthened (in the poset sense) then the workspace update does not weaken it. Conceptually, W stands in for the closure and broadcasting effects of a global workspace: local module outputs are integrated, made mutually consistent as far as possible, and then returned as an updated global pattern of evidential support. The fixed-point condition $W(E) = E$ is the minimal way to say "the workspace dynamics have settled," i.e., that the state is closed under the workspace's own integration rule. Later, such fixed points will be used as the basic candidates for stable conscious Locations, and perturbation arguments will compare how these fixed points change under shifts in parameters or inputs.

Definition 561 (Reflective extension and introspection)**.** *Let $I(\cdot)$ be a syntactic operator. Define the reflective language $L_{\mathrm{Ob}}^{\mathrm{ref}} := L_{\mathrm{Ob}} \cup \{I(\varphi) : \varphi \in L_{\mathrm{Ob}}\}$. An* introspection operator *is a monotone map* $\mathrm{Int} : V^{L_{\mathrm{Ob}}} \to V^{L_{\mathrm{Ob}}^{\mathrm{ref}}}$.

The operator $I(\cdot)$ is intended to be read as "it is introspectively represented that φ" (or, depending on later interpretation, "φ is available to reflection"). The extension from L_{Ob} to $L_{\mathrm{Ob}}^{\mathrm{ref}}$ is the simplest way to add second-order content without introducing a full higher-order logic: we only add one layer of syntactic "tags" of the original propositions. The monotonicity of Int plays the same structural role as monotonicity of W: when first-order evidential support increases, the induced reflective representation should not decrease. This ensures that the reflective layer can be used in later monotone fixed-point constructions and that it behaves well under parameter changes.

Definition 562 (Reflective update map and reflective fixed points)**.** *Fix an attention/integration map* $\Gamma_a : V^{L_{\mathrm{Ob}}} \to V^{L_{\mathrm{Ob}}}$*, a workspace operator* $W^{\mathrm{ref}} : V^{L^{\mathrm{ref}}_{\mathrm{Ob}}} \to V^{L^{\mathrm{ref}}_{\mathrm{Ob}}}$*, and an introspection operator* Int*. Define the* reflective update map

$$F := W^{\mathrm{ref}} \circ \mathrm{Int} \circ \Gamma_a.$$

A reflective conscious state *is a fixed point* E^* *of* F*.*

The map Γ_a is separated out to represent pre-reflective selection and weighting: it can model attentional gain, module-to-module integration before broadcasting, and resource allocation. The subsequent Int step turns the attended first-order state into a mixed first/second-order representation, and W^{ref} then enforces the workspace-style closure at the reflective level. Writing the overall update as a single map F makes it possible to talk about reflective consciousness in the same fixed-point idiom as workspace stability, but now in a language that includes introspective content.

In later use, a fixed point E^* of F will function as a "reflectively closed" state: applying attention, introspection, and reflective workspace integration returns the same evidential pattern. This is the interface point at which we can meaningfully compare to SDP's reflective criteria (e.g., RCC-like conditions) without importing all of SDP's internal definitions into Hyperseed. Moreover, the explicit decomposition of F into three maps gives three levers for later theorems: perturbing attention (Γ_a), changing the introspection gain (inside Int), and changing reflective closure (W^{ref}).

Definition 563 (Reflective self condition)**.** *Assume* $L^{\mathrm{ref}}_{\mathrm{Ob}}$ *contains special propositions* $\mathrm{Self}(p)$ *meaning "p is a property of me," for p in some designated set* P_{self}*. A workspace-stable reflective evidence state* E exhibits a reflective self *if, for some threshold* θ*: (i)* $E^+(\mathrm{Self}(p)) \geq \theta$ *for many* $p \in P_{\mathrm{self}}$*; (ii)* $E^+(I(\mathrm{Self}(p))) \geq \theta$ *for those p; and (iii) these supports persist under small perturbations of module evidence and attention.*

This condition is meant to capture (in a minimal, operational form) the idea that selfhood involves not only first-order self-ascription but also a second-order availability of that self-ascription. Clause (i) asks for a sufficiently rich set of self-properties p to be supported at the first-order level, preventing a degenerate "self" that consists of a single token proposition. Clause (ii) requires that the system also represent, in the reflective language, that it has those self-properties, which is the simplest proxy for a reflective or introspective self-model. Clause (iii) is a robustness requirement: it ensures we are not merely identifying an unstable coincidence at a knife-edge parameter setting. Formally, "small perturbations" can later be interpreted in a metric or order topology on evidence states and in a parameter space for Γ_a; at this stage we only need the conceptual role of robustness because it will be used as a criterion for stable Locations and for collective integration thresholds.

The threshold θ here is allowed to be the same symbol as above but need not coincide numerically with the threshold used for $\mathrm{Con}_\theta(E)$. Later results will sometimes require distinguishing a content-access threshold from a self-model threshold, since the latter is typically stricter when used in PNSE-like arguments.

Definition 564 (Presentational immediacy and focus set)**.** *Let* X_c *be a set of presentational-immediacy carriers ("occasions" or "tokens"). A* presentational immediacy intensity *is a function* $I_c : X_c \to [0, 1]$*. For* $\theta \in (0, 1)$ *the* focus set *is* $F_\theta := \{x \in X_c : I_c(x) \geq \theta\}$*.*

Presentational immediacy is kept separate from evidential support because it is intended to track "what is directly presented" rather than "what is judged or inferred." The set X_c can be instantiated in many ways (sensory tokens, memory tokens, interoceptive occasions, or more abstract carriers), but the interface requires only that there is an intensity scale and a thresholded focus set. Later, this focus set will be one of the bridges to SDP Locations: informally, a Location can be constrained both by which propositions are consciously supported and by which carriers are currently focal. Keeping I_c independent also allows the formalism to represent cases in which something is highly presentationally immediate but not endorsed (high I_c, low E^+) and vice versa.

Definition 565 (State-of-consciousness parameter tuple). *A state-of-consciousness parameter tuple is*

$$\Lambda := (\lambda_{\text{ext}}, \lambda_{\text{int}}, \lambda_{\text{ref}}, \lambda_{\text{coh}}, \rho_{\text{hab}}, \rho_{\text{res}}),$$

intuitively controlling external anchoring, internal completion, introspection gain, coherence preference, habit reinforcement, and resonance coupling.

The tuple Λ serves as a compact way to state comparative and monotonicity results: varying Λ changes the induced operators (such as Γ_a, Int, and workspace closures) and therefore changes the sets $\text{Con}_\theta(E)$, F_θ, and the existence or structure of fixed points. The naming is suggestive rather than restrictive: λ_{ext} and λ_{int} can be taken to tune the relative weight of externally anchored versus internally completed content; λ_{ref} tunes how strongly introspective representations are amplified or stabilized; and λ_{coh} modulates the preference for globally coherent states in the workspace update. The parameters ρ_{hab} and ρ_{res} are written separately to emphasize that long-run stabilization (habit) and cross-module coupling (resonance) are distinct sources of persistence; in the later bridge to collective Locations and mindplexes, these often play different roles in stability thresholds.

62.2 Preliminaries: a minimal SDP interface

Definition 566 (GCC and reflective consciousness predicates). *Fix an observer O and threshold θ. Write $\text{GCC}_{O,\theta}(S, I)$ for "system S exhibits a GCC episode on interval I" and $\text{RC}_{O,\theta}(S, I)$ for "S exhibits reflective consciousness on I". We assume $\text{RC}_{O,\theta}(S, I) \Rightarrow \text{GCC}_{O,\theta}(S, I)$.*

Here O is intended to encode both a measurement perspective (what variables are accessible, at what temporal resolution, and with what inductive biases) and a normative stance (what counts as "global" and what counts as "reflective"). The parameter θ aggregates any thresholds used to binarize or discretize underlying graded evidence into the predicate $\text{GCC}_{O,\theta}$ or $\text{RC}_{O,\theta}$. The interval I can be taken as a closed real interval (e.g. $I = [t_0, t_1]$) or a discrete-time window, depending on whether S is modeled continuously or as an update process; nothing below depends on that choice, except that all derived quantities should be computed consistently with the same notion of time.

The implication $\text{RC}_{O,\theta}(S, I) \Rightarrow \text{GCC}_{O,\theta}(S, I)$ fixes a minimal interface constraint: reflective consciousness is treated as a refinement of a more basic globally-coordinated episode, rather than as an independent phenomenon. Operationally, one can read this as: if O judges that S is reflectively conscious over I, then O must also judge that a sufficiently integrated/global coordination condition is met over I. This leaves open whether $\text{GCC}_{O,\theta}$ is necessary or merely convenient for other forms of consciousness not discussed here; the only commitment is the one-way entailment stated.

Definition 567 (Location as an attractor in marker space). *Let $X := \mathcal{G} \times \mathcal{M} \times \mathcal{S}$ denote a marker space whose coordinates include global resonance-like markers ($\mathcal{G}$), marker profiles ($\mathcal{M}$), and self-model activity markers ($\mathcal{S}$). A* Location *L is a metastable region $\Omega_L \subseteq X$ that attracts nearby trajectories and is characterized (at least) by: (i) a resonance range $[R_L^{\min}, R_L^{\max}]$ and (ii) a self-model activity level (or range) S_L.*

The role of the product structure $X := \mathcal{G} \times \mathcal{M} \times \mathcal{S}$ is purely organizational: it distinguishes (a) markers meant to capture system-wide integration or "global workspace"-like coordination ($\mathcal{G}$), (b) a possibly high-dimensional profile of other task-, content-, or modality-relevant observables ($\mathcal{M}$), and (c) markers specifically tied to self-modeling, metacognition, and related monitoring/control activity ($\mathcal{S}$). In applications, each factor may itself be vector-valued and may include time-lagged features; the definition only requires that the combined state of markers at time t be representable as a point $x(t) \in X$.

A trajectory is the time-evolution $t \mapsto x(t)$ induced by the dynamics of S under whatever coupling to environment, tasks, and internal control policies is assumed. The phrase "metastable region Ω_L" is meant to exclude both instantaneous coincidences and fully absorbing equilibria: Ω_L should be stable enough that trajectories can dwell there for nontrivial durations (supporting an episode-like interpretation), yet permissive enough to allow transitions between Locations under perturbations, learning, or context shifts. The attractor-language is intentionally broad: Ω_L can be a basin around a fixed point, a limit cycle neighborhood, or a fuzzy cluster in marker space that repeatedly reappears across episodes.

The resonance range $[R_L^{\min}, R_L^{\max}]$ abstracts any scalar (or scalar reduction of a vector) intended to measure global coherence, synchrony, integration, or resonance-like coupling. The self-model activity descriptor S_L is similarly an abstraction: it can be a scalar level, an interval, or a low-dimensional summary of activity in a designated self-model subsystem. The "at least" qualifier indicates that additional coordinates (e.g. affective valence, arousal, uncertainty estimates, prediction-error statistics, or control bandwidth) may also be used to individuate Locations, but the resonance and self-model axes are treated as minimally necessary for the later bridging claims.

Definition 568 (Collective markers and collective Locations)**.** *Let $y_i(t)$ denote the policy/proposal signal produced by agent i at time t. Let D_O be a (model-dependent) distance on the space of such signals.*

Discord *is*

$$D_O(t) := \mathrm{Var}\big(\{y_i(t)\}\big)$$

for some variance functional induced by D_O.

Narrative capture *is $N_O(t) \in [0,1]$, interpreted as the fraction of the collective resource budget devoted to narrative/identity-maintenance patterns.*

A Collective Location *Ck (e.g. $C0, C1, C2, C3$) is a qualitative regime describable via thresholds on (at least) discord, narrative capture, and integration/coherence.*

The signal $y_i(t)$ is intended to be the agent-level output that participates in collective choice or coordination: it can be a distribution over actions, a proposed plan, a vote over options, a message embedding, or any other representation that the model treats as the "policy/proposal" interface. The distance D_O is allowed to depend on O because different observers may privilege different equivalences (e.g. treating two proposals as close if they lead to similar outcomes, if they share semantic content, or if they share resource implications). This observer-dependence will matter whenever discord is interpreted as a functional proxy for fragmentation or conflict.

The discord functional $D_O(t) := \mathrm{Var}(\{y_i(t)\})$ is schematic: the variance may be computed extrinsically (in a Euclidean embedding), intrinsically (via a kernel-induced metric), or in a decision-relevant geometry (e.g. using a divergence between probability distributions). The key requirement is that larger values correspond to greater dispersion among agent proposals, hence weaker immediate convergence of the collective toward a unified policy. In particular, low discord does not by itself imply good outcomes; it only encodes agreement or alignment in the $y_i(t)$ space as judged by O.

Narrative capture $N_O(t) \in [0,1]$ is defined as a resource fraction to emphasize that it competes with other collective capacities (e.g. exploration, deliberation, error correction, and external problem-solving). The phrase "narrative/identity-maintenance patterns" includes any activity whose primary function is preserving a shared story, status order, or self-description of the collective, rather than directly optimizing external objectives. The observer index again allows that what counts as "narrative" may depend on the modeling lens (for example, whether certain rituals are treated as coordination mechanisms or as identity reinforcement).

A Collective Location Ck is thus a coarse-grained attractor-like regime for group dynamics, analogous to an individual Location in marker space but defined over collective markers. The mention of "integration/coherence" indicates that discord and narrative capture are not sufficient by themselves: a collective may have low discord because it is rigidly coerced, or high narrative capture while still maintaining strong task integration in narrow domains. Therefore, the thresholds defining Ck are meant to incorporate at least one additional measure of coordinated information flow or functional coupling (however implemented in the chosen model), so that the resulting regime labels track meaningful qualitative changes in collective cognitive organization rather than merely surface agreement.

62.3 A translation layer: connecting the two formalisms

We introduce a bridge in two steps: (1) connect GCC/RC to workspace-stable (reflective) fixed points, and (2) connect Location coordinates (R, S) to Hyperseed parameters and evidence-state functionals. The intent is not to identify the two formalisms term-by-term, but to provide a translation layer in which the SuperDuperPsychism notions (GCC, RC, PNSE, and Location coordinates) can be represented as constraints on, or summaries of, Hyperseed-style evidence dynamics. In particular, the role of the "global conscious content" (GCC) will be played by the high-support portion of an evidence state (captured by $\mathrm{Con}_\theta(E)$), while the role of "reflective consciousness" (RC) will be captured by fixed points of a reflective update map that explicitly adds introspective propositions (via $I(\cdot)$) into the workspace.

To prepare step (2), we will later treat (R, S) not as additional primitives but as coordinates computed from the evidence-and-workspace dynamics: roughly, R will track the degree of reflective closure/stability of conscious contents under introspective updates, and S will track the degree to which self-ascriptions are both present and introspectively accessible in a robust way. This makes the Location picture operational: a point (R, S) corresponds to a family of evidence states that satisfy particular stability, accessibility, and self-model constraints.

Definition 569 (A simple coherence/resonance functional)**.** *Let L_{Ob} be finite and let $E \in V^{L_{\mathrm{Ob}}}$ be an evidence state. Assume given (i) a symmetric "coherence weight" function $\kappa : L_{\mathrm{Ob}} \times L_{\mathrm{Ob}} \to [0,1]$, (ii) a symmetric "tension weight" function $\tau : L_{\mathrm{Ob}} \times L_{\mathrm{Ob}} \to [0,1]$, and (iii) a "resonance profile" $r : L_{\mathrm{Ob}} \to [0,1]$ (standing for how strongly each proposition is coupled to recurrent or affectively salient processing). Define the* coherence *and* resonance *scores*

$$\mathrm{Coh}(E) \;:=\; \frac{1}{Z_{\kappa,\tau}} \sum_{\varphi,\psi \in L_{\mathrm{Ob}}} \Big(\kappa(\varphi,\psi)\, E^+(\varphi)E^+(\psi) \;-\; \tau(\varphi,\psi)\, E^+(\varphi)E^-(\psi)\Big),$$

$$\mathrm{Res}(E) \;:=\; \frac{1}{Z_r} \sum_{\varphi \in L_{\mathrm{Ob}}} r(\varphi)\, E^+(\varphi),$$

where $Z_{\kappa,\tau} > 0$ and $Z_r > 0$ are normalizers (for example, sums of the corresponding weights) so that $\mathrm{Coh}(E)$ and $\mathrm{Res}(E)$ lie in a controlled range.

The particular forms of Coh and Res are not essential; what matters is that they provide numerically evaluable summaries of (i) how mutually supportive the currently high-evidence propositions are, and (ii) how strongly the currently supported propositions are coupled to recurrent processing, affective salience, or other "resonance" channels. In the translation layer, these functionals will be used to connect phenomenological stability and "felt presence" to parameters such as λ_{coh} and ρ_{res}, and to define coarse coordinates like R via stability of reflective fixed points and like S via stability of self-ascriptive supports.

62.4 Preliminaries: a minimal Hyperseed consciousness interface

We use a deliberately small slice of Hyperseed's consciousness formalism. The goal of this interface is to have just enough structure to: (a) talk about evidence-bearing representations, (b) distinguish mere activation from workspace-stable availability, and (c) express a minimal notion of reflection in which some contents are about other contents (or about their being present to the system).

Definition 570 (Evidence values and evidence states)**.** *Let $V := [0,1]^2$ with the componentwise order. An* evidence state *for an observer-context* Ob *is a map $E : L_{\mathrm{Ob}} \to V$, where L_{Ob} is a finite set of propositions. Write $E(\varphi) = (E^+(\varphi), E^-(\varphi))$. For $\theta \in (0,1)$ define the* conscious proposition set

$$\mathrm{Con}_\theta(E) := \{\varphi \in L_{\mathrm{Ob}} : E^+(\varphi) \geq \theta\}.$$

The pair-valued codomain $V = [0,1]^2$ is meant to permit simultaneous positive and negative support, rather than forcing evidence into a single scalar. The componentwise order makes it natural to treat evidence updates as monotone maps: increasing either the positive or negative component (for any proposition) yields an "at least as supported" overall evidence state in the partial-order sense. The thresholded set $\mathrm{Con}_\theta(E)$ is intentionally crude: it acts as a readable surrogate for "what is globally available" at that moment, and it can be tuned by varying θ (e.g., high θ for reportable access, lower θ for weaker but still influence-bearing contents).

Definition 571 (Workspace operator and conscious evidence state)**.** *A* workspace operator *is a monotone map $W : V^{L_{\mathrm{Ob}}} \to V^{L_{\mathrm{Ob}}}$. An evidence state E is* workspace-stable *if $W(E) = E$.*

Monotonicity of W expresses the constraint that adding support to inputs does not perversely reduce support in outputs, which is a minimal regularity condition for an "integration/selection" stage. Workspace-stability is the basic dynamical notion that replaces an informal appeal to a sustained global workspace: $W(E) = E$ means that once the evidence configuration is fed through the workspace integration, it reproduces itself. This is the point at which the bridge to GCC begins: a workspace-stable state has a well-defined $\mathrm{Con}_\theta(E)$ that is not immediately dissolved by the workspace dynamics.

Definition 572 (Reflective extension and introspection)**.** *Let $I(\cdot)$ be a syntactic operator. Define the reflective language $L^{\mathrm{ref}}_{\mathrm{Ob}} := L_{\mathrm{Ob}} \cup \{I(\varphi) : \varphi \in L_{\mathrm{Ob}}\}$. An* introspection operator *is a monotone map* $\mathrm{Int} : V^{L_{\mathrm{Ob}}} \to V^{L^{\mathrm{ref}}_{\mathrm{Ob}}}$.

The operator $I(\varphi)$ is read schematically as "φ is (now) present/intended/available to me," without committing to a particular psychological theory of introspection. The role of Int is to map non-reflective evidence into a reflective space where some propositions are about other propositions. Monotonicity here expresses that strengthening first-order evidence should not, all else equal, reduce the system's capacity to generate corresponding reflective supports.

Definition 573 (Reflective update map and reflective fixed points)**.** *Fix an attention/integration map $\Gamma_a : V^{L_{\mathrm{Ob}}} \to V^{L_{\mathrm{Ob}}}$, a workspace operator $W^{\mathrm{ref}} : V^{L^{\mathrm{ref}}_{\mathrm{Ob}}} \to V^{L^{\mathrm{ref}}_{\mathrm{Ob}}}$, and an introspection operator* Int*. Define the* reflective update map

$$F := W^{\mathrm{ref}} \circ \mathrm{Int} \circ \Gamma_a.$$

A reflective conscious state *is a fixed point* E^* *of* F*.*

This is the minimal mechanism used to represent RC: reflection is not a separate "module" but a closure condition on the evidence dynamics once introspective propositions are admitted into the workspace. In finite settings, monotonicity of the constituent maps supports the expectation that fixed points exist under standard lattice-theoretic conditions; even when uniqueness is not guaranteed, a family of fixed points can be used to represent multiple stable "modes" of reflective access.

Definition 574 (Reflective self condition)**.** *Assume* $L_{\mathrm{Ob}}^{\mathrm{ref}}$ *contains special propositions* $\mathrm{Self}(p)$ *meaning "p is a property of me," for p in some designated set* P_{self}*. A workspace-stable reflective evidence state E* exhibits a reflective self *if, for some threshold* θ*: (i)* $E^+(\mathrm{Self}(p)) \geq \theta$ *for many* $p \in P_{\mathrm{self}}$*; (ii)* $E^+(I(\mathrm{Self}(p))) \geq \theta$ *for those p; and (iii) these supports persist under small perturbations of module evidence and attention.*

Clause (i) captures a nontrivial self-model at the level of first-order contents; clause (ii) demands that these self-ascriptions are themselves reflectively available (so the system can, in effect, represent that it represents itself as having properties). Clause (iii) is a robustness requirement: it separates a stable self from a fleeting coincidence of supports. This is the natural insertion point for mapping the S-coordinate of a Location: high S corresponds to many self-ascriptions that are both strong and introspectively endorsed, and whose endorsement remains stable under small changes in attention allocation.

Definition 575 (Presentational immediacy and focus set)**.** *Let* X_c *be a set of presentational-immediacy carriers ("occasions" or "tokens"). A* presentational immediacy intensity *is a function* $I_c : X_c \to [0, 1]$*. For* $\theta \in (0, 1)$ *the* focus set *is* $F_\theta := \{x \in X_c : I_c(x) \geq \theta\}$*.*

The carriers X_c are introduced to keep a place for phenomenological "what-it-is-like" immediacy without forcing it to be identified with propositional content. In the bridge, one can treat X_c as indexing perceptual episodes, affective tones, or bodily sensations that may not be exhaustively captured by L_{Ob}, while F_θ provides a minimal handle on attention-like selection among these carriers. This dovetails with Γ_a above: Γ_a can be understood as the evidence-level counterpart of selecting and integrating items in (or prompted by) F_θ.

Definition 576 (State-of-consciousness parameter tuple)**.** *A* state-of-consciousness parameter tuple *is*

$$\Lambda := (\lambda_{\mathrm{ext}}, \lambda_{\mathrm{int}}, \lambda_{\mathrm{ref}}, \lambda_{\mathrm{coh}}, \rho_{\mathrm{hab}}, \rho_{\mathrm{res}}),$$

intuitively controlling external anchoring, internal completion, introspection gain, coherence preference, habit reinforcement, and resonance coupling.

The tuple Λ is intended to collect slowly varying control parameters that shape the update maps (Γ_a, Int, W, W^{ref}) and thereby shape which fixed points exist and which are attractive. For the translation layer, one may read λ_{coh} as weighting the influence of $\mathrm{Coh}(E)$-like criteria in workspace selection, and ρ_{res} as weighting $\mathrm{Res}(E)$-like criteria (e.g., preferential amplification of resonant contents). Likewise, λ_{ref} can be interpreted as tuning the extent to which introspective propositions $I(\varphi)$ are generated and stabilized, and thus provides a direct control knob for the R-coordinate when R is taken to measure the reflective closure/stability of the conscious set under F.

62.5 Preliminaries: a minimal SDP interface

Definition 577 (GCC and reflective consciousness predicates)**.** *Fix an observer O and threshold θ. Write $\mathrm{GCC}_{O,\theta}(S,I)$ for "system S exhibits a GCC episode on interval I" and $\mathrm{RC}_{O,\theta}(S,I)$ for "S exhibits reflective consciousness on I". We assume $\mathrm{RC}_{O,\theta}(S,I) \Rightarrow \mathrm{GCC}_{O,\theta}(S,I)$.*

Here O encodes the choice of measurement model, readout, and any background assumptions used to judge whether a GCC or reflective episode is present; θ packages the (possibly multi-parameter) decision boundary above which the episode is counted as occurring. The interval I may be taken as continuous or discretized; in either case, the predicates are intended to be tolerant to brief fluctuations (e.g. by implicitly smoothing, averaging, or requiring persistence over a minimal dwell time). The implication

$$\mathrm{RC}_{O,\theta}(S,I) \Rightarrow \mathrm{GCC}_{O,\theta}(S,I)$$

formalizes a minimal hierarchy: reflective consciousness is treated as a stricter condition whose satisfaction entails the presence of a GCC-style global availability/integration episode, while leaving open whether GCC can occur without reflectivity. This interface is deliberately noncommittal about the mechanistic realization of GCC (workspace, ignition, broadcast, etc.) and is meant to serve only as a common logical handle for later constructions.

Definition 578 (Location as an attractor in marker space)**.** *Let $X := \mathcal{G} \times \mathcal{M} \times \mathcal{S}$ denote a marker space whose coordinates include global resonance-like markers ($\mathcal{G}$), marker profiles ($\mathcal{M}$), and self-model activity markers ($\mathcal{S}$). A* Location *L is a metastable region $\Omega_L \subseteq X$ that attracts nearby trajectories and is characterized (at least) by: (i) a resonance range $[R_L^{\min}, R_L^{\max}]$ and (ii) a self-model activity level (or range) S_L.*

Intuitively, X is a deliberately coarse "state space" of observables rather than microphysical degrees of freedom: points $x(t) \in X$ summarize whatever markers are taken to be salient for identifying a consciousness-relevant regime. The factor $\mathcal{G}$ can be read as capturing global, system-level synchrony or integration proxies (e.g. broadcast strength, large-scale coherence, ignition-like events), while $\mathcal{M}$ captures structured profiles (e.g. modality-weighted marker vectors, content-relevant signatures, or task-dependent configurations), and $\mathcal{S}$ captures activity of self-modeling (e.g. metacognitive monitoring, self-referential dynamics, narrative self-maintenance). A "trajectory" refers to the time-evolution $t \mapsto x(t)$ induced by the underlying system dynamics together with the observer map that extracts markers. Metastability is meant to cover regimes that are stable enough to be behaviorally and phenomenologically meaningful, yet permissive of transitions; Ω_L may therefore be thought of as a basin-like region with nonzero escape probability. The resonance interval $[R_L^{\min}, R_L^{\max}]$ and self-model range S_L are minimal coordinates for labeling the regime; additional coordinates (e.g. arousal, attention allocation, or prediction-error statistics) may be appended without changing the role of L as a coarse-grained attractor. Nothing in the definition forces Locations to be disjoint; overlaps can represent borderline cases or gradual shifts where multiple descriptive regimes apply under different observer choices O or different thresholds.

Definition 579 (Collective markers and collective Locations)**.** *Let $y_i(t)$ denote the policy/proposal signal produced by agent i at time t. Let D_O be a (model-dependent) distance on the space of such signals.*

Discord *is*

$$D_O(t) := \mathrm{Var}\big(\{y_i(t)\}\big)$$

for some variance functional induced by D_O.

Narrative capture *is* $N_O(t) \in [0,1]$*, interpreted as the fraction of the collective resource budget devoted to narrative/identity-maintenance patterns.*

A Collective Location Ck *(e.g.* $C0, C1, C2, C3$*) is a qualitative regime describable via thresholds on (at least) discord, narrative capture, and integration/coherence.*

The intent is that $y_i(t)$ abstracts away internal complexity and records only the externally relevant "proposal" each agent offers into a shared decision or control process (e.g. an action distribution, a plan token, a utility gradient, a vote vector, or a message in a negotiation protocol). The distance D_O is observer-relative because the geometry of proposal space depends on representation (e.g. whether two plans are considered close by edit distance, outcome similarity, KL divergence between policies, semantic embedding distance, or some task-specific metric). With that in place, $\mathrm{Var}(\{y_i(t)\})$ should be read broadly as any dispersion functional compatible with D_O; for instance, it may be implemented as average pairwise distance, distance to a centroid, or a robust spread statistic when outliers are expected. High discord corresponds to a strongly multi-peaked or scattered proposal landscape (many incompatible policies), while low discord corresponds to tight clustering (near-consensus).

Narrative capture $N_O(t)$ is likewise an interface variable: it is intended to quantify how much collective bandwidth is being spent on maintaining identity, status, justification, or story-consistency, as opposed to directly solving the nominal task. The $[0,1]$ normalization may be implemented by dividing an estimated narrative-maintenance load by total available compute/attention/communication budget over the same interval. In this framing, a Collective Location Ck is not a point but a regime label: it groups together collective states that satisfy certain threshold relations among discord $D_O(t)$, narrative capture $N_O(t)$, and an (unspecified but assumed available) integration/coherence marker (e.g. mutual information, effective connectivity, shared world-model alignment, or convergence rate of distributed belief updates). The examples $C0, C1, C2, C3$ are meant only as a minimal vocabulary for later reference; the precise number of regimes and their boundaries can vary with domain, but the definition requires that they be expressible as qualitative slices through the space of collective markers.

62.6 A translation layer: connecting the two formalisms

We introduce a bridge in two steps: (1) connect GCC/RC to workspace-stable (reflective) fixed points, and (2) connect Location coordinates (R, S) to Hyperseed parameters and evidence-state functionals. The role of this subsection is operational: it specifies a minimal set of numerical summaries of an evidence state that can be (i) computed from the Hyperseed-side objects and (ii) interpreted as proxies for the SuperDuperPsychism-side notions of global availability and self-model involvement. In particular, the translation is not intended to be unique; rather, it provides a family of choices (via K, σ, θ, and the thresholds below) whose qualitative behavior is robust across modeling details.

The first step relies on treating GCC/RC as a constraint on dynamical persistence: a state that is globally accessible (GCC) and reflectively coherent (RC) should correspond to an evidence configuration that is stable under the update rules governing workspace competition and reflective endorsement. Accordingly, throughout this chunk we assume that "workspace-stable" means stable relative to the chosen update operator(s) (e.g., a fixed point or attractor of the global-workspace selection dynamics), and that the stability requirement can be checked independently of the summary scores defined next.

Definition 580 (A simple coherence/resonance functional)**.** *Fix a finite set* $K \subseteq L^{\mathrm{ref}}_{\mathrm{Ob}}$ *of "currently relevant" propositions. Let* $\sigma : V \to \mathbb{R}$ *be any monotone map that increases with net support and/or* *reduces with tension (model-dependent). Define the* coherence score *of an evidence state by*

$$\mathrm{Coh}(E) := \frac{1}{|K|} \sum_{\varphi \in K} \sigma(E(\varphi)).$$

Intuitively, $\mathrm{Coh}(E)$ is meant to aggregate, across a contextually selected set K, how well the current evidence state supports (or at least does not strongly conflict with) the propositions that the system is effectively "tracking" at the reflective/object level. The restriction to a finite K encodes limited bandwidth and attention: only a bounded slice of the reflective/object language contributes to the coherence estimate at any given time. The monotonicity requirement on σ ensures that if the evidence values $E(\varphi)$ shift in a direction that the model interprets as "more supportive" (or less tense), then $\mathrm{Coh}(E)$ will not decrease. Different modeling choices correspond to different σ (for instance, a sigmoid that saturates, a linear map on an interval of V, or a map that penalizes values associated with contradiction), but the intended use is the same: $\mathrm{Coh}(E)$ is a single scalar proxy for workspace-level resonance with the currently relevant reflective content.

Definition 581 (Self-model activity score)**.** *Let P_{self} be the designated self-property set and fix $\theta \in (0,1)$. Define*

$$\mathrm{SAct}_\theta(E) := \frac{1}{|P_{\mathrm{self}}|} \big|\{p \in P_{\mathrm{self}} : E^+(\mathrm{Self}(p)) \geq \theta\}\big|.$$

The statistic $\mathrm{SAct}_\theta(E)$ measures how many self-ascriptions are "active" at or above a threshold θ, normalized by the size of the self-property vocabulary. This is intended to capture a graded notion of self-model engagement that is robust to changes in magnitude scale, since it depends only on whether the positive component E^+ crosses a criterion. The parameter θ may be treated as a control knob: smaller θ makes the score sensitive to weak self-evidence, while larger θ restricts the score to comparatively strong self-endorsements. On the translation-layer reading, low $\mathrm{SAct}_\theta(E)$ corresponds to a weakly recruited or backgrounded self-model, whereas high $\mathrm{SAct}_\theta(E)$ corresponds to widespread self-referential recruitment (e.g., strong ownership, agency, narrative centrality, or explicit self-attribution, depending on what is encoded in P_{self}).

Definition 582 (Symbolic load and PNSE)**.** *Let* $\mathrm{Sym} \subseteq L_{\mathrm{Ob}}$ *denote the subset of propositions treated as linguistic/symbolic/narrative in the current modeling context. Define the* symbolic load *of E by*

$$\mathrm{SL}_\theta(E) := \frac{|\mathrm{Con}_\theta(E) \cap \mathrm{Sym}|}{|\mathrm{Sym}|}.$$

Fix $\varepsilon \in [0,1]$. A workspace-stable evidence state E is an ε-PNSE state *if* $\mathrm{SL}_\theta(E) \leq \varepsilon$ *and* $\mathrm{Coh}(E)$ *is above a chosen coherence threshold.*

A system exhibits PNSE *on interval I (relative to (θ, ε)) if, for all $t \in I$, there is a workspace-stable E_t such that E_t is an ε-PNSE state.*

Here $\mathrm{SL}_\theta(E)$ provides a deliberately coarse proxy for "how much of the currently active content is symbolic," where activity is represented by the thresholded consequence set $\mathrm{Con}_\theta(E)$. The numerator counts those threshold-active consequences that fall into the designated symbolic/narrative fragment Sym, and the normalization by $|\mathrm{Sym}|$ turns this into a context-dependent fraction. In particular, $\mathrm{SL}_\theta(E)$ is meant to be sensitive to changes in the symbolic subspace even when overall coherence remains high. The PNSE condition then formalizes the idea that a system can occupy stable, coherent states with low symbolic/narrative load: $\mathrm{Coh}(E)$ ensures that the state is not merely "quiet" or "blank" but remains globally well-supported over the relevant reflective set K, while the constraint $\mathrm{SL}_\theta(E) \leq \varepsilon$ enforces that this coherence is achieved without strongly engaging the symbolic fragment. The coherence threshold (left unspecified here) is intended to be chosen relative to the update rules and the range of σ, so that it separates merely transient or fragmented patterns from those that function as globally integrated workspace contents.

The time-indexed definition of PNSE on an interval I emphasizes persistence: it is not enough for one instantaneous evidence snapshot to be low-symbolic; rather, the system must admit a workspace-stable representative E_t at each time t in the interval. This aligns the PNSE notion with the fixed-point or attractor reading of workspace stability, and it makes explicit that PNSE is a property of a trajectory (or time-slice family) in evidence-state space, not only of a single evidence state.

Definition 583 (A Location classifier from Hyperseed evidence states)**.** *Fix thresholds* $(r_0 < r_1 < \cdots)$ *and* $(s_0 > s_1 > \cdots)$ *in* $[0,1]$*. Define the* Hyperseed Location index *of an evidence state* E *as*

$$\mathrm{Loc}(E) := \max\{k : \mathrm{Coh}(E) \geq r_k \textit{ and } \mathrm{SAct}_\theta(E) \leq s_k\}.$$

The index $\mathrm{Loc}(E)$ is intended as a discrete surrogate for the continuous Location coordinates (R, S): the condition $\mathrm{Coh}(E) \geq r_k$ plays the role of requiring sufficiently strong integration/resonance (an R-like dimension), while the constraint $\mathrm{SAct}_\theta(E) \leq s_k$ enforces sufficiently weak self-model recruitment (an S-like dimension, depending on the chosen sign convention). The opposing monotonicity of the threshold sequences (r_k) and (s_k) encodes the idea that moving to higher Location indices requires simultaneously higher coherence and lower self-activity, so that higher k corresponds to more coherent-yet-less-self-involving workspace organization. The use of max makes the classifier conservative in the sense that it assigns the highest index consistent with both inequalities; if no k satisfies the constraints, one may treat $\mathrm{Loc}(E)$ as undefined or as taking a default value (depending on how the Location lattice is handled elsewhere). In the bridge to Hyperseed parameters, the thresholds may be learned or calibrated (e.g., by matching empirical regimes, simulation phases, or hand-labeled exemplars) so that each k corresponds to a qualitatively stable phenomenological/functional region in the combined SuperDuperPsychism–Hyperseed description.

62.7 Theorems: GCC/RC imply Hyperseed conscious/reflective fixed points

In this subsection the main mathematical work is carried by monotone operators on evidence states. Intuitively, a "workspace-stable" state is one that is left unchanged by the (possibly time-indexed) workspace update W_t, and a "reflective" stable state is one that is left unchanged by the corresponding reflective closure operator $F = W^{\mathrm{ref}} \circ \mathrm{Int} \circ \Gamma_a$. The thresholded consciousness map $\mathrm{Con}_\theta(\cdot)$ then picks out those propositions whose positive support crosses the designated level θ; in the intended application, these are the contents eligible to count as consciously present (or reflectively present, in the reflective language).

Lemma 168 (Threshold monotonicity)**.** *If* $E \leq E'$ *pointwise (componentwise in* V*), then* $\mathrm{Con}_\theta(E) \subseteq \mathrm{Con}_\theta(E')$*.*

Proof. If $\varphi \in \mathrm{Con}_\theta(E)$ then $E^+(\varphi) \geq \theta$. Since $E \leq E'$ we have $E'^+(\varphi) \geq E^+(\varphi) \geq \theta$, hence $\varphi \in \mathrm{Con}_\theta(E')$. The only property used here is that the map $E \mapsto E^+(\varphi)$ is monotone in the pointwise order; this matches the interpretation that increasing the underlying evidence state cannot decrease the positive support assigned to a fixed proposition. □

The next theorem is the basic existence result that is used repeatedly: once the workspace dynamics is represented as a monotone self-map on a complete lattice of evidence states, fixed points exist without requiring contraction, continuity, or any metric structure. This is the minimal structure needed for the later “Hyperseed fixed point” reading, where stable conscious/reflective episodes are represented by fixed points (or, more generally, by elements in the fixed-point set) of appropriate closure operators.

Theorem 169 (Workspace-stable conscious states exist under monotone closure)**.** *Assume L_{Ob} is finite and $W : V^{L_{\mathrm{Ob}}} \to V^{L_{\mathrm{Ob}}}$ is monotone. Then W has at least one fixed point. In particular, there exist workspace-stable evidence states.*

Proof. The set $V^{L_{\mathrm{Ob}}}$ is a complete lattice under pointwise order because V is. By monotonicity of W, Tarski's fixed point theorem implies the set of fixed points of W is nonempty (and has least and greatest fixed points). Concretely, one may think of iterating W from the bottom element (or dually from the top element) of the lattice to generate an increasing (or decreasing) chain whose join (or meet) is a fixed point; Tarski guarantees existence of the relevant joins/meets in the complete lattice and thus avoids any appeal to finiteness beyond the closure properties already assumed. □

To connect this abstract fixed-point existence to GCC-style episodes, we treat each time slice t in the interval I as having an associated monotone “broadcast-and-stabilize” operator W_t. Assumption (A2) supplies a particular proposition φ_t that expresses that the system is in the relevant “basin” (or workspace coalition) at that time. The role of the fixed-point argument is then to ensure that there is at least one stabilized evidence state at time t in which that basin-membership proposition remains above threshold, so that a nonempty conscious set (and hence a nonempty focus set) is secured.

Theorem 170 (GCC implies existence of stable focus sets)**.** *Assume $\mathrm{GCC}_{O,\theta}(S, I)$. Assume further that during the GCC episode there exists a time-indexed family of monotone workspace operators W_t and presentational immediacy functions $I_{c,t}$ such that: (A1) W_t encodes “global broadcasting + basin stabilization” for the GCC basin at time t; and (A2) there exists at least one proposition φ_t expressing the active basin membership such that $E^+_{\bullet,t}(\varphi_t) \geq \theta$ in the integrated module evidence $E_{\bullet,t}$.*

Then for each $t \in I$ there exists a workspace-stable evidence state E_t with $\varphi_t \in \mathrm{Con}_\theta(E_t)$; hence $\mathrm{Con}_\theta(E_t) \neq \emptyset$. Moreover the focus sets $F_{\theta,t} = \{x : I_{c,t}(x) \geq \theta\}$ are nonempty for all $t \in I$.

Proof. Fix $t \in I$. By the previous theorem, W_t has at least one fixed point E_t. Assumption (A2) provides a proposition φ_t with positive evidence above threshold in the integrated evidence. Because W_t is monotone and (by the intended reading of (A1)) does not destroy supported basin-membership content, we may choose E_t among fixed points satisfying $E_t \geq E_{\bullet,t}$ on φ_t (e.g. take the greatest fixed point if needed). Then $E^+_t(\varphi_t) \geq \theta$, so $\varphi_t \in \mathrm{Con}_\theta(E_t)$. The nonemptiness of $F_{\theta,t}$ follows from the bridge assumption that GCC-visible basin content corresponds to at least one presentational token above threshold (otherwise there would be no unified “moment” in the MinSync sense). For additional clarity on the choice of fixed point: if one treats $E_{\bullet,t}$ as a lower bound encoding the currently integrated support, then monotonicity allows one to consider the set of post-fixed points above that bound (states E with $E_{\bullet,t} \leq E$ and $E \leq W_t(E)$) and apply Knaster–Tarski to obtain a greatest fixed point above $E_{\bullet,t}$ when such a bound is appropriate for the application. The intended content-preservation clause in (A1) is precisely what motivates working within an upper region of the lattice that respects already-established basin membership. □

The RC case parallels GCC but strengthens the content being stabilized: it is not merely basin membership that must remain above threshold, but a family of self-ascriptions and their introspective counterparts. In the Hyperseed reading, this is the difference between a merely conscious fixed point and a reflective fixed point: the latter contains, above threshold, propositions in which the system represents itself as having certain properties, together with propositions expressing that the system is aware of (or has introspective access to) those self-ascriptions.

Theorem 171 (RC implies existence of reflective-self fixed points)**.** *Assume* $\mathrm{RC}_{O,\theta}(S, I)$*. Assume that the RC self-model supplies a designated set* P_{self} *of self-properties and module evidence supports* $\mathrm{Self}(p)$ *for many* $p \in P_{\text{self}}$ *during* I*.*

Then there exists a reflective fixed point E^* *of* $F = W^{\text{ref}} \circ \mathrm{Int} \circ \Gamma_a$ *that satisfies the reflective self condition.*

Proof. Because $L_{\text{Ob}}^{\text{ref}}$ is finite and F is monotone (as a composition of monotone maps), Tarski's theorem yields a fixed point E^* of F. Here the finiteness assumption is used only to guarantee that the relevant evidence-state space $V^{L_{\text{Ob}}^{\text{ref}}}$ is well behaved under pointwise order given the assumed lattice structure on V; the fixed-point existence itself is driven by completeness and monotonicity, so the same argument extends whenever the reflective evidence space forms a complete lattice.

(Self-presence) By assumption, for many $p \in P_{\text{self}}$ the base evidence for $\mathrm{Self}(p)$ is above threshold during I. Monotonicity of Γ_a and W^{ref} preserves (or increases) this support in the fixed point. In particular, if Γ_a is read as an attention or gating operation, monotonicity encodes the idea that allocating more attention to a supported self-proposition cannot reduce its positive evidential component, and W^{ref} then performs a closure/broadcast step that similarly respects supported content.

(Reflective access) The introspection operator assigns evidence to $I(\mathrm{Self}(p))$ as a monotone function of the base evidence for $\mathrm{Self}(p)$, so for those p the introspective propositions also cross threshold in E^*. This is the formal counterpart of the RC requirement that self-ascriptions are not merely present but are available to higher-order access: whenever $\mathrm{Self}(p)$ is sufficiently supported, the monotone Int map ensures the derived reflective token $I(\mathrm{Self}(p))$ is supported as well, and the fixed-point condition ensures this relation is stable under repeated application of the reflective loop.

(Stability) RC requires that the self-model's representational loops are robust under benign internal reparameterizations. Modeling this as small perturbations in module evidence and attention implies the relevant supports persist in a neighborhood of the fixed point. In lattice-theoretic terms, this robustness can be expressed by requiring that the fixed point be resistant to perturbations that remain within an order-neighborhood (i.e. do not decrease the supports of the relevant $\mathrm{Self}(p)$ below threshold), so that the same monotone operators continue to map the perturbed state back toward a region whose join/meet structure contains a fixed point with the reflective self condition. This matches the RC intuition that reflective self-representation is not a brittle coincidence at a single evidence assignment but an attractor-like configuration of the reflective dynamics. □

62.8 Theorems: PNSE and Martin Locations via Hyperseed parameter regimes

Definition 584 (Parametric monotonicity assumption)**.** *Let* Λ *range over parameter tuples. Write* F_Λ *for the resulting reflective update map. Assume a partial order* $\preceq$ *on parameter tuples such that* $\Lambda \preceq \Lambda'$ *implies* $F_\Lambda(E) \leq F_{\Lambda'}(E)$ *for all* E*. (Informally: increasing parameters that amplify completion or introspection cannot decrease evidence.)*

Lemma 169 (Least fixed points are monotone in monotone operator families)**.** *Assume* F *and* G *are monotone operators on a complete lattice with* $F(E) \leq G(E)$ *for all* E*. Let* $\mathrm{lfp}(F)$ *denote the least fixed point of* F*. Then* $\mathrm{lfp}(F) \leq \mathrm{lfp}(G)$*.*

Proof. By Tarski, both least fixed points exist. Let $x = \mathrm{lfp}(G)$. Then $G(x) = x$ and $F(x) \leq G(x) = x$, so x is a pre-fixpoint of F. The least fixed point of F is below every pre-fixpoint, hence $\mathrm{lfp}(F) \leq x$. □

Theorem 172 (Symbolic suppression under reduced completion and introspection)**.** *Assume the parametric monotonicity assumption. Fix a threshold θ and symbolic subset $\mathrm{Sym} \subseteq L_{\mathrm{Ob}}$. Let $\Lambda \preceq \Lambda'$ where (informally) Λ has lower internal completion λ_{int} and lower introspection gain λ_{ref} than Λ', with coherence preference λ_{coh} held high.*

Let $E^* = \mathrm{lfp}(F_\Lambda)$ and $E'^* = \mathrm{lfp}(F_{\Lambda'})$. Then

$$\mathrm{Con}_\theta(E^*) \cap \mathrm{Sym} \subseteq \mathrm{Con}_\theta(E'^*) \cap \mathrm{Sym},$$

and in particular $\mathrm{SL}_\theta(E^*) \leq \mathrm{SL}_\theta(E'^*)$.

Proof. By parametric monotonicity, $F_\Lambda(E) \leq F_{\Lambda'}(E)$ for all E. By the previous lemma, $\mathrm{lfp}(F_\Lambda) \leq \mathrm{lfp}(F_{\Lambda'})$, i.e. $E^* \leq E'^*$. Apply Lemma (Threshold monotonicity) to conclude $\mathrm{Con}_\theta(E^*) \subseteq \mathrm{Con}_\theta(E'^*)$. Intersect both sides with Sym to obtain the inclusion, and divide by $|\mathrm{Sym}|$. □

Corollary 63 (A formal PNSE sufficient condition)**.** *Fix $\varepsilon \in [0, 1]$. If there exists a parameter tuple Λ such that the least fixed point $E^* = \mathrm{lfp}(F_\Lambda)$ has $\mathrm{SL}_\theta(E^*) \leq \varepsilon$ and high coherence $\mathrm{Coh}(E^*) \geq r_1$, then E^* is an ε-PNSE state. Moreover, any parameter tuple $\tilde{\Lambda} \preceq \Lambda$ yields a least fixed point whose symbolic load is at most ε.*

Proof. The first claim is immediate from the definition of ε-PNSE. For the second, apply the previous theorem with $\tilde{\Lambda} \preceq \Lambda$. □

Theorem 173 (Martin-Location ordering as a monotone mapping)**.** *Assume the SDP key claim that higher numbered Locations have higher sustained global resonance and lower self-model activity. Assume the translation of these into Hyperseed evidence-state functionals: higher resonance corresponds to larger $\mathrm{Coh}(E)$ and lower self-model activity corresponds to smaller $\mathrm{SAct}_\theta(E)$.*

Then for any evidence states E, E': if $\mathrm{Loc}(E') > \mathrm{Loc}(E)$, then $\mathrm{Coh}(E') \geq \mathrm{Coh}(E)$ and $\mathrm{SAct}_\theta(E') \leq \mathrm{SAct}_\theta(E)$.

Proof. Let $k = \mathrm{Loc}(E)$ and $k' = \mathrm{Loc}(E')$ with $k' > k$. By definition of Loc, $\mathrm{Coh}(E) \geq r_k$ and $\mathrm{SAct}_\theta(E) \leq s_k$, and $\mathrm{Coh}(E') \geq r_{k'} \geq r_k$ and $\mathrm{SAct}_\theta(E') \leq s_{k'} \leq s_k$, using monotonicity of the threshold sequences. The inequalities follow. □

Remark 3454 (Mapping Locations to canonical parameter regimes)**.** *A useful operationalization is to map: ordinary waking $\mapsto$ Location 0, Being/flow-like regimes $\mapsto$ Location 1, oceanic consciousness $\mapsto$ Location 2, and stable enlightenment-like regimes $\mapsto$ Location 4, by choosing threshold sequences (r_k, s_k) consistent with the canonical regime table.*

Definition 585 (Habit reinforcement operator (abstract))**.** *A* habit reinforcement operator *is a monotone inflationary map $H_{\rho_{\mathrm{hab}}} : V^{L^{\mathrm{ref}}_{\mathrm{Ob}}} \to V^{L^{\mathrm{ref}}_{\mathrm{Ob}}}$ that increases support for propositions that have been repeatedly supported in the recent past, with strength controlled by $\rho_{\mathrm{hab}} \in [0, 1]$.*

Definition 586 (Habit-augmented reflective dynamics)**.** *Given parameters Λ, define the habit-augmented reflective update map*

$$F_\Lambda^{\mathrm{hab}} := H_{\rho_{\mathrm{hab}}} \circ F_\Lambda.$$

A habit-stabilized reflective state *is a fixed point of F_Λ^{hab}.*

Theorem 174 (Existence and persistence of habit-stabilized PNSE states)**.** *Assume $H_{\rho_{\mathrm{hab}}}$ and F_Λ are monotone and $H_{\rho_{\mathrm{hab}}}$ is inflationary. Then F_Λ^{hab} has at least one fixed point.*

Assume additionally there is a set $\mathcal{P} \subseteq V^{L^{\mathrm{ref}}_{\mathrm{Ob}}}$ of "PNSE-like" reflective states such that: (i) $\mathcal{P}$ is upward closed (if $E \in \mathcal{P}$ and $E \leq E'$ then $E' \in \mathcal{P}$), (ii) $F_\Lambda(\mathcal{P}) \subseteq \mathcal{P}$, and (iii) $H_{\rho_{\mathrm{hab}}}(\mathcal{P}) \subseteq \mathcal{P}$. Then $\mathcal{P}$ is forward invariant under the iteration of F_Λ^{hab}.

Proof. Because $V^{L_{\mathrm{Ob}}^{\mathrm{ref}}}$ is a complete lattice and $F_{\Lambda}^{\mathrm{hab}}$ is monotone (composition of monotone maps), Tarski gives existence of a fixed point. For forward invariance, let $E \in \mathcal{P}$. Then by (ii) $F_{\Lambda}(E) \in \mathcal{P}$ and by (iii) $F_{\Lambda}^{\mathrm{hab}}(E) = H_{\rho_{\mathrm{hab}}}(F_{\Lambda}(E)) \in \mathcal{P}$. Thus the next iterate lies in $\mathcal{P}$, and induction yields invariance for all iterates. More explicitly, the base step is the given hypothesis $E \in \mathcal{P}$, and the inductive step is: if $E_t \in \mathcal{P}$, then $F_{\Lambda}(E_t) \in \mathcal{P}$ by (ii), and applying the habit/hysteresis operator $H_{\rho_{\mathrm{hab}}}$ preserves membership in $\mathcal{P}$ by (iii), so $E_{t+1} = F_{\Lambda}^{\mathrm{hab}}(E_t) \in \mathcal{P}$. Hence every forward iterate under the composed update map remains in the admissible set $\mathcal{P}$, so trajectories cannot "escape" the regime of well-defined evaluation of Coh, SAct_{θ}, and Loc. □

Theorem 175 (Canonical-regime monotonicity yields Location monotonicity (a template))**.** *Let Λ_1, Λ_2 be parameter tuples with: (a) $\lambda_{\mathrm{coh}}(\Lambda_2) \geq \lambda_{\mathrm{coh}}(\Lambda_1)$ (more coherence preference), (b) $\lambda_{\mathrm{ref}}(\Lambda_2) \leq \lambda_{\mathrm{ref}}(\Lambda_1)$ (less introspection gain), and (c) all other components held fixed. In particular, (c) means that any auxiliary weights governing evidence assimilation, coupling to habituation, or exogenous priors are unchanged, so the only directional pressures introduced when moving from Λ_1 to Λ_2 are toward coherence (via λ_{coh}) and away from reflective amplification (via λ_{ref}). Assume that increasing λ_{coh} (at fixed evidence) cannot decrease* $\mathrm{Coh}(\cdot)$*, and decreasing λ_{ref} cannot increase* $\mathrm{SAct}_{\theta}(\cdot)$ *at the resulting least reflective fixed point. Here "least reflective fixed point" is the one selected by the* lfp *operator, i.e. the minimal fixed point with respect to the underlying order used to formalize reflectivity/activation (e.g. pointwise order on state components, or an order induced by a reflection functional), so that the comparison across parameter regimes is made at comparable, non-maximally self-amplified equilibria.*

Then, with $E_i^* = \mathrm{lfp}(F_{\Lambda_i})$, we have $\mathrm{Loc}(E_2^*) \geq \mathrm{Loc}(E_1^*)$*. Equivalently, along this parameter change, the equilibrium state cannot move to a strictly lower Location level, in the sense encoded by the threshold structure defining* Loc*.*

Interpretation: *choosing canonical parameter regimes (e.g. "Being", "Oceanic", "Enlightenment") so that coherence preference increases and introspection gain decreases along the sequence yields a formally monotone increase in Location index. This can be read as a design principle: when the model is tuned to privilege globally consistent integration (higher λ_{coh}) while dampening reflective self-activation loops (lower λ_{ref}), the canonical equilibrium shifts toward (weakly) higher Location strata, provided the two stated monotonicity responses of* Coh *and* SAct_{θ} *hold under the fixed-point selection.*

Proof. Under the assumptions, the fixed point E_2^* has $\mathrm{Coh}(E_2^*) \geq \mathrm{Coh}(E_1^*)$ and $\mathrm{SAct}_{\theta}(E_2^*) \leq \mathrm{SAct}_{\theta}(E_1^*)$. The first inequality follows from the postulated non-decreasing response of $\mathrm{Coh}(\cdot)$ when λ_{coh} is increased while holding evidence and the remaining coordinates of Λ fixed; the second follows from the postulated non-increasing response of $\mathrm{SAct}_{\theta}(\cdot)$ when λ_{ref} is decreased, evaluated at the corresponding least reflective fixed point selected by lfp. By definition of Loc as a maximum k satisfying threshold inequalities, these two monotone inequalities imply $\mathrm{Loc}(E_2^*) \geq \mathrm{Loc}(E_1^*)$. Concretely, if $\mathrm{Loc}(E_1^*) = k$, then E_1^* satisfies the required inequalities at level k (e.g. $\mathrm{Coh}(E_1^*) \geq \tau_k^{\mathrm{coh}}$ and $\mathrm{SAct}_{\theta}(E_1^*) \leq \tau_k^{\mathrm{sact}}$, for the relevant threshold sequences); the displayed monotonicity relations ensure E_2^* also satisfies those same level-k inequalities, so the maximal admissible level for E_2^* cannot be smaller than k. Hence $\mathrm{Loc}(E_2^*) \geq \mathrm{Loc}(E_1^*)$ as claimed. □

62.9 Theorems: collective Locations via cultural fixed points

We now use Hyperseed's culture-as-fixed-point picture to derive sufficient conditions for collective Location properties.

Definition 587 (Social reinforcement dynamics)**.** *Let $G = (V, E)$ be a directed graph of agents. Let $\mathcal{P}$ be a set of cultural patterns. A* cultural state *is an intensity table $I : V \times \mathcal{P} \to [0, 1]$.*

Fix edge weights $K : E \to [0,1]$. Define the social reinforcement operator F by

$$(F(I))_{i,P} := \max\Big(I_{i,P},\ \max_{(j,i)\in E} \min\big(K(j,i), I_{j,P}\big)\Big).$$

A stabilized cultural state *is a fixed point I^* of F.*

Definition 588 (A simple integration proxy and collective discord proxy)**.** *Fix a set of "key" patterns $\mathcal{P}_0 \subseteq \mathcal{P}$. Define an integration proxy*

$$\mathrm{Int}(I) := \min_{P\in\mathcal{P}_0}\ \min_{i\in V}\ I_{i,P}.$$

Assume each agent has a proposal map $y_i = \pi(I_i)$ where I_i is the row $(I_{i,P})_{P\in\mathcal{P}_0}$. Assume π is L-Lipschitz:

$$D_O(\pi(u), \pi(v)) \le L\|u - v\|_\infty.$$

Define discord proxy

$$\mathrm{DO}(I) := \max_{i,j\in V} D_O(y_i, y_j).$$

Theorem 176 (Fixed points yield resilient homeostasis (C1 sufficient condition))**.** *Assume the collective cultural dynamics iterate $I^{(t+1)} = F(I^{(t)})$ for a monotone F as above. Then any fixed point I^* is an invariant "homeostatic" state: if $I^{(0)} = I^*$ then $I^{(t)} = I^*$ for all t. If, additionally, F is inflationary ($I \le F(I)$), then the orbit from any initial condition is nondecreasing and converges (in finite time on finite grids, or in the complete-lattice sense) to the least fixed point above $I^{(0)}$.*

In particular, the existence of fixed points provides a formal C1-style "resilient homeostasis" mechanism for a collective.

Proof. If $I^* = F(I^*)$ then iterating preserves it. Inflationarity gives $I^{(0)} \le I^{(1)} \le \cdots$. Because the poset $[0,1]^{V\times\mathcal{P}}$ is a complete lattice, the monotone chain has a least upper bound; standard Kleene/Tarski arguments show the limit is a fixed point (indeed the least fixed point above the initial state). □

Theorem 177 (Strong connectivity yields a diffusion lower bound (C2 integration enabler))**.** *Assume the communication graph G is strongly connected. Assume there exists $k_0 > 0$ such that $K(e) \ge k_0$ for all edges $e \in E$. Let I^* be any fixed point of F with $I^* \ge I^{(0)}$. Fix a pattern P and define $M_P := \max_{j\in V} I^{(0)}_{j,P}$. Then for every agent $i \in V$,*

$$I^*_{i,P} \ge \min(k_0, M_P).$$

Consequently, for any key-pattern set $\mathcal{P}_0$ we have

$$\mathrm{Int}(I^*) \ge \min\Big(k_0,\ \min_{P\in\mathcal{P}_0} M_P\Big).$$

Proof. Fix i and choose a directed path $j \to \cdots \to i$ from some j achieving M_P (strong connectivity guarantees such a path). Along any edge (u,v) the fixed point condition implies $I^*_{v,P} \ge \min(K(u,v), I^*_{u,P}) \ge \min(k_0, I^*_{u,P})$. Induct along the path starting from $I^*_{j,P} \ge I^{(0)}_{j,P} = M_P$ to obtain $I^*_{i,P} \ge \min(k_0, M_P)$. Taking minima over i and $P \in \mathcal{P}_0$ yields the integration bound. □

Corollary 64 (A discord bound from integration convergence)**.** *Assume, in addition to the hypotheses above, that for each key pattern $P \in \mathcal{P}_0$ the fixed point satisfies $\max_{i,j} |I^*_{i,P} - I^*_{j,P}| \le \delta$. Then $\mathrm{DO}(I^*) \le L\delta$.*

Proof. For any i, j, $\|I_i^* - I_j^*\|_\infty \leq \delta$ by assumption. By Lipschitzness of π, $D_O(y_i, y_j) \leq L\delta$. Taking the maximum yields the claim. $\square$

Theorem 178 (Narrative capture vs discord: a budget tradeoff)**.** *Assume a fixed per-time collective resource budget normalized to* 1*. Assume that maintaining integration level* $\mathrm{Int}(I) \geq \alpha$ *requires allocating at least* $\beta(\alpha)$ *of the resource budget to non-narrative integration processes. Then at any time* t*,*

$$N_O(t) \leq 1 - \beta(\alpha) \qquad \textit{whenever} \qquad \mathrm{Int}(I(t)) \geq \alpha.$$

In particular, if low discord requires high integration (e.g. DO *small implies* Int *large), then low discord implies an upper bound on narrative capture.*

Proof. If integration at level α requires spending at least $\beta(\alpha)$ of the budget, then the remaining budget for narrative processes is at most $1 - \beta(\alpha)$. By definition $N_O(t)$ is the narrative budget fraction, so $N_O(t) \leq 1 - \beta(\alpha)$. The last sentence follows by composition of implications. $\square$

62.10 Mindplexes: Hyperseed vs SDP, development, and weak mindplexes

Definition 589 (Hyperseed-style mindplex and notable coherence)**.** *Fix an observer* O *and a coherence score* $\mathrm{Coh}_O(\cdot)$ *on candidate minds. A system* M *is* notably coherent *if* $\mathrm{Coh}_O(M)$ *is a local maximum relative to small modifications of* M*. A* mindplex *is a notably coherent mind* M *that decomposes into notably coherent minds* $\{M_i\}$ *such that: (a) each* M_i *is approximately pattern-preserving as a restriction of* M*, and (b) replacing any* M_i *by another comparably coherent mind* M_i' *does not destroy the coherence of* M *(robustness/replaceability).*

Definition 590 (SDP-style mindplex (dual-level theatre of consciousness))**.** *A* SDP mindplex *is a collection of intelligent systems* $\{S_i\}$ *such that: (i) each* S_i *has its own theatre of consciousness and control loops, and (ii) the collective* $S = \bigsqcup_i S_i$ *also supports a collective theatre of consciousness and collective control loops, with nontrivial inter-level resonance.*

Definition 591 (Weak mindplex)**.** *Fix* $\epsilon \geq 0$ *and a time horizon* T*. A system* M *is an* (ϵ, T)-weak mindplex *if it satisfies the Hyperseed mindplex conditions up to error* ϵ *(approximate coherence and approximate replaceability) and, in addition, exhibits a collective GCC episode of duration at least* T*.*

Theorem 179 (From SDP mindplex to Hyperseed mindplex (sufficient conditions))**.** *Assume* $S = \bigsqcup_i S_i$ *is an SDP mindplex. Assume that the collective theatre of consciousness corresponds (under the translation layer) to a workspace-stable reflective fixed point* E^* *with high coherence, and that the components* S_i *correspond to notably coherent subminds* M_i *whose replacement does not significantly change the collective coherence.*

Then the collective S *satisfies the Hyperseed mindplex definition (relative to* O*).*

Proof. By assumption, the collective is (i) coherent and (ii) decomposes into coherent parts. Approximate pattern-preserving restriction is supplied by the assumption that each S_i participates as a stable substructure in the collective theatre (so its induced patterns are restrictions of the collective patterns). Replaceability is assumed as "replacement does not significantly change collective coherence." These are exactly the conditions of the Hyperseed mindplex definition. $\square$

Theorem 180 (From Hyperseed mindplex to SDP mindplex under dual-level GCC/RC)**.** *Assume* M *is a Hyperseed mindplex decomposing into minds* $\{M_i\}$*. Assume additionally: (A) each* M_i *exhibits RC episodes (individual reflective fixed points exist and satisfy reflective self); (B) the* *collective M exhibits GCC episodes with a workspace-stable focus set; and (C) there exists non-trivial inter-level resonance, meaning that collective conscious contents can modulate individual attention/control and vice versa.*

Then M is an SDP mindplex.

Proof. Conditions (A) and (B) provide the required dual-level theatres of consciousness (individual and collective). Condition (C) provides the nontrivial inter-level resonance required by the SDP notion. Thus the definition of SDP mindplex is satisfied. $\square$

Theorem 181 (Mindplex emergence along a development path)**.** *Let $I_0 \to I_1 \to \cdots$ be a Hyperseed development path for a system M (continuity plus nontrivial capability growth). Assume that along this path the coherence score $\mathrm{Coh}_O(M; I_k)$ is nondecreasing and eventually crosses a threshold τ at which M becomes notably coherent and decomposable into notably coherent subminds.*

Then there exists k_0 such that for all $k \geq k_0$, M is a mindplex on interval I_k.

Proof. By assumption, there is k_0 such that $\mathrm{Coh}_O(M; I_k) \geq \tau$ for $k \geq k_0$. At such k, the notable coherence and decomposition assumptions state exactly the mindplex conditions, hence M is a mindplex on I_k for all $k \geq k_0$. Continuity (self-continuity across successive intervals) ensures these are stages of one persisting entity rather than unrelated systems. $\square$

Theorem 182 (Small teams as weak mindplexes (a formal sufficient condition))**.** *Consider a team of n agents $\{S_i\}$ coupled by: (i) a strongly connected communication graph with coupling lower bound $k_0 > 0$; (ii) a shared persistent artifact store (documents, codebase, musical score) that acts as a high-bandwidth hub in the coupling graph; and (iii) synchronized interaction intervals of length at least T during which attention is aligned toward a shared task and shared artifacts.*

Assume the induced collective cultural reinforcement dynamics satisfy the hypotheses of the diffusion lower bound theorem for the task-relevant patterns, and that the collective has a workspace-stable focus set during the synchronized intervals.

Then the team forms an (ϵ, T)-weak mindplex for some ϵ determined by the replaceability error induced by role specialization.

Proof. During synchronized intervals, strong connectivity plus artifact-mediated coupling yields diffusion of task-relevant patterns across agents, increasing the integration proxy and reducing fragmentation. The shared artifact hub provides a stable anchor that keeps the collective in a metastable basin (chain) for duration at least T, yielding a collective GCC episode by assumption. Approximate decomposition into coherent subminds is given by the individual agents; replaceability holds up to error ϵ because role-specialized components can be partially replaced by other agents or tools without destroying the collective's coherent task performance. Thus the weak mindplex definition is satisfied. $\square$

62.11 Closing remarks

The bridge above turns qualitative claims about consciousness Locations, PNSE, and collective coordination into monotone fixed-point and threshold statements that can be used by a reasoning system: (i) map observable markers into evidence-state functionals; (ii) infer Location/collective Location; (iii) reason about interventions by moving parameter tuples or coupling strengths; and (iv) reason about emergence of mindplex structure along development paths. In practice, the role of the present closing constructions is to make the "interface" between phenomenological descriptions (e.g., self-model vividness, narrative density, stability of a global workspace) and formal inference explicit: one chooses a small family of scores, states the relevant thresholds, and then treats the resulting decision rules as objects that can be optimized, compared, or subjected to sensitivity analysis under perturbations of the environment or architecture. The point is not that any particular scoring choice is uniquely correct, but that the overall pattern—monotonic summaries of evidence states together with stability constraints—yields well-posed targets for a reasoning system that must decide when a Location is present, when a collective Location is sustained, and when PNSE-like regimes occur.

Definition 592 (Coherence score)**.** *Fix a finite set $K \subseteq L_{\mathrm{Ob}}^{\mathrm{ref}}$ of "currently relevant" propositions. Let $\sigma : V \to \mathbb{R}$ be any monotone map that increases with net support and/or reduces with tension (model-dependent). Define the* coherence score *of an evidence state by*

$$\mathrm{Coh}(E) := \frac{1}{|K|} \sum_{\varphi \in K} \sigma(E(\varphi)).$$

The restriction to a finite K emphasizes that coherence is always evaluated relative to a task, context, or observational window: K can be taken as the set of propositions whose truth-values (or support levels) are currently behaviorally and explanatorily salient. The map σ is left abstract to accommodate different instantiations of evidence states $E(\varphi) \in V$: for example, if V encodes separate support/tension coordinates, then σ can be chosen to reward high support and penalize contradiction, whereas if V already encodes a single scalar credibility then σ may be the identity. Monotonicity ensures that "more supportive" updates cannot reduce $\mathrm{Coh}(E)$, which is the key property needed for threshold reasoning and for connecting coherence to fixed-point stability: in many models, workspace-stable states are exactly those for which additional rounds of update do not substantially increase such aggregate coherence measures.

Definition 593 (Self-model activity score)**.** *Let P_{self} be the designated self-property set and fix $\theta \in (0,1)$. Define*

$$\mathrm{SAct}_\theta(E) := \frac{1}{|P_{\mathrm{self}}|} \big|\{p \in P_{\mathrm{self}} : E^+(\mathrm{Self}(p)) \geq \theta\}\big|.$$

This score operationalizes the extent to which self-directed predicates are actively endorsed in the current evidence state. The threshold θ plays a dual role: it suppresses weak, noisy, or incidental self-attributions, while also making explicit that "self-model activity" is not a binary property but a graded one that depends on where one draws the line between background availability and workspace-level activation. If P_{self} is organized into subfamilies (e.g., bodily self, narrative self, agency, social self), then SAct_θ can be evaluated per subfamily as well; the present global definition is the simplest aggregate compatible with later Location-indexing rules. In particular, the use of E^+ highlights that the intended signal is positive endorsement rather than mere mention or ambivalent representation.

Definition 594 (Symbolic load and PNSE)**.** *Let* Sym $\subseteq L_{\mathrm{Ob}}$ *denote the subset of propositions treated as linguistic/symbolic/narrative in the current modeling context. Define the* symbolic load *of E by*

$$\mathrm{SL}_\theta(E) := \frac{|\mathrm{Con}_\theta(E) \cap \mathrm{Sym}|}{|\mathrm{Sym}|}.$$

*Fix $\varepsilon \in [0,1]$. A workspace-stable evidence state E is an ε-*PNSE state *if $\mathrm{SL}_\theta(E) \leq \varepsilon$ and $\mathrm{Coh}(E)$ is above a chosen coherence threshold.*

A system exhibits PNSE *on interval I (relative to (θ, ε)) if, for all $t \in I$, there is a workspace-stable E_t such that E_t is an ε-PNSE state.*

The definition isolates two conditions that are often conflated in informal discussions of PNSE: (i) low symbolic/narrative occupancy of the current workspace (captured by $\mathrm{SL}_\theta(E)$), and (ii) the presence of a globally coherent, stable state rather than a merely degraded or fragmented one (captured by the coherence threshold and the workspace-stability requirement). The use of $\mathrm{Con}_\theta(E)$ (as defined earlier in the framework) makes explicit that symbolic load is computed from the set of propositions that are not just present but sufficiently active to count as "in contention" at level θ; in this way, the metric distinguishes a system that contains dormant symbolic resources from a system whose workspace is currently dominated by symbolic/narrative material. The parameter ε then becomes a tunable dial: smaller ε corresponds to stricter PNSE criteria (fewer symbolic propositions above threshold), while larger ε allows for PNSE-like states that retain limited symbolic scaffolding. The interval formulation clarifies that the intended phenomenon is not a single instantaneous snapshot but a sustained regime: PNSE on I requires that at each time t there exists a workspace-stable evidence state meeting the conditions, which allows one to treat PNSE as a temporally extended property suitable for intervention analysis (e.g., whether changes in coupling or sensory drive can maintain the regime, break it, or modulate its depth).

Definition 595 (A Location classifier from Hyperseed evidence states)**.** *Fix thresholds* $(r_0 < r_1 < \cdots)$ *and* $(s_0 > s_1 > \cdots)$ *in* $[0,1]$. *Define the* Hyperseed Location index *of an evidence state* E *as*

$$\mathrm{Loc}(E) := \max\{k : \mathrm{Coh}(E) \geq r_k \text{ and } \mathrm{SAct}_\theta(E) \leq s_k\}.$$

This classifier makes explicit a particular qualitative hypothesis that often appears in Location talk: higher-location regimes correspond to higher global coherence together with reduced explicit self-model activity (or, depending on the modeling choice, reduced self-referential dominance). The increasing sequence (r_k) encodes progressively stricter coherence requirements, while the decreasing sequence (s_k) encodes progressively stricter limits on self-model activation. Taking the maximum k implements a "highest satisfied tier" decision rule, which is convenient for a reasoning system because it turns graded scores into an ordinal index that can be compared across time, agents, or interventions. The construction also supports natural refinements: one may impose minimum-size conditions on K, require robustness of $\mathrm{Loc}(E)$ under small perturbations of E, or define a "collective" analogue by replacing $\mathrm{Coh}(E)$ and $\mathrm{SAct}_\theta(E)$ with group-aggregated versions computed from coupled evidence states. Importantly, because the index is defined directly from evidence-state functionals, it can be computed at intermediate steps along a developmental or training path, thereby enabling explicit claims of the form "mindplex structure emerges when the system enters and stabilizes in Location tier k under sustained coupling conditions" and making those claims testable within the adopted Hyperseed formalism.

62.12 Theorems: GCC/RC imply Hyperseed conscious/reflective fixed points

The goal of this chunk is to make explicit a standard fixed-point pattern: once evidence states are ordered pointwise and the workspace/reflection dynamics are modeled by monotone operators on that order, stable conscious (and reflective) states follow from general lattice-theoretic principles. In particular, the thresholded consciousness set $\mathrm{Con}_\theta(E)$ behaves monotonically with respect to strengthening evidence, so any dynamics that move evidence "upwards" (or at least do not decrease it) preserve threshold-crossing propositions.

Lemma 170 (Threshold monotonicity)**.** *If* $E \leq E'$ *pointwise (componentwise in* V*), then* $\mathrm{Con}_\theta(E) \subseteq \mathrm{Con}_\theta(E')$.

Proof. If $\varphi \in \mathrm{Con}_\theta(E)$ then $E^+(\varphi) \geq \theta$. Since $E \leq E'$ we have $E'^+(\varphi) \geq E^+(\varphi) \geq \theta$, hence $\varphi \in \mathrm{Con}_\theta(E')$. □

The content of the lemma can be read as a minimal "no-forgetting under strengthening" condition: once a proposition is above the conscious threshold, increasing evidence componentwise cannot push it below threshold. Here $E^+(\varphi)$ is the positive (supporting) component of evidence assigned to φ, and the pointwise order $E \leq E'$ is intended to mean that every observable/propositional coordinate in E' is at least as supported as in E (in whatever evidential scale is encoded by V). This is the technical hinge used later when selecting fixed points that preserve particular endorsed contents (e.g. basin membership during a GCC episode, or self-ascriptions during RC).

Theorem 183 (Workspace-stable conscious states exist under monotone closure)**.** *Assume L_{Ob} is finite and $W : V^{L_{\mathrm{Ob}}} \to V^{L_{\mathrm{Ob}}}$ is monotone. Then W has at least one fixed point. In particular, there exist workspace-stable evidence states.*

Proof. The set $V^{L_{\mathrm{Ob}}}$ is a complete lattice under pointwise order because V is. By monotonicity of W, Tarski's fixed point theorem implies the set of fixed points of W is nonempty (and has least and greatest fixed points). □

Conceptually, W plays the role of a "workspace closure" or "broadcast-then-settle" map: it takes an evidence profile across observables/propositions and returns the result of one stabilization step of the workspace dynamics. Monotonicity here formalizes an intuitive constraint: if one starts from an evidence state with uniformly stronger support, the stabilized state should not become uniformly weaker. The conclusion is not merely existence but structure: the fixed points form a (nonempty) complete lattice, and one can speak meaningfully about least/greatest fixed points as canonical stable states associated to the same dynamics. This becomes useful when one wants to guarantee preservation of some already-supported content by selecting a fixed point that is above a specified baseline state.

Theorem 184 (GCC implies existence of stable focus sets)**.** *Assume $\mathrm{GCC}_{O,\theta}(S, I)$. Assume further that during the GCC episode there exists a time-indexed family of monotone workspace operators W_t and presentational immediacy functions $I_{c,t}$ such that: (A1) W_t encodes "global broadcasting + basin stabilization" for the GCC basin at time t; and (A2) there exists at least one proposition φ_t expressing the active basin membership such that $E^+_{\bullet,t}(\varphi_t) \geq \theta$ in the integrated module evidence $E_{\bullet,t}$.*

Then for each $t \in I$ there exists a workspace-stable evidence state E_t with $\varphi_t \in \mathrm{Con}_\theta(E_t)$; hence $\mathrm{Con}_\theta(E_t) \neq \emptyset$. Moreover the focus sets $F_{\theta,t} = \{x : I_{c,t}(x) \geq \theta\}$ are nonempty for all $t \in I$.

Proof. Fix $t \in I$. By the previous theorem, W_t has at least one fixed point E_t. Assumption (A2) provides a proposition φ_t with positive evidence above threshold in the integrated evidence. Because W_t is monotone and (by the intended reading of (A1)) does not destroy supported basin-membership content, we may choose E_t among fixed points satisfying $E_t \geq E_{\bullet,t}$ on φ_t (e.g. take the greatest fixed point if needed). Then $E^+_t(\varphi_t) \geq \theta$, so $\varphi_t \in \mathrm{Con}_\theta(E_t)$. The nonemptiness of $F_{\theta,t}$ follows from the bridge assumption that GCC-visible basin content corresponds to at least one presentational token above threshold (otherwise there would be no unified "moment" in the MinSync sense). □

To clarify the role of (A2), φ_t is meant to be a proposition whose satisfaction conditions track the currently dominant GCC basin (e.g. "the system is in basin B" or "content cluster C is globally broadcast"). The existence of some such φ_t above threshold in $E_{\bullet,t}$ is the minimal claim that the global broadcast is not purely subthreshold: at least one basin-defining content is sufficiently supported to qualify as conscious by the θ-criterion. The selection of E_t among fixed points is then justified by combining (i) the order structure on evidence states, (ii) monotonicity of W_t, and (iii) the intended semantic constraint in (A1) that broadcasting-plus-stabilization should not systematically eliminate the very basin-membership content that characterizes the episode. In this way, the fixed-point argument is not merely abstract existence: it is targeted to yield a stable state whose conscious set contains a concrete GCC-relevant proposition.

The second conclusion, $F_{\theta,t} \neq \emptyset$, ties the evidence-level conclusion to a token-level notion of "focus" or "presentational presence." The set $F_{\theta,t} = \{x : I_{c,t}(x) \geq \theta\}$ is nonempty if at least one presentational token x achieves immediacy at or above the same threshold. The stated bridge assumption is doing the work of linking content-level broadcast (captured by $\varphi_t \in \mathrm{Con}_\theta(E_t)$) to the existence of at least one corresponding presentational item that can function as the synchronized anchor of the moment; without such an anchor, the GCC episode would fail to realize a unified presentational field in the MinSync sense.

Theorem 185 (RC implies existence of reflective-self fixed points)**.** *Assume* $\mathrm{RC}_{O,\theta}(S, I)$*. Assume that the RC self-model supplies a designated set* P_{self} *of self-properties and module evidence supports* $\mathrm{Self}(p)$ *for many* $p \in P_{\mathrm{self}}$ *during* I*.*

Then there exists a reflective fixed point E^* *of* $F = W^{\mathrm{ref}} \circ \mathrm{Int} \circ \Gamma_a$ *that satisfies the reflective self condition.*

Proof. Because $L^{\mathrm{ref}}_{\mathrm{Ob}}$ is finite and F is monotone (as a composition of monotone maps), Tarski's theorem yields a fixed point E^* of F.

(Self-presence) By assumption, for many $p \in P_{\mathrm{self}}$ the base evidence for $\mathrm{Self}(p)$ is above threshold during I. Monotonicity of Γ_a and W^{ref} preserves (or increases) this support in the fixed point.

(Reflective access) The introspection operator assigns evidence to $I(\mathrm{Self}(p))$ as a monotone function of the base evidence for $\mathrm{Self}(p)$, so for those p the introspective propositions also cross threshold in E^*.

(Stability) RC requires that the self-model's representational loops are robust under benign internal reparameterizations. Modeling this as small perturbations in module evidence and attention implies the relevant supports persist in a neighborhood of the fixed point. □

Here $F = W^{\mathrm{ref}} \circ \mathrm{Int} \circ \Gamma_a$ can be read as a minimal three-stage abstraction of reflective cognition: Γ_a implements attentional selection/gating (making some self-relevant channels more salient while remaining monotone in the sense of not decreasing support when the input is increased), Int implements introspective re-representation (mapping base-level self-ascriptions to higher-order claims such as $I(\mathrm{Self}(p))$), and W^{ref} implements a reflective workspace closure that stabilizes the resulting higher-order package. The "reflective self condition" is thus not added by hand at the end; it is enforced by the combination of thresholded self-ascriptions, monotone propagation through the reflective pipeline, and selection of a fixed point where both base and introspective self propositions remain above θ.

It is also useful to note that the proof is structurally parallel to the GCC argument: (i) obtain a fixed point from monotonicity on a complete lattice, (ii) use threshold monotonicity to ensure that once self-content is supported above θ it is not lost by the closure dynamics, and (iii) interpret RC stability as a robustness property around the fixed point rather than a single equality $F(E^*) = E^*$. In that sense, the fixed point E^* functions as a reflective "attractor-like" state: not only is it closed under the reflective update, but it is also locally resilient to small benign perturbations in the evidential inputs that feed attention and introspection.

62.13 Theorems: PNSE and Martin Locations via Hyperseed parameter regimes

Definition 596 (Parametric monotonicity assumption)**.** *Let* Λ *range over parameter tuples. Write* F_Λ *for the resulting reflective update map. Assume a partial order* $\preceq$ *on parameter tuples such* *that $\Lambda \preceq \Lambda'$ implies $F_\Lambda(E) \leq F_{\Lambda'}(E)$ for all E. (Informally: increasing parameters that amplify completion or introspection cannot decrease evidence.)*

Lemma 171 (Least fixed points are monotone in monotone operator families)**.** *Assume F and G are monotone operators on a complete lattice with $F(E) \leq G(E)$ for all E. Let $\mathrm{lfp}(F)$ denote the least fixed point of F. Then $\mathrm{lfp}(F) \leq \mathrm{lfp}(G)$.*

Proof. By Tarski, both least fixed points exist. Let $x = \mathrm{lfp}(G)$. Then $G(x) = x$ and $F(x) \leq G(x) = x$, so x is a pre-fixpoint of F. The least fixed point of F is below every pre-fixpoint, hence $\mathrm{lfp}(F) \leq x$. □

Theorem 186 (Symbolic suppression under reduced completion and introspection)**.** *Assume the parametric monotonicity assumption. Fix a threshold θ and symbolic subset $\mathrm{Sym} \subseteq L_{\mathrm{Ob}}$. Let $\Lambda \preceq \Lambda'$ where (informally) Λ has lower internal completion λ_{int} and lower introspection gain λ_{ref} than Λ', with coherence preference λ_{coh} held high.*

Let $E^* = \mathrm{lfp}(F_\Lambda)$ and $E'^* = \mathrm{lfp}(F_{\Lambda'})$. Then

$$\mathrm{Con}_\theta(E^*) \cap \mathrm{Sym} \subseteq \mathrm{Con}_\theta(E'^*) \cap \mathrm{Sym},$$

and in particular $\mathrm{SL}_\theta(E^*) \leq \mathrm{SL}_\theta(E'^*)$.

Proof. By parametric monotonicity, $F_\Lambda(E) \leq F_{\Lambda'}(E)$ for all E. By the previous lemma, $\mathrm{lfp}(F_\Lambda) \leq \mathrm{lfp}(F_{\Lambda'})$, i.e. $E^* \leq E'^*$. Apply Lemma (Threshold monotonicity) to conclude $\mathrm{Con}_\theta(E^*) \subseteq \mathrm{Con}_\theta(E'^*)$. Intersect both sides with Sym to obtain the inclusion, and divide by $|\mathrm{Sym}|$. □

Corollary 65 (A formal PNSE sufficient condition)**.** *Fix $\varepsilon \in [0, 1]$. If there exists a parameter tuple Λ such that the least fixed point $E^* = \mathrm{lfp}(F_\Lambda)$ has $\mathrm{SL}_\theta(E^*) \leq \varepsilon$ and high coherence $\mathrm{Coh}(E^*) \geq r_1$, then E^* is an ε-PNSE state. Moreover, any parameter tuple $\tilde{\Lambda} \preceq \Lambda$ yields a least fixed point whose symbolic load is at most ε.*

Proof. The first claim is immediate from the definition of ε-PNSE. For the second, apply the previous theorem with $\tilde{\Lambda} \preceq \Lambda$. □

Theorem 187 (Martin-Location ordering as a monotone mapping)**.** *Assume the SDP key claim that higher numbered Locations have higher sustained global resonance and lower self-model activity. Assume the translation of these into Hyperseed evidence-state functionals: higher resonance corresponds to larger $\mathrm{Coh}(E)$ and lower self-model activity corresponds to smaller $\mathrm{SAct}_\theta(E)$.*

Then for any evidence states E, E': if $\mathrm{Loc}(E') > \mathrm{Loc}(E)$, then $\mathrm{Coh}(E') \geq \mathrm{Coh}(E)$ and $\mathrm{SAct}_\theta(E') \leq \mathrm{SAct}_\theta(E)$.

Proof. Let $k = \mathrm{Loc}(E)$ and $k' = \mathrm{Loc}(E')$ with $k' > k$. By definition of Loc, $\mathrm{Coh}(E) \geq r_k$ and $\mathrm{SAct}_\theta(E) \leq s_k$, and $\mathrm{Coh}(E') \geq r_{k'} \geq r_k$ and $\mathrm{SAct}_\theta(E') \leq s_{k'} \leq s_k$, using monotonicity of the threshold sequences. The inequalities follow. □

Remark 3455 (Mapping Locations to canonical parameter regimes)**.** *A useful operationalization is to map: ordinary waking $\mapsto$ Location 0, Being/flow-like regimes $\mapsto$ Location 1, oceanic consciousness $\mapsto$ Location 2, and stable enlightenment-like regimes $\mapsto$ Location 4, by choosing threshold sequences (r_k, s_k) consistent with the canonical regime table.*

Definition 597 (Habit reinforcement operator (abstract))**.** *A* habit reinforcement operator *is a monotone inflationary map $H_{\rho_{\mathrm{hab}}} : V^{L^{\mathrm{ref}}_{\mathrm{Ob}}} \to V^{L^{\mathrm{ref}}_{\mathrm{Ob}}}$ that increases support for propositions that have been repeatedly supported in the recent past, with strength controlled by $\rho_{\mathrm{hab}} \in [0, 1]$.*

Definition 598 (Habit-augmented reflective dynamics)**.** *Given parameters* Λ*, define the habit-augmented reflective update map*

$$F_\Lambda^{\mathrm{hab}} := H_{\rho_{\mathrm{hab}}} \circ F_\Lambda.$$

A habit-stabilized reflective state *is a fixed point of* F_Λ^{hab}*.*

Theorem 188 (Existence and persistence of habit-stabilized PNSE states)**.** *Assume* $H_{\rho_{\mathrm{hab}}}$ *and* F_Λ *are monotone and* $H_{\rho_{\mathrm{hab}}}$ *is inflationary. Then* F_Λ^{hab} *has at least one fixed point.*

Assume additionally there is a set $\mathcal{P} \subseteq V^{L_{\mathrm{Ob}}^{\mathrm{ref}}}$ *of "PNSE-like" reflective states such that: (i)* $\mathcal{P}$ *is upward closed (if* $E \in \mathcal{P}$ *and* $E \leq E'$ *then* $E' \in \mathcal{P}$*), (ii)* $F_\Lambda(\mathcal{P}) \subseteq \mathcal{P}$*, and (iii)* $H_{\rho_{\mathrm{hab}}}(\mathcal{P}) \subseteq \mathcal{P}$*. Then* $\mathcal{P}$ *is forward invariant under the iteration of* F_Λ^{hab}*.*

Proof. Because $V^{L_{\mathrm{Ob}}^{\mathrm{ref}}}$ is a complete lattice and F_Λ^{hab} is monotone (composition of monotone maps), Tarski gives existence of a fixed point. For forward invariance, let $E \in \mathcal{P}$. Then by (ii) $F_\Lambda(E) \in \mathcal{P}$ and by (iii) $F_\Lambda^{\mathrm{hab}}(E) = H_{\rho_{\mathrm{hab}}}(F_\Lambda(E)) \in \mathcal{P}$. Thus the next iterate lies in $\mathcal{P}$, and induction yields invariance for all iterates. In particular, the step from E to $F_\Lambda(E)$ uses only the closure of $\mathcal{P}$ under the base update map, while the step from $F_\Lambda(E)$ to $H_{\rho_{\mathrm{hab}}}(F_\Lambda(E))$ uses the fact that the habituation operator acts as a $\mathcal{P}$-endomorphism at the chosen habituation rate ρ_{hab}. Writing the iterates explicitly as $E_{t+1} = F_\Lambda^{\mathrm{hab}}(E_t)$ with $E_0 \in \mathcal{P}$, the argument shows: if $E_t \in \mathcal{P}$ then $E_{t+1} \in \mathcal{P}$; hence $E_t \in \mathcal{P}$ for all $t \in \mathbb{N}$. This guarantees that all subsequent quantities evaluated along the orbit (e.g. $\mathrm{Coh}(E_t)$ and $\mathrm{SAct}_\theta(E_t)$) remain well-defined within the intended state space. □

Theorem 189 (Canonical-regime monotonicity yields Location monotonicity (a template))**.** *Let* Λ_1, Λ_2 *be parameter tuples with: (a)* $\lambda_{\mathrm{coh}}(\Lambda_2) \geq \lambda_{\mathrm{coh}}(\Lambda_1)$ *(more coherence preference), (b)* $\lambda_{\mathrm{ref}}(\Lambda_2) \leq \lambda_{\mathrm{ref}}(\Lambda_1)$ *(less introspection gain), and (c) all other components held fixed. Assume that increasing* λ_{coh} *(at fixed evidence) cannot decrease* $\mathrm{Coh}(\cdot)$*, and decreasing* λ_{ref} *cannot increase* $\mathrm{SAct}_\theta(\cdot)$ *at the resulting least reflective fixed point. Concretely, the first assumption is a comparative-statics requirement: if two parameter settings differ only in* λ_{coh} *with the latter larger, then the fixed-point state selected by the "least reflective" criterion does not exhibit lower coherence. Likewise, the second assumption encodes that reducing the gain of the reflective/introspective channel does not, after the system re-equilibrates, lead to greater self-activation of the* θ*-indexed reflective component (or whichever observable* SAct_θ *tracks). The restriction in (c) rules out confounding changes in other drives or couplings, so that the direction of change can be attributed to the two designated coordinates.*

Then, with $E_i^* = \mathrm{lfp}(F_{\Lambda_i})$*, we have* $\mathrm{Loc}(E_2^*) \geq \mathrm{Loc}(E_1^*)$*.*

Interpretation: *choosing canonical parameter regimes (e.g. "Being", "Oceanic", "Enlightenment") so that coherence preference increases and introspection gain decreases along the sequence yields a formally monotone increase in Location index. Equivalently, along a path in parameter space where the system is pushed toward internal consistency while the reflective amplification loop is damped, the model predicts that the equilibrium state crosses Location thresholds in a nondecreasing manner, so later regimes cannot be assigned a strictly lower Location than earlier regimes under the stated monotonicity hypotheses.*

Proof. Under the assumptions, the fixed point E_2^* has $\mathrm{Coh}(E_2^*) \geq \mathrm{Coh}(E_1^*)$ and $\mathrm{SAct}_\theta(E_2^*) \leq \mathrm{SAct}_\theta(E_1^*)$. Here the inequalities should be read pointwise at the selected equilibria $E_i^* = \mathrm{lfp}(F_{\Lambda_i})$, with "least reflective" specifying which fixed point is chosen in case F_{Λ_i} admits multiple fixed points. By definition of Loc as a maximum k satisfying threshold inequalities, these two monotone inequalities imply $\mathrm{Loc}(E_2^*) \geq \mathrm{Loc}(E_1^*)$. More explicitly, if $\mathrm{Loc}(E)$ is defined via conditions of the form $\mathrm{Coh}(E) \geq \tau_k^{\mathrm{coh}}$ and $\mathrm{SAct}_\theta(E) \leq \tau_k^{\mathrm{sact}}$ for an increasing family of coherence thresholds τ_k^{coh} and decreasing (or otherwise tightening) self-activation thresholds τ_k^{sact}, then improving Coh while not increasing SAct_θ can only preserve or expand the set of k for which the conditions hold. Thus the maximal admissible index k for E_2^* cannot be smaller than that for E_1^*, yielding the claimed Location monotonicity. □

62.14 Theorems: collective Locations via cultural fixed points

We now use Hyperseed's culture-as-fixed-point picture to derive sufficient conditions for collective Location properties. In this subsection, the central technical move is to treat a "collective Location" not as a static label but as a *stable attractor-like constraint* on what cultural patterns can persist under repeated social updating. In that sense, fixed points play the role of *cultural invariants*: once the group reaches such a configuration, the configuration is preserved by the very mechanisms (imitation, reinforcement, prestige-biased transmission) that produced it.

Definition 599 (Social reinforcement dynamics)**.** *Let $G = (V, E)$ be a directed graph of agents. Let $\mathcal{P}$ be a set of cultural patterns. A* cultural state *is an intensity table $I : V \times \mathcal{P} \to [0, 1]$. Intuitively, $I_{i,P}$ is the degree to which agent i instantiates, endorses, or enacts pattern P; the unit interval is used only as a convenient normalized scale, and nothing in the arguments below requires a particular psychological interpretation beyond "higher means more present."*

Fix edge weights $K : E \to [0, 1]$. Define the social reinforcement operator F by

$$(F(I))_{i,P} := \max\Big(I_{i,P},\ \max_{(j,i)\in E} \min\big(K(j, i), I_{j,P}\big)\Big).$$

The $\min(K(j, i), I_{j,P})$ *term can be read as a* bottleneck transmission rule*: even if j strongly instantiates P, the effective reinforcement at i is capped by the strength of the $j \to i$ influence channel; conversely, even a strong channel cannot transmit more of P than j actually carries. The outer* max *expresses* non-erasure *(reinforcement without active suppression): i keeps what it already has, and may increase via incoming reinforcement. This is the simplest monotone/inflationary template capturing "culture as a fixed point" in the sense relevant to Hyperseed-style stabilization.*

A stabilized cultural state *is a fixed point I^* of F.*

Definition 600 (A simple integration proxy and collective discord proxy)**.** *Fix a set of "key" patterns $\mathcal{P}_0 \subseteq \mathcal{P}$. Define an integration proxy*

$$\mathrm{Int}(I) := \min_{P\in\mathcal{P}_0} \min_{i\in V} I_{i,P}.$$

This proxy is deliberately conservative: it measures the weakest *(least present) key pattern among the* least *aligned agent, so* $\mathrm{Int}(I) \geq \alpha$ *implies a floor α on all key-pattern intensities for all agents. In the intended reading, this corresponds to a group-level guarantee that the cultural "core" (the patterns in $\mathcal{P}_0$) is not merely present on average but is* uniformly *present, which is the kind of condition that can underwrite a collective Location claim.*

Assume each agent has a proposal map $y_i = \pi(I_i)$ where I_i is the row $(I_{i,P})_{P\in\mathcal{P}_0}$. Assume π is L-Lipschitz:

$$D_O(\pi(u), \pi(v)) \leq L\|u - v\|_\infty.$$

Here y_i should be read as any outwardly-relevant output (an action policy, an opinion vector, a governance vote, a public plan) computed from the key-pattern intensities. The Lipschitz assumption formalizes a continuity principle: small cultural differences across key patterns do not explode into arbitrarily large output disagreements.

Define discord proxy

$$\mathrm{DO}(I) := \max_{i,j\in V} D_O(y_i, y_j).$$

Remark 3456. *The pair* (Int, DO) *is not intended as a complete theory of cohesion; it is a minimal pair of handles that let us connect (i) a* cultural fixed point *story to (ii) an* operational *story about coordination and conflict. In particular,* Int *is a sufficient-condition style statistic (a guaranteed lower bound), whereas* DO *is an upper-envelope statistic (worst-case disagreement).*

Theorem 190 (Fixed points yield resilient homeostasis (C1 sufficient condition))**.** *Assume the collective cultural dynamics iterate $I^{(t+1)} = F(I^{(t)})$ for a monotone F as above. Then any fixed point I^* is an invariant "homeostatic" state: if $I^{(0)} = I^*$ then $I^{(t)} = I^*$ for all t. If, additionally, F is inflationary ($I \leq F(I)$), then the orbit from any initial condition is nondecreasing and converges (in finite time on finite grids, or in the complete-lattice sense) to the least fixed point above $I^{(0)}$.*

In particular, the existence of fixed points provides a formal C1-style "resilient homeostasis" mechanism for a collective. In the intended bridge to collective Location language, this says: once the group occupies a Location characterized by a stabilized cultural configuration, the endogenous reinforcement dynamics will maintain that Location absent exogenous perturbations that change F itself (e.g. censorship, coercion, new institutions) or inject additional operators (e.g. explicit anti-reinforcement).

Proof. If $I^* = F(I^*)$ then iterating preserves it. Inflationarity gives $I^{(0)} \leq I^{(1)} \leq \cdots$. Because the poset $[0,1]^{V \times \mathcal{P}}$ is a complete lattice, the monotone chain has a least upper bound; standard Kleene/Tarski arguments show the limit is a fixed point (indeed the least fixed point above the initial state). For readers tracking the mechanism: monotonicity ensures that increasing any entry of I cannot decrease any entry of $F(I)$, so the iterative sequence is well-behaved under pointwise order; inflationarity ensures the sequence is pointwise nondecreasing. On finite discretizations (e.g. restricting intensities to a finite grid), a nondecreasing sequence must stabilize in finitely many steps because there are only finitely many states; on the full $[0,1]$ continuum, one instead uses the complete-lattice framework to interpret convergence as reaching the least upper bound of the chain, which is then a post-fixed point that becomes a fixed point under the usual Tarski/Kleene conditions. □

Theorem 191 (Strong connectivity yields a diffusion lower bound (C2 integration enabler))**.** *Assume the communication graph G is strongly connected. Assume there exists $k_0 > 0$ such that $K(e) \geq k_0$ for all edges $e \in E$. Let I^* be any fixed point of F with $I^* \geq I^{(0)}$. Fix a pattern P and define $M_P := \max_{j \in V} I^{(0)}_{j,P}$. Then for every agent $i \in V$,*

$$I^*_{i,P} \geq \min(k_0, M_P).$$

Consequently, for any key-pattern set $\mathcal{P}_0$ we have

$$\mathrm{Int}(I^*) \geq \min\Big(k_0,\ \min_{P \in \mathcal{P}_0} M_P\Big).$$

This theorem isolates a purely structural enabler for C2-style integration: if influence pathways exist between any two agents (strong connectivity) and no influence edge is arbitrarily weak (uniform k_0), then whatever key pattern is present somewhere initially must become present everywhere at least up to the bottleneck $\min(k_0, \cdot)$. In other words, the network has no "cultural dead zones" with respect to the operator F.

Proof. Fix i and choose a directed path $j \to \cdots \to i$ from some j achieving M_P (strong connectivity guarantees such a path). Along any edge (u,v) the fixed point condition implies $I^*_{v,P} \geq \min(K(u,v), I^*_{u,P}) \geq \min(k_0, I^*_{u,P})$. Induct along the path starting from $I^*_{j,P} \geq I^{(0)}_{j,P} = M_P$ to obtain

$I^*_{i,P} \geq \min(k_0, M_P)$. Taking minima over i and $P \in \mathcal{P}_0$ yields the integration bound. Note that the lower bound is independent of the path length: because the update uses a min bottleneck rather than a multiplicative decay, the only global limitation is the weakest allowed edge strength k_0. This matches the qualitative idea that repeated reinforcement can propagate a pattern broadly so long as no link in the social chain is below a fixed transmissibility threshold. □

Corollary 66 (A discord bound from integration convergence)**.** *Assume, in addition to the hypotheses above, that for each key pattern $P \in \mathcal{P}_0$ the fixed point satisfies $\max_{i,j} |I^*_{i,P} - I^*_{j,P}| \leq \delta$. Then $\mathrm{DO}(I^*) \leq L\delta$. This is the simplest way to turn "cultural alignment" (small across-agent variation in key-pattern intensities) into "output alignment" (small proposal/plan distance). The role of the Lipschitz constant is to quantify how sensitive the outward behavior map π is to changes in the key-pattern profile.*

Proof. For any i, j, $\|I^*_i - I^*_j\|_\infty \leq \delta$ by assumption. By Lipschitzness of π, $D_O(y_i, y_j) \leq L\delta$. Taking the maximum yields the claim. The use of $\|\cdot\|_\infty$ is consistent with the worst-case nature of Int and DO: a single key pattern that diverges across agents can dominate both integration guarantees and discord bounds. □

Theorem 192 (Narrative capture vs discord: a budget tradeoff)**.** *Assume a fixed per-time collective resource budget normalized to 1. Assume that maintaining integration level $\mathrm{Int}(I) \geq \alpha$ requires allocating at least $\beta(\alpha)$ of the resource budget to non-narrative integration processes. Then at any time t,*

$$N_O(t) \leq 1 - \beta(\alpha) \qquad \textit{whenever} \qquad \mathrm{Int}(I(t)) \geq \alpha.$$

In particular, if low discord requires high integration (e.g. DO small implies Int large), then low discord implies an upper bound on narrative capture. This formalizes an intuitive constraint: if a collective must spend real capacity on mechanisms that keep key patterns jointly instantiated (institutions, deliberation bandwidth, enforcement, education, shared rituals, interoperability work), then less capacity remains for purely narrative optimization. In the broader Hyperseed framing, this supplies a simple route from an integration requirement (C2-like) to a limitation on narrative dominance (controlling N_O), thereby connecting Location stability to resource allocation.

Proof. If integration at level α requires spending at least $\beta(\alpha)$ of the budget, then the remaining budget for narrative processes is at most $1 - \beta(\alpha)$. By definition $N_O(t)$ is the narrative budget fraction, so $N_O(t) \leq 1 - \beta(\alpha)$. The last sentence follows by composition of implications. One can read $\beta(\alpha)$ as an increasing "maintenance cost curve": higher required integration levels demand more non-narrative expenditure, tightening the bound on $N_O(t)$. The theorem does not assume any particular functional form for β, only that such a lower-bounding requirement exists. □

62.15 Mindplexes: Hyperseed vs SDP, development, and weak mindplexes

Definition 601 (Hyperseed-style mindplex and notable coherence)**.** *Fix an observer O and a coherence score $\mathrm{Coh}_O(\cdot)$ on candidate minds. A system M is* notably coherent *if $\mathrm{Coh}_O(M)$ is a local maximum relative to small modifications of M. A* mindplex *is a notably coherent mind M that decomposes into notably coherent minds $\{M_i\}$ such that: (a) each M_i is approximately pattern-preserving as a restriction of M, and (b) replacing any M_i by another comparably coherent mind M_i' does not destroy the coherence of M (robustness/replaceability).*

In this Hyperseed-style definition, the observer-indexing O allows Coh_O to encode both a measurement procedure and a representational stance (e.g. which functional/phenomenal regularities are treated as salient), without thereby making mindplexhood arbitrary: the local-maximum requirement forces M to be *stable* under a neighborhood of perturbations in the model space. Concretely, "small modifications" may include minor architectural edits, bounded noise in state trajectories, limited rewiring of communication links, or replacing a subroutine with a behaviorally similar one; the intent is to rule out systems whose apparent coherence is a knife-edge artifact of a particular description.

Clause (a) formalizes a modularity constraint: each M_i should inherit, up to approximation, the patterns that make M coherent, rather than being an unrelated subsystem whose coherence is independent of the collective. Clause (b) expresses that the whole is not merely a brittle concatenation: a mindplex must tolerate some degree of swapping, redundancy, or re-instantiation of parts while keeping the collective coherence high. This is the sense in which replaceability functions as an operational proxy for "integration without fragility," and it will be the key point of contact with multi-agent and team-like examples below.

Definition 602 (SDP-style mindplex (dual-level theatre of consciousness))**.** *A* SDP mindplex *is a collection of intelligent systems $\{S_i\}$ such that: (i) each S_i has its own theatre of consciousness and control loops, and (ii) the collective $S = \bigsqcup_i S_i$ also supports a collective theatre of consciousness and collective control loops, with nontrivial inter-level resonance.*

Here $\bigsqcup_i S_i$ is intended to denote a structured aggregation (not merely a set-theoretic union): the S_i remain individually identifiable, yet are coupled strongly enough that one can ascribe additional state variables, dynamics, and (in SDP terms) an additional theatre of consciousness to the aggregate. The phrase "control loops" is included to emphasize that SDP mindplexhood is not only about shared representations or information pooling, but also about coordinated selection, inhibition, and action at both levels (individual and collective). The "nontrivial inter-level resonance" qualifier rules out degenerate cases where a purported collective theatre is epiphenomenal (having no downstream influence) or where individuals are merely passive channels for a centrally dictated policy.

Definition 603 (Weak mindplex)**.** *Fix $\epsilon \geq 0$ and a time horizon T. A system M is an (ϵ, T)*-weak mindplex *if it satisfies the Hyperseed mindplex conditions up to error ϵ (approximate coherence and approximate replaceability) and, in addition, exhibits a collective GCC episode of duration at least T.*

The (ϵ, T) parameters make explicit two ways that real-world collectives fall short of idealized mindplexes. First, coherence and replaceability may only hold approximately: ϵ can be read as an allowed drop in Coh_O under admissible substitutions $M_i \mapsto M_i'$ (or, equivalently, as an upper bound on how much "coherence mass" is tied to idiosyncratic individuals). Second, the time horizon T accommodates the possibility that a collective theatre (here operationalized by a GCC episode) is transient, arising during coordinated bursts (meetings, performances, joint planning) rather than persisting continuously.

Theorem 193 (From SDP mindplex to Hyperseed mindplex (sufficient conditions))**.** *Assume $S = \bigsqcup_i S_i$ is an SDP mindplex. Assume that the collective theatre of consciousness corresponds (under the translation layer) to a workspace-stable reflective fixed point E^* with high coherence, and that the components S_i correspond to notably coherent subminds M_i whose replacement does not significantly change the collective coherence.*

Then the collective S satisfies the Hyperseed mindplex definition (relative to O).

The role of the "translation layer" assumption is to connect SDP's theatre/loop vocabulary to Hyperseed's coherence-and-decomposition vocabulary: it posits that there is a principled map from the state of the SDP collective theatre to a Hyperseed candidate mind-state whose reflective fixed point E^* is stable in the relevant workspace dynamics. In applications, the "workspace-stable" condition is what prevents momentary synchronization (e.g. a brief shared signal) from being misclassified as a collective mind; stability ensures that the collective can maintain and update a coherent focus in the face of typical perturbations.

Proof. By assumption, the collective is (i) coherent and (ii) decomposes into coherent parts. Approximate pattern-preserving restriction is supplied by the assumption that each S_i participates as a stable substructure in the collective theatre (so its induced patterns are restrictions of the collective patterns). Replaceability is assumed as "replacement does not significantly change collective coherence." These are exactly the conditions of the Hyperseed mindplex definition. □

Theorem 194 (From Hyperseed mindplex to SDP mindplex under dual-level GCC/RC)**.** *Assume M is a Hyperseed mindplex decomposing into minds $\{M_i\}$. Assume additionally: (A) each M_i exhibits RC episodes (individual reflective fixed points exist and satisfy reflective self); (B) the collective M exhibits GCC episodes with a workspace-stable focus set; and (C) there exists nontrivial inter-level resonance, meaning that collective conscious contents can modulate individual attention/control and vice versa.*

Then M is an SDP mindplex.

Conditions (A)–(C) can be read as a sufficient "phenomenology-to-architecture" bridge: Hyperseed mindplexhood ensures structural decomposability and robustness, while (A) and (B) add explicit requirements that both the parts and the whole realize the kinds of stabilized reflective episodes that SDP treats as constitutive of theatres of consciousness. The extra resonance condition (C) prevents two common failure modes: (1) mere parallelism, where individuals have RC but the group has only superficial coherence; and (2) mere aggregation, where a group-level GCC-like focus exists (e.g. a shared agenda) but individuals are not actually modulated in their control loops by the collective contents (or cannot influence the collective in return).

Proof. Conditions (A) and (B) provide the required dual-level theatres of consciousness (individual and collective). Condition (C) provides the nontrivial inter-level resonance required by the SDP notion. Thus the definition of SDP mindplex is satisfied. □

Theorem 195 (Mindplex emergence along a development path)**.** *Let $I_0 \to I_1 \to \cdots$ be a Hyperseed development path for a system M (continuity plus nontrivial capability growth). Assume that along this path the coherence score $\mathrm{Coh}_O(M; I_k)$ is nondecreasing and eventually crosses a threshold τ at which M becomes notably coherent and decomposable into notably coherent subminds.*

Then there exists k_0 such that for all $k \geq k_0$, M is a mindplex on interval I_k.

This emergence statement isolates a common pattern in developmental and training narratives: increases in capability can act as control parameters that push a system across a qualitative boundary where (i) coherence becomes locally maximal (so the mind is no longer an easily-improved patchwork) and (ii) coherent substructures become both identifiable and robustly swappable. The use of interval-indexed coherence $\mathrm{Coh}_O(M; I_k)$ emphasizes that mindplexhood is assessed over temporally extended behavior, not instantaneous snapshots; in particular, a system may transiently satisfy decomposition and replaceability while failing to maintain them across an interval where tasks, contexts, and internal states vary.

Proof. By assumption, there is k_0 such that $\mathrm{Coh}_O(M; I_k) \geq \tau$ for $k \geq k_0$. At such k, the notable coherence and decomposition assumptions state exactly the mindplex conditions, hence M is a mindplex on I_k for all $k \geq k_0$. Continuity (self-continuity across successive intervals) ensures these are stages of one persisting entity rather than unrelated systems. □

Theorem 196 (Small teams as weak mindplexes (a formal sufficient condition))**.** *Consider a team of n agents $\{S_i\}$ coupled by: (i) a strongly connected communication graph with coupling lower bound $k_0 > 0$; (ii) a shared persistent artifact store (documents, codebase, musical score) that acts as a high-bandwidth hub in the coupling graph; and (iii) synchronized interaction intervals of length at least T during which attention is aligned toward a shared task and shared artifacts.*

Assume the induced collective cultural reinforcement dynamics satisfy the hypotheses of the diffusion lower bound theorem for the task-relevant patterns, and that the collective has a workspace-stable focus set during the synchronized intervals.

Then the team forms an (ϵ, T)-weak mindplex for some ϵ determined by the replaceability error induced by role specialization.

The coupling hypotheses (i)–(iii) are designed to make the team behave less like a loose federation and more like a temporarily integrated cognitive unit. Strong connectivity and a coupling lower bound k_0 ensure that information (task constraints, partial solutions, error signals) can percolate throughout the team rather than remaining trapped in isolated subgroups. The persistent artifact store plays a dual role: it is both a communication amplifier (high bandwidth, asynchronous access) and an externalized memory that stabilizes shared context, thereby helping to produce the "workspace-stable focus set" required for a GCC episode. Finally, synchronized interaction intervals matter because weak mindplexhood is explicitly time-bounded: what is being guaranteed is a collective episode of coordinated cognition lasting at least T, not a permanently unified collective agent.

The parameter ϵ is naturally linked to specialization: teams often have critical roles (domain expert, coordinator, maintainer) whose replacement is only approximately feasible. The theorem therefore predicts weak mindplexhood when specialization is present but not so extreme that swapping or tool-assisted substitution collapses coherence, aligning the formalism with familiar phenomena such as resilient teams that can absorb absences, onboarding, or partial automation.

Proof. During synchronized intervals, strong connectivity plus artifact-mediated coupling yields diffusion of task-relevant patterns across agents, increasing the integration proxy and reducing fragmentation. The shared artifact hub provides a stable anchor that keeps the collective in a metastable basin (chain) for duration at least T, yielding a collective GCC episode by assumption. Approximate decomposition into coherent subminds is given by the individual agents; replaceability holds up to error ϵ because role-specialized components can be partially replaced by other agents or tools without destroying the collective's coherent task performance. Thus the weak mindplex definition is satisfied. □

62.16 Closing remarks

The bridge above turns qualitative claims about consciousness Locations, PNSE, and collective coordination into monotone fixed-point and threshold statements that can be used by a reasoning system: (i) map observable markers into evidence-state functionals; (ii) infer Location/collective Location; (iii) reason about interventions by moving parameter tuples or coupling strengths; and (iv) reason about emergence of mindplex structure along development paths.

62.17 Five basic theorems about GTGI-style general intelligence measures

Standing notation. Fix a task set $\mathcal{T}$ (Hyperseed-Concept "Task families") equipped with a probability distribution $D \in \Delta(\mathcal{T})$ (a "task environment"). Fix an agent Ag. Let $\kappa_{Ag} : \mathcal{T} \to [0,1]$ denote the agent's taskwise capability/competence function (e.g. $\kappa_{Ag}(T) := \mathrm{Comp}(Ag;T)$ in the sense of the competence scalarization already defined in Hyperseed's tasks section). Let

$$\mathrm{Cap}(Ag;\mathcal{T},D) \;:=\; \mathbb{E}_{T\sim D}\big[\kappa_{Ag}(T)\big]$$

denote the (distributional) capability score, and for $\varepsilon \in [0,1]$ let

$$\mathrm{Br}_\varepsilon(Ag;\mathcal{T},D) \;:=\; D\big(\{T \in \mathcal{T} : \kappa_{Ag}(T) \geq 1-\varepsilon\}\big)$$

denote ε-breadth ("good-enough mass"). We write log for $\log_2$.

Theorem 197 (Universal intelligence is a special case of pragmatic intelligence)**.** *Assume universal intelligence is defined as an* unnormalized *weighted aggregate*

$$\Upsilon_w(Ag) \;:=\; \sum_{T\in\mathcal{T}} w(T)\,\kappa_{Ag}(T), \tag{42}$$

for some weight function $w : \mathcal{T} \to (0,\infty)$ with finite normalizer

$$Z_w \;:=\; \sum_{T\in\mathcal{T}} w(T) \;<\; \infty.$$

Define the corresponding normalized "pragmatic" task distribution $D_w \in \Delta(\mathcal{T})$ by

$$D_w(T) \;:=\; \frac{w(T)}{Z_w}.$$

Then

$$\Upsilon_w(Ag) \;=\; Z_w \cdot \mathrm{Cap}(Ag;\mathcal{T},D_w), \tag{43}$$

i.e. $\mathrm{Cap}(Ag;\mathcal{T},D_w) = \Upsilon_w(Ag)/Z_w$.

In particular, taking $w(T) = 2^{-K(T)}$ for a chosen description-complexity K (as in Def. 336) makes universal intelligence a rescaled pragmatic intelligence (Def. 340).

Proof. By definition of $\mathrm{Cap}(\cdot)$ and D_w,

$$\mathrm{Cap}(Ag;\mathcal{T},D_w) = \sum_{T\in\mathcal{T}} D_w(T)\,\kappa_{Ag}(T) = \sum_{T\in\mathcal{T}} \frac{w(T)}{Z_w}\,\kappa_{Ag}(T) = \frac{1}{Z_w}\sum_{T\in\mathcal{T}} w(T)\,\kappa_{Ag}(T) = \frac{1}{Z_w}\Upsilon_w(Ag).$$

Rearranging yields (43). □

Theorem 198 (Bounding efficient pragmatic GI by pragmatic GI under bounded resource costs)**.** *Assume efficient pragmatic general intelligence is defined by a resource-normalized average (Def. 342) of the form*

$$\Pi^{\mathrm{eff}}(Ag;\mathcal{T},D) \;:=\; \mathbb{E}_{T\sim D}\left[\frac{\kappa_{Ag}(T)}{c_{Ag}(T)}\right], \tag{44}$$

where $c_{Ag}(T) > 0$ is the (expected or deterministic) resource cost incurred by Ag on task T.

Suppose there exist constants $0 < c_{\min} \leq c_{\max} < \infty$ such that for all $T \in \mathcal{T}$,

$$c_{\min} \;\leq\; c_{Ag}(T) \;\leq\; c_{\max}.$$

Then

$$\frac{1}{c_{\max}}\,\mathrm{Cap}(Ag;\mathcal{T},D) \;\leq\; \Pi^{\mathrm{eff}}(Ag;\mathcal{T},D) \;\leq\; \frac{1}{c_{\min}}\,\mathrm{Cap}(Ag;\mathcal{T},D). \tag{45}$$

Proof. For each task T, the cost bounds imply

$$\frac{1}{c_{\max}} \;\le\; \frac{1}{c_{Ag}(T)} \;\le\; \frac{1}{c_{\min}}.$$

Since $\kappa_{Ag}(T) \in [0,1]$, multiplying preserves inequalities:

$$\frac{1}{c_{\max}}\,\kappa_{Ag}(T) \;\le\; \frac{\kappa_{Ag}(T)}{c_{Ag}(T)} \;\le\; \frac{1}{c_{\min}}\,\kappa_{Ag}(T).$$

Taking expectations over $T \sim D$ yields

$$\frac{1}{c_{\max}}\mathbb{E}_{T\sim D}[\kappa_{Ag}(T)] \;\le\; \mathbb{E}_{T\sim D}\left[\frac{\kappa_{Ag}(T)}{c_{Ag}(T)}\right] \;\le\; \frac{1}{c_{\min}}\mathbb{E}_{T\sim D}[\kappa_{Ag}(T)].$$

The middle term is $\Pi^{\text{eff}}(Ag;\mathcal{T},D)$ by (44), and the outer expectations are $\mathrm{Cap}(Ag;\mathcal{T},D)$, giving (45). ☐

Theorem 199 (Breadth–capability inequalities)**.** *Fix $(\mathcal{T},D)$, agent Ag, and $\varepsilon \in [0,1]$. Then*

$$(1-\varepsilon)\,\mathrm{Br}_\varepsilon(Ag;\mathcal{T},D) \;\le\; \mathrm{Cap}(Ag;\mathcal{T},D) \;\le\; (1-\varepsilon)+\varepsilon\,\mathrm{Br}_\varepsilon(Ag;\mathcal{T},D). \tag{46}$$

Equivalently, for $\varepsilon \in (0,1]$,

$$\mathrm{Br}_\varepsilon(Ag;\mathcal{T},D) \;\ge\; \frac{\mathrm{Cap}(Ag;\mathcal{T},D)-(1-\varepsilon)}{\varepsilon}. \tag{47}$$

Proof. Let $G_\varepsilon := \{T \in \mathcal{T} : \kappa_{Ag}(T) \ge 1-\varepsilon\}$, so $\mathrm{Br}_\varepsilon(Ag;\mathcal{T},D) = D(G_\varepsilon)$. Split the expectation defining capability:

$$\mathrm{Cap}(Ag;\mathcal{T},D) = \mathbb{E}_{T\sim D}[\kappa_{Ag}(T)] = \mathbb{E}[\kappa_{Ag}(T)\mathbf{1}_{G_\varepsilon}(T)] + \mathbb{E}[\kappa_{Ag}(T)\mathbf{1}_{\mathcal{T}\setminus G_\varepsilon}(T)].$$

Lower bound. On G_ε we have $\kappa_{Ag}(T) \ge 1-\varepsilon$, and on $\mathcal{T}\setminus G_\varepsilon$ we have $\kappa_{Ag}(T) \ge 0$. Hence

$$\mathrm{Cap}(Ag;\mathcal{T},D) \ge (1-\varepsilon)\,\mathbb{E}[\mathbf{1}_{G_\varepsilon}(T)] = (1-\varepsilon)\,D(G_\varepsilon) = (1-\varepsilon)\,\mathrm{Br}_\varepsilon(Ag;\mathcal{T},D).$$

Upper bound. On G_ε we have $\kappa_{Ag}(T) \le 1$, and on $\mathcal{T}\setminus G_\varepsilon$ we have $\kappa_{Ag}(T) < 1-\varepsilon$, hence $\kappa_{Ag}(T) \le 1-\varepsilon$. Therefore

$$\mathrm{Cap}(Ag;\mathcal{T},D) \le 1\cdot\mathbb{E}[\mathbf{1}_{G_\varepsilon}(T)]+(1-\varepsilon)\cdot\mathbb{E}[\mathbf{1}_{\mathcal{T}\setminus G_\varepsilon}(T)] = D(G_\varepsilon)+(1-\varepsilon)(1-D(G_\varepsilon)) = (1-\varepsilon)+\varepsilon D(G_\varepsilon),$$

which is the right-hand inequality in (46). Rearranging the upper bound yields (47) for $\varepsilon > 0$. ☐

Theorem 200 (Invariance of taskwise competence (and derived GI scores) under reduction-equivalence)**.** *Let $\mathcal{T}$ and $\mathcal{T}'$ be task sets and let $\phi : \mathcal{T} \to \mathcal{T}'$ be a bijection. Assume that for each $T \in \mathcal{T}$, the tasks T and $\phi(T)$ are reduction-equivalent in the sense that there exist task reductions both ways (as in Hyperseed's task reduction definition and Lemma "reductions form a preorder; equivalence is an equivalence relation").*

Choose, for each $T \in \mathcal{T}$, a concrete reduction

$$G_T : \; \phi(T) \;\to\; T.$$

Given an agent Ag defined on the interface of tasks in $\mathcal{T}$, define an induced agent ϕ_*Ag on $\mathcal{T}'$ by porting *Ag along each G_T when facing task $\phi(T)$ (i.e. apply the "agent transfer along a reduction" rule).*

Let $D \in \Delta(\mathcal{T})$ and define the pushforward distribution $\phi_* D \in \Delta(\mathcal{T}')$ by

$$(\phi_* D)(T') \ := \ D(\phi^{-1}(T')).$$

Then for every $T \in \mathcal{T}$,

$$\kappa_{Ag}(T) \ = \ \kappa_{\phi_* Ag}(\phi(T)), \tag{48}$$

and consequently for every $\varepsilon \in [0, 1]$,

$$\mathrm{Cap}(Ag; \mathcal{T}, D) \ = \ \mathrm{Cap}(\phi_* Ag; \mathcal{T}', \phi_* D), \qquad \mathrm{Br}_\varepsilon(Ag; \mathcal{T}, D) \ = \ \mathrm{Br}_\varepsilon(\phi_* Ag; \mathcal{T}', \phi_* D). \tag{49}$$

In particular, any GI measure defined purely as an expectation (or threshold-mass) over taskwise competence is invariant under replacing tasks by reduction-equivalent presentations.

Proof. Fix $T \in \mathcal{T}$ and write $T' := \phi(T)$. By construction, $\phi_* Ag$ on task T' is obtained by porting Ag along the reduction $G_T : T' \to T$. Hyperseed's "value/competence preservation under task reduction" result states that porting along a reduction preserves task value and hence preserves the scalar competence score. Therefore $\kappa_{\phi_* Ag}(T') = \kappa_{Ag}(T)$, which is (48).

For capability, using the definition of pushforward measure and (48),

$$\mathrm{Cap}(\phi_* Ag; \mathcal{T}', \phi_* D) = \sum_{T' \in \mathcal{T}'} (\phi_* D)(T')\, \kappa_{\phi_* Ag}(T') = \sum_{T \in \mathcal{T}} D(T)\, \kappa_{\phi_* Ag}(\phi(T)) = \sum_{T \in \mathcal{T}} D(T)\, \kappa_{Ag}(T) = \mathrm{Cap}(Ag; \mathcal{T}, D).$$

For breadth, define $G_\varepsilon := \{T \in \mathcal{T} : \kappa_{Ag}(T) \geq 1 - \varepsilon\}$ and $G'_\varepsilon := \{T' \in \mathcal{T}' : \kappa_{\phi_* Ag}(T') \geq 1 - \varepsilon\}$. Equation (48) implies $T \in G_\varepsilon \iff \phi(T) \in G'_\varepsilon$, hence $G'_\varepsilon = \phi(G_\varepsilon)$. Therefore, by definition of pushforward distribution,

$$\mathrm{Br}_\varepsilon(\phi_* Ag; \mathcal{T}', \phi_* D) = (\phi_* D)(G'_\varepsilon) = (\phi_* D)(\phi(G_\varepsilon)) = D(G_\varepsilon) = \mathrm{Br}_\varepsilon(Ag; \mathcal{T}, D).$$

This proves (49). $\square$

Theorem 201 (Entropy bounds for intellectual breadth)**.** *Assume intellectual breadth is defined (Def. 343) by Shannon entropy of a normalized "intelligence-mass" distribution across tasks/contexts:*

$$m_{Ag}(T) \ := \ D(T)\, \kappa_{Ag}(T), \qquad Z \ := \ \sum_{T \in \mathcal{T}} m_{Ag}(T), \qquad p_{Ag}(T) \ := \ \frac{m_{Ag}(T)}{Z},$$

where $Z > 0$ (i.e. Ag has nonzero intelligence mass on the task ecology). Let

$$\mathrm{IB}(Ag; \mathcal{T}, D) \ := \ H(p_{Ag}) \ := \ -\sum_{T \in \mathcal{T}} p_{Ag}(T) \log p_{Ag}(T),$$

with the convention $0 \log 0 := 0$. Assume $\mathcal{T}$ is finite with $|\mathcal{T}| = N$.

Then

$$0 \ \leq \ \mathrm{IB}(Ag; \mathcal{T}, D) \ \leq \ \log N. \tag{50}$$

Moreover:

- $\mathrm{IB}(Ag; \mathcal{T}, D) = \log N$ *iff p_{Ag} is uniform on $\mathcal{T}$.*
- $\mathrm{IB}(Ag; \mathcal{T}, D) = 0$ *iff p_{Ag} is a point mass (all intelligence mass concentrated on a single task).*

Proof. Nonnegativity: since $p_{Ag}(T) \in [0, 1]$, we have $\log p_{Ag}(T) \leq 0$, hence $-p_{Ag}(T) \log p_{Ag}(T) \geq 0$ for each term; summing gives IB ≥ 0. For the upper bound, let u be the uniform distribution on $\mathcal{T}$, i.e. $u(T) = 1/N$. (Here $N := |\mathcal{T}| < \infty$ so that u is well-defined and $\log N$ is finite; throughout, the base of the logarithm fixes the units of information, e.g. base-2 gives bits and base-e gives nats.) Consider the KL divergence

$$\mathrm{KL}(p_{Ag} \| u) \;:=\; \sum_{T \in \mathcal{T}} p_{Ag}(T) \log \frac{p_{Ag}(T)}{u(T)} \;\geq\; 0.$$

The inequality $\mathrm{KL}(p_{Ag} \| u) \geq 0$ is the standard nonnegativity (Gibbs' inequality), and it holds for any two distributions on the same finite support; in particular, we adopt the usual convention that terms with $p_{Ag}(T) = 0$ contribute 0 to the sum (since $\lim_{x \to 0^+} x \log x = 0$), so the expression is well-defined even when p_{Ag} has zeros. Expanding with $u(T) = 1/N$ yields

$$\mathrm{KL}(p_{Ag} \| u) = \sum_T p_{Ag}(T) \log p_{Ag}(T) - \sum_T p_{Ag}(T) \log(1/N) = -H(p_{Ag}) + \log N = -\mathrm{IB}(Ag; \mathcal{T}, D) + \log N.$$

In the middle step we used $\sum_T p_{Ag}(T) = 1$, so the second sum simplifies as

$$-\sum_T p_{Ag}(T) \log(1/N) = -\log(1/N) \sum_T p_{Ag}(T) = -\log(1/N) = \log N,$$

making explicit why the upper bound is controlled only by the cardinality of $\mathcal{T}$ (and not by finer details of p_{Ag}). Thus $\mathrm{IB}(Ag; \mathcal{T}, D) \leq \log N$, proving (50). Equivalently, this rederives the classical entropy bound $H(p_{Ag}) \leq \log |\mathcal{T}|$, so the "IB" quantity here inherits the same extremal behavior as Shannon entropy on a finite set.

The equality condition IB $= \log N$ holds iff $\mathrm{KL}(p_{Ag} \| u) = 0$, which occurs iff $p_{Ag} = u$, i.e. p_{Ag} is uniform. Intuitively, this is the case of maximal uncertainty over $\mathcal{T}$: the agent-induced distribution assigns equal mass to each $T \in \mathcal{T}$, and therefore achieves the largest possible value of $H(p_{Ag})$ (hence of IB) among all distributions on $\mathcal{T}$.

Finally, IB $= 0$ iff $H(p_{Ag}) = 0$, which holds exactly when the distribution is supported on a single point (since $-x \log x > 0$ for all $x \in (0, 1)$, entropy can vanish only if one probability is 1 and the rest are 0). This is the opposite extremal regime: all probability mass concentrates on a unique $T^\star \in \mathcal{T}$, so there is no residual uncertainty to be measured by the entropy (and therefore no "breadth" in the induced distribution over $\mathcal{T}$). □

63 Deeper theorems for TyLAA-based Universal Grammar

This section states and proves five "deeper" theorems that make the TyLAA/TUG formalism useful as an *automated-reasoning substrate* inside Hyperseed: we relate (i) interface choice to quotient strength; (ii) TyLAA weakness to Hyperseed weakness/effort; (iii) trace-classes to canonical proto-time posets; and (iv–v) two classic Minimalist locality effects (phase impenetrability and relativized minimality) to resource scoping/consumption. Concretely, the goal is to show that the objects that are natural from the TyLAA side (derivations, swaps, congruences, and trace quotients) align with the objects that are natural from the Hyperseed side (observables, cost/effort, and proto-time structure), so that one can move back and forth between "linguistic" statements about derivations and "computational" statements about what an automated reasoner can safely identify, ignore, or factor out. In particular, throughout this section the phrase "quotient strength" should be read as: how aggressively an interface (and the associated congruence) identifies operational histories, and hence how much operational detail the proof system is permitted to forget while remaining sound for the chosen notion of observation.

Hyperseed concepts covered here. TyLAA (**??**); TyLAA-based Universal Grammar / TUG (**??**); TUG observation interface (**??**); TUG congruence (**??**); TUG independence and trace skeleton (**??**, **??**); externalization parameters (**??**); phase-locality as resource scoping (**??**); relativized minimality as competitive feature checking (**??**); and, for the Hyperseed bridge, weakness and quantale weakness (202, 143), effort/simplicity (100, 169), and proto-time (142). It may be helpful to keep in mind that the first cluster of notions (TyLAA/TUG, interface, congruence, independence) fixes what counts as the *computational dynamics* and what counts as a *permitted invariance* of those dynamics, while the second cluster (weakness/effort/proto-time) fixes how those invariances are evaluated as abstractions: weakness measures the extent of identification (and thus the informational coarseness), effort measures the induced proof/derivation complexity after quotienting, and proto-time records the partial-order content that remains once irrelevant sequential detail has been factored away.

63.1 Standing notation (recall)

We assume the basic TyLAA/TUG setup from the prior UG sections: an operational "red" system with complete derivations $\mathrm{Deriv}(s)$ from a state s, an observation interface O (Def. **??**) inducing observational equivalence $\equiv^{O}_{\mathrm{obs}}$ on derivations (Def. **??**), and the *weakest red congruence* (maximal sound congruence) $\equiv^{O}_{\mathrm{w}}$ (Def. **??**). Intuitively, $\mathrm{Deriv}(s)$ is the collection of all full operational histories that start from the same initial configuration s and run until a designated completeness condition (e.g. convergence, termination, or a finished externalization) is met; the theorems below will frequently quantify over $\mathrm{Deriv}(s)$ and then pass to quotients of $\mathrm{Deriv}(s)$ by various equivalence relations. The interface O should be read as a choice of *what counts as observable output* of a derivation (for example, phonological yield, a feature footprint, a dependency graph, or any other interface-specific projection), and $\equiv^{O}_{\mathrm{obs}}$ is the resulting indistinguishability relation: two derivations are observationally equivalent exactly when O cannot tell them apart. The congruence $\equiv^{O}_{\mathrm{w}}$ is then the most permissive identification of derivations that is still sound with respect to O and stable under the red operational composition principles fixed earlier; this is the sense in which it is "weakest": it forgets as much red structure as possible without collapsing distinctions that O can observe.

We also assume the TUG-visible alphabet Lab_V, the instance-level independence relation $\perp$ (Def. **??**), a symmetry group Γ acting on visible labels (Def. **??**), and the induced swap-mod-Γ congruence $\equiv_{\perp,\Gamma}$ (Def. **??**). Here Lab_V is the set of labels whose occurrences are treated as externally meaningful at the TUG level (as opposed to purely administrative or hidden steps), so that derivations may be compared via their visible label sequences (or more generally, via visible-labeled traces). The relation $\perp$ captures when two *particular step instances* commute: if two steps are independent in the relevant sense (no shared resource, no feature interaction, no causal constraint), then swapping their execution order should not affect any interface-respecting outcome. The group Γ formalizes uniform renamings and symmetries of visible labels that the theory decides to treat as inessential (for example, -renaming of indices, automorphisms of a feature coding, or permutations induced by externalization parameters), so that equivalence is not forced to remember arbitrary naming choices. Accordingly, $\equiv_{\perp,\Gamma}$ identifies derivations that can be transformed into one another by a finite sequence of swaps of adjacent $\perp$-independent steps, together with the allowed Γ-actions on visible labels; the resulting quotient is the standard "trace" view enriched by an explicit symmetry principle.

When the TyLAA orthogonality hypotheses hold (Assumption **??**), $\equiv_{\mathrm{w}}^{O}$ coincides with $\equiv_{\perp,\Gamma}$ for the corresponding interface. This coincidence is the key technical hinge for several of the deeper theorems: orthogonality ensures that the only sound way to identify derivations (relative to the chosen O) is to factor out exactly (a) those reorderings that are justified by independence and (b) those renamings that are justified by symmetry, with no additional "mysterious" identifications. Equivalently, under orthogonality, the interface-induced abstraction is complete for the syntactic/operational commutations captured by $\perp$ and Γ, so the quotient by $\equiv_{\mathrm{w}}^{O}$ can be computed and reasoned about using the more concrete swap-based presentation $\equiv_{\perp,\Gamma}$, which is what ultimately connects trace-classes to the proto-time posets studied later in this section.

63.2 Interface refinement yields canonical quotient maps

Theorem 202 (Interface refinement monotonicity and quotient-map functoriality)**.** *Let O_1 and O_2 be two observation interfaces (Hyperseed-Concept* **??***) on the same underlying operational system, and suppose O_2 is a* refinement *of O_1 (i.e. O_2 can distinguish at least as much as O_1):*

$$\pi_1 \equiv_{\mathrm{obs}}^{O_2} \pi_2 \quad \Rightarrow \quad \pi_1 \equiv_{\mathrm{obs}}^{O_1} \pi_2 \qquad \text{for all derivations } \pi_1, \pi_2.$$

Then:

1. ***Observational equivalence refines monotonically:*** $\equiv_{\mathrm{obs}}^{O_2} \subseteq \equiv_{\mathrm{obs}}^{O_1}$.
2. ***Weakest-red congruence refines monotonically:*** $\equiv_{\mathrm{w}}^{O_2} \subseteq \equiv_{\mathrm{w}}^{O_1}$.
3. ***There is a canonical surjection between quotients:*** *the map*

$$q_{2\to1} : \mathrm{Deriv}(s)/\equiv_{\mathrm{w}}^{O_2} \;\to\; \mathrm{Deriv}(s)/\equiv_{\mathrm{w}}^{O_1}, \qquad q_{2\to1}([\pi]_{O_2}) := [\pi]_{O_1}$$

   is well-defined and surjective.

Moreover, $q_{2\to1}$ is the unique map making the canonical projections compatible in the sense that, writing $\eta_i : \mathrm{Deriv}(s) \to \mathrm{Deriv}(s)/\equiv_{\mathrm{w}}^{O_i}$ for $\eta_i(\pi) := [\pi]_{O_i}$, one has

$$\eta_1 \;=\; q_{2\to1} \circ \eta_2,$$

so $q_{2\to1}$ is the canonical "forgetful" (coarsening) map induced by refinement.

Proof. (1) This is exactly the refinement assumption rewritten as a set inclusion: if every O_2-indistinguishable pair is also O_1-indistinguishable, then the relationf $\equiv_{\mathrm{obs}}^{O_2}$ is a subset of $\equiv_{\mathrm{obs}}^{O_1}$. (Here "relationf" is to be read as "relation".) Equivalently, among equivalence relations on $\mathrm{Deriv}(s)$ ordered by inclusion, refinement corresponds to moving *downward* (fewer pairs identified), so the observational equivalence relation becomes strictly finer or equal.

(2) By definition, $\equiv_{\mathrm{w}}^{O}$ is the *largest sound congruence* for O, i.e. the largest congruence π satisfying $\pi \subseteq\equiv_{\mathrm{obs}}^{O}$. From (1), $\equiv_{\mathrm{obs}}^{O_2}\subseteq\equiv_{\mathrm{obs}}^{O_1}$, so any congruence sound for O_2 (contained in $\equiv_{\mathrm{obs}}^{O_2}$) is automatically sound for O_1 (contained in $\equiv_{\mathrm{obs}}^{O_1}$). In particular, the *largest* such congruence for O_2 cannot exceed the largest such congruence for O_1; hence $\equiv_{\mathrm{w}}^{O_2}\subseteq\equiv_{\mathrm{w}}^{O_1}$. One can also view this as a monotonicity property of the "closure-to-a-congruence" operator: tightening the observational indistinguishability constraint can only tighten the largest congruence compatible with it.

(3) Define $q_{2\to1}([\pi]_{O_2}) := [\pi]_{O_1}$. To see this is well-defined, suppose $[\pi]_{O_2} = [\pi']_{O_2}$, i.e. $\pi \equiv_{\mathrm{w}}^{O_2} \pi'$. By (2), $\equiv_{\mathrm{w}}^{O_2}\subseteq\equiv_{\mathrm{w}}^{O_1}$, so $\pi \equiv_{\mathrm{w}}^{O_1} \pi'$, hence $[\pi]_{O_1} = [\pi']_{O_1}$. Surjectivity is immediate: for any $[\pi]_{O_1}$, pick the same representative π and observe that $q_{2\to1}([\pi]_{O_2}) = [\pi]_{O_1}$. It is also useful to note the induced factorization of projections, namely $\eta_1 = q_{2\to1} \circ \eta_2$, which expresses precisely that passing to the finer quotient (via O_2) retains enough information to recover the coarser quotient (via O_1) by a canonical collapse of classes. $\square$

Remark 3457. *This theorem is the clean formal reason that "parameters" appear when one observes more of the interface (Hyperseed-Concept* **??***): each coarse class $[\pi]_{O_1}$ is a union of refined classes in the fiber $q_{2\to1}^{-1}([\pi]_{O_1})$. In particular, when O_1 is LF-only and O_2 is LF+PF, the fiber can be read as the space of externalization variants consistent with a fixed LF core. Equivalently, $q_{2\to1}$ packages the idea that additional interface structure does not change the underlying LF-denotation of a derivation, but it can split a single LF-denotation into multiple PF-realization classes; the "parameter space" is exactly the collection of these split components.*

Remark 3458. *When refinements compose (e.g. O_3 refines O_2 refines O_1), the corresponding quotient maps compose as well: the canonical maps satisfy $q_{3\to1} = q_{2\to1} \circ q_{3\to2}$, since all are defined by sending a class represented by π to the class of the same π in the coarser quotient. Thus, the assignment $O \mapsto \mathrm{Deriv}(s)/\equiv^O_{\mathrm{w}}$ is naturally contravariant with respect to refinement: making an interface more discriminating yields a finer quotient together with a canonical surjection back to any coarser view.*

63.3 TyLAA weakness as Hyperseed weakness-maximization

Theorem 203 (Weakest-red maximizes Hyperseed weakness among sound congruences)**.** *Fix a state s and let $D := \mathrm{Deriv}(s)$ be the set of complete derivations from s. Equip D with a weight/measure $\mu : D \to V$ into the same quantale used for Hyperseed weakness (Hyperseed-Concepts 202, 143). For any congruence $\approx$ on D, write*

$$H_{\approx} \;:=\; \{(\pi,\pi') \in D \times D :\; \pi \approx \pi'\}.$$

Define the Hyperseed weakness *of $\approx$ by*

$$\mathsf{W}(\approx) \;:=\; w(H_{\approx}),$$

where $w(\cdot)$ is the quantale-weakness functional (cf. Hyperseed-Concept 143). Intuitively, $H_{\approx}$ is the set of derivation-pairs that the grammar (via $\approx$) treats as indistinguishable, and $\mathsf{W}(\approx)$ is the aggregate "amount" of such indistinguishability measured in the same scale V as Hyperseed weakness. In particular, enlarging $\approx$ (identifying more derivations) enlarges $H_{\approx}$ as a subset of $D \times D$, and the theorem below states that the weakest-red congruence achieves the largest possible weakness subject to the constraint of remaining sound for the chosen observation interface.

Let O be an observation interface and let $\equiv^O_{\mathrm{w}}$ be the weakest-red congruence (maximal sound congruence) for O (Def. **??***). Then for every sound congruence $\approx$ (i.e. every congruence with $\approx \subseteq \equiv^O_{\mathrm{obs}}$),*

$$\mathsf{W}(\approx) \;\le\; \mathsf{W}(\equiv^O_{\mathrm{w}}).$$

Moreover, if D is finite then

$$|D/\equiv^O_{\mathrm{w}}| \;\le\; |D/\approx|,$$

so the weakest red also minimizes the number of equivalence classes (a crude proxy for representational effort; Hyperseed-Concepts 100, 169). Equivalently, among all sound ways of quotienting derivations by observational indistinguishability, $\equiv^O_{\mathrm{w}}$ is simultaneously the coarsest (largest relation) and thus the one that, in the finite case, yields the smallest quotient object in the set-theoretic sense.

Proof. Because $\equiv^O_{\mathrm{w}}$ is the *maximal* sound congruence for O, every sound congruence $\approx$ satisfies $\approx \subseteq \equiv^O_{\mathrm{w}}$ as relations on $D \times D$. Thus $H_{\approx} \subseteq H_{\equiv^O_{\mathrm{w}}}$. This inclusion is just the relational unwrapping of $\approx \subseteq \equiv^O_{\mathrm{w}}$: if a pair (π, π') is already identified by $\approx$, then it is also identified by the maximal sound relation, so it lies in the latter pair-set as well. By monotonicity of weakness under inclusion (Theorem 1),

$$w(H_{\approx}) \;\le\; w(H_{\equiv^O_{\mathrm{w}}}),$$

i.e. $\mathsf{W}(\approx) \le \mathsf{W}(\equiv^O_{\mathrm{w}})$. Here the order $\le$ is the quantale order on V, so the statement is independent of the particular numerical or logical realization of weakness: it applies uniformly whether V is, say, $[0,\infty]$ (with $\le$ the usual order) or a truth-valued quantale (with $\le$ as entailment), provided w is monotone in its argument as required by Hyperseed-Concept 143.

For the cardinality claim (finite D), if $\approx\subseteq\equiv^O_{\mathrm{w}}$ then $\equiv^O_{\mathrm{w}}$ is *coarser* (identifies at least as many elements), hence each $\equiv^O_{\mathrm{w}}$-class is a union of $\approx$-classes. Therefore the quotient by $\equiv^O_{\mathrm{w}}$ has no more classes than the quotient by $\approx$: $|D/\equiv^O_{\mathrm{w}}| \le |D/\approx|$. One way to see this explicitly is to consider the canonical surjection $D/\approx \twoheadrightarrow D/\equiv^O_{\mathrm{w}}$ that sends an $\approx$-class to the unique $\equiv^O_{\mathrm{w}}$-class containing it; surjectivity follows from coarseness, and finiteness of D then implies the stated inequality of cardinalities. (For infinite D, the same map still exists, but cardinal comparison may require additional set-theoretic care, so the theorem restricts to the finite case for a clean statement.) □

Remark 3459. *This is the precise Hyperseed bridge: TyLAA's slogan "do not maintain a distinction unless the interface forces you to" becomes a literal weakness-maximization statement when one reads "maintaining distinctions" as the complement of Hyperseed weakness (Hyperseed-Concept 202) and reads "effort" as the cost of representing many equivalence classes (Hyperseed-Concepts 100, 169). In particular, a "distinction" between π and π' corresponds to* excluding *the pair (π,π') from $H_{\approx}$, whereas "not maintaining" it corresponds to* including *that pair. Since the weakest-red congruence is maximal among sound congruences, it includes every pair that can be included without violating observational soundness, and therefore attains the largest admissible weakness value in the quantale sense. This makes the link to TyLAA structural rather than rhetorical: the interface constraint is precisely what bounds weakness from above.*

63.4 Trace-classes as canonical proto-times

Theorem 204 (Canonical poset representation of TUG trace-classes)**.** *Let $w = \ell_1\ell_2\cdots\ell_n \in \mathrm{Lab}_V^*$ be a visible trace word (in instance labels, so that $\perp$ is defined on the ℓ_i; Def. **??**). Define a directed graph G_w on vertices $\{1,\dots,n\}$ by putting an edge $i \to j$ iff $i<j$ and $\ell_i \not\perp \ell_j$ (i.e. the occurrences are dependent). Let $\le_w$ be the reachability preorder of G_w and write $P(w)$ for the induced partial order on occurrences (identify $i \sim j$ iff $i \le_w j$ and $j \le_w i$; this does nothing here because edges strictly increase indices, hence no cycles). In particular, $P(w)$ remembers* occurrences *(positions) rather than just labels: two equal labels $\ell_i = \ell_j$ with $i \ne j$ are still distinct elements of the poset, and the labeling of the poset is the evident map $i \mapsto \ell_i$. Equivalently, G_w is the "immediate" dependency graph induced by the word order together with the dependence relation, and $\le_w$ is its transitive closure, so that $i \le_w j$ expresses that i must causally precede j via a (possibly multi-step) chain of dependences.*

Then:

1. *$P(w)$ is a finite* proto-time *(a finite strict partial order) of the visible actions (Hyperseed-Concept 142).*

2. *If $w \equiv_\perp w'$ (swap-equivalent via adjacent swaps of independent labels), then $P(w)$ and $P(w')$ are isomorphic as labeled posets (up to the obvious renaming of occurrence-indices). In other words, the trace-equivalence class forgets only the arbitrary interleaving choices among independent actions, and the resulting invariant is exactly the induced partial order of necessary precedence constraints.*

3. *Conversely, the set of all words in the $\equiv_\perp$-class of w is exactly the set of linear extensions of $P(w)$ (i.e. all total orders of the occurrences consistent with $\le_w$), read back as words by listing the corresponding labels. Thus, $\equiv_\perp$-classes coincide with "all schedules consistent with the same dependency constraints", which is the usual Mazurkiewicz-trace viewpoint specialized to the present TUG setting.*

Proof. (1) By construction, every edge $i \to j$ satisfies $i < j$, so G_w is acyclic. Reachability therefore defines a strict partial order on occurrences. More explicitly, if $i \le_w j$ and $j \le_w i$, then there are directed paths $i \to^* j$ and $j \to^* i$, which would form a directed cycle; acyclicity forces $i = j$, so antisymmetry holds and the quotienting step "identify $i \sim j$" is indeed trivial in this particular construction.

(2) It suffices to consider one generating swap. Suppose $w' = u\,ab\,v$ and $w = u\,ba\,v$ differ by swapping adjacent letters a, b with $a \perp b$. Define a bijection σ on occurrences that swaps the two adjacent positions and fixes all others. Because $a \perp b$, there is *no* dependency edge between these two occurrences in either direction. For any third occurrence k, the relative order between k and each of the swapped occurrences is unchanged (they remain on the same side of k), so the presence/absence of edges to k is unchanged as well. To spell this out: for k outside the swapped block, either k lies in u (hence k precedes both swapped occurrences in both words) or k lies in v (hence k follows both swapped occurrences in both words), so the condition "$k <$ (swapped position)" (or its converse) is invariant under the swap, and the dependence predicate $\not\perp$ depends only on labels, not on positions. Hence σ carries edges of G_w to edges of $G_{w'}$, and therefore induces an isomorphism $P(w) \cong P(w')$. Since $\equiv_\perp$ is generated by such swaps, invariance holds for all $w \equiv_\perp w'$.

(3) Any word w is, tautologically, a linear extension of its own precedence constraints: if $\ell_i \not\perp \ell_j$ and $i < j$, then i must precede j in any realization, and w indeed lists i before j. So every word in the swap class yields a linear extension. Equivalently, swapping adjacent independent letters never violates the constraint that whenever there is a dependency edge $i \to j$ (hence $i < j$ and $\ell_i \not\perp \ell_j$), the occurrence i remains to the left of j; any allowed swap exchanges only a pair with $\perp$, so it cannot flip the order of a dependent pair.

Conversely, let L be any linear extension of $P(w)$. Starting from the word w, repeatedly swap adjacent occurrences that are out of order relative to L. Such a swap is always between two occurrences that are *incomparable* in $P(w)$ (otherwise L could not place them in the swapped order), and incomparability in $P(w)$ implies there is no dependency path between them, in particular no direct dependency edge, hence the two occurrences are independent and may be swapped. Here one uses the fact that if two occurrences $p < q$ in the *current* word were dependent, then by definition there would be an edge $p \to q$ (hence $p \le_w q$), so they could not be incomparable; therefore any adjacent pair eligible for reordering towards L must satisfy $\perp$. This "bubble-sort along incomparable adjacent pairs" terminates (it strictly decreases the number of inversions relative to L), yielding exactly the word corresponding to L. Therefore every linear extension is reachable by $\equiv_\perp$-swaps, i.e. belongs to the $\equiv_\perp$-class of w. ☐

Remark 3460. *Operationally, Theorem 204 says a trace class has a canonical "DAG/time" representation (Hyperseed-Concept* **??***) and ordinary sequential traces are just linearizations of it. This is precisely the data structure an automated reasoner wants: store the partial order (constraints), not an arbitrary interleaving (choices). Concretely, when two actions are independent, the poset leaves them incomparable, so a solver can postpone committing to their relative order until some later step (e.g. when synchronizing with additional constraints or matching against a target pattern).*

Remark 3461. *When $P(w)$ is finite, existence of at least one linear extension is guaranteed by* *the general linear-extension theorem already developed for proto-times (Theorem 27). Thus, the canonical trace-poset always admits at least one executable schedule when finite. Note that the finiteness assumption is automatic here because w has finite length n, hence the vertex set $\{1, \dots, n\}$ is finite; what matters in practice is that the induced constraints are consistent (acyclic), which is ensured by the index-increasing edge construction.*

63.5 Phase impenetrability from resource inaccessibility

The classical motivation for "phase impenetrability" is that certain domains behave as if they become inaccessible once a boundary is crossed. In the TUG setting, this is treated not as a special-purpose syntactic stipulation but as a direct consequence of the general resource discipline: once a resource leaves the active pool, any step whose *rely-footprint* requires that resource simply becomes disabled. The result below packages this intuition into a form that is stable under the quotienting that produces the TUG core, so that phase locality is preserved even when we identify derivations up to independence swaps and symmetries.

Theorem 205 (Phase locality as resource scoping; quotient-stability)**.** *Assume the TUG resource discipline (Def. **??**) with an "active resource pool"* $\mathrm{Active}(s) \subseteq \mathrm{Res}$ *for each state s, and an enabling condition: a visible label ℓ is enabled at s only if* $\mathrm{rely}(\ell) \subseteq \mathrm{Active}(s)$ *(Def. **??**). In particular, labels may be thought of as* capabilities *that are only available when all resources they rely on are currently in scope; this is the only mechanism used below.*

Fix a phase identifier π and a phase resource $\mathrm{Phase}(\pi) \in \mathrm{Res}$ *(Hyperseed-Concept **??**). Assume there is a phase-closing label* $\mathrm{Close}(\pi)$ *such that executing* $\mathrm{Close}(\pi)$ *removes the resource:*

$$\mathrm{Phase}(\pi) \in \mathrm{Active}(s) \quad \textit{and} \quad \mathrm{Active}(s \xrightarrow{\mathrm{Close}(\pi)} s') \;=\; \mathrm{Active}(s) \setminus \{\mathrm{Phase}(\pi)\}.$$

This expresses "closure" purely as a change in the static availability of a designated resource, and makes no further assumptions about how states encode structure. Note also that nothing here requires Active *to be globally monotone: we only use that* $\mathrm{Close}(\pi)$ *eliminates* $\mathrm{Phase}(\pi)$ *at the moment it occurs.*

Assume also that every "extraction across π" label $\mathrm{Hop}(\pi, \dots)$ *satisfies* $\mathrm{Phase}(\pi) \in \mathrm{rely}(\mathrm{Hop}(\pi, \dots))$*. Thus, the only way a derivation can perform an across-phase hop is by invoking an operation whose well-formedness (enabling) explicitly depends on the continued availability of the phase resource.*

Then:

1. ***(Impenetrability)*** *In any derivation, no* $\mathrm{Hop}(\pi, \dots)$ *can occur* after *a* $\mathrm{Close}(\pi)$ *step. Equivalently, if* $\mathrm{Close}(\pi)$ *occurs at some point in a derivation, then all subsequent steps are "blind" to the internal structure protected by* $\mathrm{Phase}(\pi)$*. Here "blind" is meant in the operational sense induced by the enabling condition: once the resource is absent, no later enabled label may have that resource in its rely-footprint, so no later label can be one whose intended interpretation requires access mediated by* $\mathrm{Phase}(\pi)$*.*

2. ***(Quotient-stability)*** *If* $\pi_1 \equiv_{\perp,\Gamma} \pi_2$ *are two derivations equivalent under the TUG congruence (Def. **??**), then π_1 satisfies the impenetrability constraint above iff π_2 does. In other words, phase locality is not an artifact of a particular linearization of independent actions: it is invariant under the observational identifications that define the quotient model.*

Proof. (1) Let $s \xrightarrow{\mathrm{Close}(\pi)} s'$ be an occurrence of $\mathrm{Close}(\pi)$ in a derivation. By hypothesis, $\mathrm{Phase}(\pi) \notin \mathrm{Active}(s')$. But every $\mathrm{Hop}(\pi, \dots)$ requires $\mathrm{Phase}(\pi) \in \mathrm{rely}(\mathrm{Hop}(\pi, \dots))$, hence $\mathrm{rely}(\mathrm{Hop}(\pi, \dots)) \nsubseteq \mathrm{Active}(s')$, so $\mathrm{Hop}(\pi, \dots)$ is not enabled at s'. Therefore no $\mathrm{Hop}(\pi, \dots)$ can occur after $\mathrm{Close}(\pi)$.

Put differently, the contradiction is purely local in time: it arises already at the immediate post-state s' because enabling consults $\mathrm{Active}(s')$ and $\mathrm{Close}(\pi)$ has just removed the needed resource.

(2) In the TUG congruence, the only reordering steps allowed are swaps of *independent* adjacent labels. But $\mathrm{Close}(\pi)$ and $\mathrm{Hop}(\pi, \dots)$ share the resource $\mathrm{Phase}(\pi)$, hence are dependent ($\mathrm{Close}(\pi) \not\perp \mathrm{Hop}(\pi, \dots)$ by Def. **??**). Therefore $\equiv_\perp$-swaps cannot move a $\mathrm{Hop}(\pi, \dots)$ from before $\mathrm{Close}(\pi)$ to after it (or vice versa): the relative precedence constraint between dependent occurrences is fixed across the swap class (Theorem 204). Equivalently, in the trace-poset semantics, any event labeled $\mathrm{Hop}(\pi, \dots)$ must be ordered before any event labeled $\mathrm{Close}(\pi)$ whenever both occur in the same computation, since they cannot be made concurrent by independence. Additionally, Γ-symmetries are assumed to preserve the rely/independence structure (Def. **??**), so applying Γ does not change whether the constraint holds. Thus the constraint is invariant under $\equiv_{\perp,\Gamma}$. □

Remark 3462. *The point is not that phases are metaphysically fundamental; it is that* a scoping discipline on resources *survives maximal quotienting and so becomes a "principle" of the TUG core (Hyperseed-Concept* **??***). For automated reasoning, this is ideal: locality becomes a static well-formedness condition on the trace-poset rather than an opaque procedural ban. Concretely, given a candidate trace (or its partial-order representation), one can check that there is no* $\mathrm{Hop}(\pi, \dots)$ *event that is causally (or linearly) after a* $\mathrm{Close}(\pi)$ *event, without reconstructing any hidden structural representation of the phase interior.*

63.6 Relativized Minimality from competitive feature checking

Theorem 206 (Relativized Minimality as competitive resource consumption; quotient-stability)**.** *Assume the same enabling/resource discipline as in Theorem 205. Fix a probe X and an uninterpretable feature F, represented by a resource* $\mathrm{FRes}(X, F) \in \mathrm{Res}$ *(Hyperseed-Concept* **??***). Consider two potential Agree labels*

$$\mathrm{Agree}(X, Y, F) \quad \textit{and} \quad \mathrm{Agree}(X, Z, F),$$

both of which require the probe feature resource:

$$\mathrm{FRes}(X, F) \in \mathrm{rely}(\mathrm{Agree}(X, Y, F)) \cap \mathrm{rely}(\mathrm{Agree}(X, Z, F)).$$

Assume one-time feature checking*: executing any Agree label that checks* $\mathrm{FRes}(X, F)$ *consumes it:*

$$\mathrm{Active}(s \xrightarrow{\mathrm{Agree}(X,*,F)} s') \;=\; \mathrm{Active}(s) \setminus \{\mathrm{FRes}(X, F)\}.$$

Then:

1. ***(Mutual exclusion)*** *No complete derivation can contain* both $\mathrm{Agree}(X, Y, F)$ *and* $\mathrm{Agree}(X, Z, F)$.
2. ***(Blocking pattern)*** *If a derivation contains* $\mathrm{Agree}(X, Z, F)$*, then it cannot contain any later occurrence of* $\mathrm{Agree}(X, Y, F)$ *(and symmetrically with Y, Z swapped).*
3. ***(Quotient-stability)*** *The mutual exclusion / blocking pattern is invariant under the TUG congruence $\equiv_{\perp,\Gamma}$.*

Proof. (1) Suppose for contradiction that a derivation contains both Agree steps. Whichever occurs first (say $\mathrm{Agree}(X, Z, F)$) consumes $\mathrm{FRes}(X, F)$ by hypothesis, so in the subsequent state s' we have $\mathrm{FRes}(X, F) \notin \mathrm{Active}(s')$. But $\mathrm{Agree}(X, Y, F)$ requires $\mathrm{FRes}(X, F) \in \mathrm{rely}(\mathrm{Agree}(X, Y, F))$, so it is not enabled at s' and can never occur after that point. Contradiction.

(2) This is the same argument without contradiction: once $\mathrm{Agree}(X, Z, F)$ fires, $\mathrm{FRes}(X, F)$ is removed, so any later Agree requiring $\mathrm{FRes}(X, F)$ is disabled.

(3) The two Agree labels are dependent (they share $\mathrm{FRes}(X, F)$), so $\equiv_\perp$ cannot swap them past each other (only independent adjacent swaps are allowed). Moreover, the consumption rule is a semantic invariant of the labeled transition system, not of a particular interleaving. Thus, if a derivation has consumed $\mathrm{FRes}(X, F)$ at some point, every $\equiv_\perp$-equivalent derivation has consumed it at the corresponding point in the trace-poset representation (Theorem 204), and therefore cannot contain a later Agree requiring it. Finally, Γ preserves the rely/consumption structure by assumption (Def. **??**), so Γ-renaming does not change the mutual exclusion pattern.

To connect this explicitly to the usual RM intuition: the "intervener" effect arises here because the probe-side feature token $\mathrm{FRes}(X, F)$ functions as an exclusive capability. If Z is checked first, then Z has effectively "used up" the only opportunity for X to discharge F, and any later attempt to relate X to Y via the same feature is not merely dispreferred but formally ill-typed (disabled) with respect to the enabling relation. In particular, no additional representational device is required to encode a separate minimality filter: it is already enforced by the resource accounting in $\mathrm{Active}(\cdot)$ together with the rely condition.

It is also worth noting that this argument does not depend on the identity of Y and Z beyond the shared requirement on $\mathrm{FRes}(X, F)$. In other words, the proof shows a general "single-discharge" principle: for any probe-side feature resource, there is at most one successful consumption event per derivation, and any two candidate consumptions are in direct competition. This abstraction will be used later when multiple probes/features are present and the trace skeleton decomposes into several such competitive cliques. ☐

Corollary 67 (Uniqueness of successful checking for a fixed probe-feature)**.** *Fix X and F as in Theorem 206. In any complete derivation, there is at most one label of the form* $\mathrm{Agree}(X, *, F)$*. Moreover, if some* $\mathrm{Agree}(X, W, F)$ *occurs, then every later transition must be labeled by an action whose rely set does not include* $\mathrm{FRes}(X, F)$*.*

Proof. The first claim is the mutual exclusion clause instantiated with an arbitrary pair of distinct potential goals. The second claim is exactly the blocking clause rephrased in terms of the rely predicate: after consumption, $\mathrm{FRes}(X, F) \notin \mathrm{Active}(\cdot)$, so any label that relies on it is disabled. ☐

Remark 3463. *This theorem is deliberately phrased as a* resource-competition invariant*, because that is what an AI reasoner can exploit directly: RM is detectable as a finite-resource conflict in the trace skeleton (Hyperseed-Concept* **??***), not as a language-specific stipulation.*

Remark 3464. *A useful reading is that "minimality" is not a separate global preference ordering over candidates, but an emergent property of local enablement under exclusive resources. If one wishes to recover the familiar intervening-configuration narrative, one can treat the earlier consumer of* $\mathrm{FRes}(X, F)$ *as the formal counterpart of an intervener: it blocks later dependencies not by distance per se but by resource preemption. On this view, locality effects follow whenever the derivation mechanics make it possible for a closer (or earlier-triggered) goal to consume* $\mathrm{FRes}(X, F)$ *before a more distant (or later-triggered) goal. Conversely, apparent "RM violations" correspond to theories in which either (i)* $\mathrm{FRes}(X, F)$ *is not consumed (one allows repeated checking), or (ii) the relevant dependencies do not in fact share a probe-feature resource (they are independent in the rely graph), in which case $\equiv_\perp$-commutation and coexistence become possible.*

64 Universal Grammar Cores in Cultures, Mindplexes, and Dynamical Archetypes

Glossary cross-references used in this section. We explicitly reference the glossary concepts: Universal Grammar (interface-theoretic) (Concept 220), Trace-based Universal Grammar (Concept 221), Observation interface (Concept 222), Grammatical independence (Concept 225), Label symmetry group (Concept 226), Trace quotient induced by $(\perp, \Gamma)$ (Concept 227), Principles-and-parameters as invariants (Concept 228), Culture (Concept 91), Collective mind system (Concept **??**), Mindplex (Concept 113), Collective Consciousness Location (Concept 75), Efficient pragmatic general intelligence (Concept 217), and Archetypes (Concept 58).

64.1 From individual trace quotients to a collective UG core

A single mind's interface-theoretic UG can be viewed as a *weakest interface theory*: we quotient derivations by whatever reorderings and symmetries the interface cannot (or chooses not to) distinguish (Concepts 220–227). For a *community*—a culture, a scientific field, a multi-agent lab, or a mindplex—each member may carry a different "language of thought" (different $(O, \perp, \Gamma)$ choices). This raises a concrete question: what is the mathematically canonical way to extract a *shared* core, and how does it behave as the group scales or integrates?

Definition 604 (Congruence closure and collective UG cores)**.** *Let M be a monoid. A* (monoid) congruence *on M is an equivalence relation $R \subseteq M \times M$ such that for all $u, v, u', v' \in M$,*

$$u \, R \, v \text{ and } u' \, R \, v' \quad \Longrightarrow \quad uu' \, R \, vv'.$$

Write $\mathsf{Cong}(M)$ for the set of congruences on M.

For any binary relation $E \subseteq M \times M$, define its congruence closure *by*

$$\langle E \rangle_{\mathrm{cong}} \;:=\; \bigcap \{ R \in \mathsf{Cong}(M) : E \subseteq R \}.$$

(So $\langle E \rangle_{\mathrm{cong}}$ is the smallest congruence containing E.)

Now fix a community I of individuals. Assume each individual $i \in I$ induces a TUG-style congruence $\approx_i \in \mathsf{Cong}(M)$ on a shared interface monoid M (e.g. take $M = \mathrm{Lab}_V^*$ and $\approx_i = \approx_{\perp_i, \Gamma_i}$ as in Concept 227).

Define two canonical collective *congruences:*

$$\approx_\wedge \;:=\; \bigcap_{i \in I} \approx_i, \qquad \approx_\vee \;:=\; \left\langle \bigcup_{i \in I} \approx_i \right\rangle_{\mathrm{cong}}.$$

We call $\approx_\wedge$ the strict shared UG core *(unanimous identifications), and $\approx_\vee$ the* translation-closure UG core *(identifications generated by the union).*

Conceptual explanation (what this theorem is saying). The strict core $\approx_\wedge$ captures what *everyone* already treats as "the same". The translation-closure core $\approx_\vee$ captures what the *community as a whole* can treat as "the same" once we allow chains of intertranslation and closure under compositional contexts. This aligns naturally with the idea that culture is a stabilized intersubjective pattern web (Concept 91): stabilized meaning is not only what each individual collapses, but what the intersubjective network *collectively* collapses.

Theorem 207 (Collective UG cores exist canonically and scale monotonically)**.** *Let M be a monoid and $\{\approx_i\}_{i\in I} \subseteq \mathsf{Cong}(M)$. Then $\approx_\wedge$ and $\approx_\vee$ (Definition 604) are congruences on M.*

Moreover:

1. ***(Lattice structure.)*** *$\mathsf{Cong}(M)$ is a complete lattice: arbitrary meets are intersections, and arbitrary joins are congruence-closures of unions.*

2. ***(Monotonicity in group size.)*** *If $J \subseteq I$ then*

$$\bigcap_{i\in I} \approx_i \subseteq \bigcap_{j\in J} \approx_j, \qquad \left\langle \bigcup_{j\in J} \approx_j \right\rangle_{\text{cong}} \subseteq \left\langle \bigcup_{i\in I} \approx_i \right\rangle_{\text{cong}}.$$

   So: adding members makes the strict core stricter *(fewer unanimous identifications) and makes the translation-closure core* weaker *(more collectively admitted identifications).*

3. ***(Principles as invariants.)*** *Let $f : M \to N$ be a monoid homomorphism. Then f is invariant under every $\approx_i$ iff f is invariant under $\approx_\vee$. Equivalently, $\bigcup_i \approx_i \subseteq \ker(f)$ iff $\approx_\vee \subseteq \ker(f)$. In particular, the "hard core" invariants common across members are exactly the homomorphic invariants of the join core $\approx_\vee$ (cf. Concept 228).*

Proof. First, $\approx_\wedge$ is an equivalence relation as an intersection of equivalence relations. If $u \approx_\wedge v$ and $u' \approx_\wedge v'$, then for each i we have $u \approx_i v$ and $u' \approx_i v'$, so $uu' \approx_i vv'$ by congruence of $\approx_i$. Thus $uu' \approx_\wedge vv'$, proving $\approx_\wedge \in \mathsf{Cong}(M)$.

Next, by definition $\approx_\vee$ is an intersection of congruences (those containing the union), hence itself a congruence.

For (1): arbitrary intersections of congruences are congruences (meets). For joins: given any family $\{R_k\} \subseteq \mathsf{Cong}(M)$, the relation $\langle \cup_k R_k \rangle_{\text{cong}}$ is a congruence containing each R_k, and is contained in every congruence that contains all R_k; hence it is the least upper bound.

For (2): if $J \subseteq I$ then $\cap_{i\in I} \approx_i \subseteq \cap_{j\in J} \approx_j$ is immediate. Also $\cup_{j\in J} \approx_j \subseteq \cup_{i\in I} \approx_i$, so monotonicity of congruence closure implies the join inclusion.

For (3): if f is a monoid homomorphism then $\ker(f) = \{(u, v) : f(u) = f(v)\}$ is a congruence. If f is invariant under every $\approx_i$, then $\cup_i \approx_i \subseteq \ker(f)$. Since $\ker(f)$ is a congruence containing the union and $\approx_\vee$ is the smallest such congruence, we get $\approx_\vee \subseteq \ker(f)$, i.e. invariance under $\approx_\vee$. Conversely, each $\approx_i \subseteq \approx_\vee$, so invariance under $\approx_\vee$ implies invariance under every $\approx_i$. □

64.2 Culture as a fixed point: stabilization of a shared grammar

Culture is defined in Hyperseed as a stabilized intersubjective pattern web, i.e. a fixed point of a societal update operator (Concept 91). The same fixed-point idea can be applied to the *meaning equivalences* that constitute a shared language. In this reading, the evolving "shared language" is not primarily a list of sentences but a collectively maintained criterion for when two expressions are treated as interchangeable *for the purposes of coordination.* The formal object that captures this criterion is a congruence relation: it remembers not only which tokens are identified, but also that identifications are stable under composition (so that replacing a subexpression by an equivalent one does not change the meaning of the whole).

Conceptual explanation (what this theorem is saying). Think of "what counts as the same meaning" as part of the cultural web. Repeated successful communications, teaching, norms, and institutionalization are then an update rule that can only *add* identifications (or at least is monotone in a suitable sense). In finite interface regimes, any such monotone reinforcement must stabilize: there is a well-defined limiting collective core. Equivalently, once the community has a finite repertoire of relevant compositional interfaces (a finite stock of forms and combinators, or a bounded set of interactional contexts that matter for interpretation), then iterated reinforcement cannot strictly increase forever: at some point, all further "learning" of equivalences is redundant because it is already implied by what has been institutionalized.

One can also read the statement operationally: start with a baseline of agreed identifications R_0 (perhaps minimal mutual intelligibility), and apply an update F that encodes the effect of a round of cultural reinforcement (new teaching episodes, newly salient analogies, newly standardized usage). Monotonicity means that if a society begins with more identifications, the same reinforcement cannot yield fewer; inflationarity means that reinforcement never retracts an established identification. Under these hypotheses, the limit R_{t_*} is path-independent in the sense that it depends only on R_0 and F (not on any external scheduling), and it is the smallest stable (institutionalized) equivalence compatible with that starting point.

Theorem 208 (Finite stabilization of a reinforced collective UG)**.** *Let M be a finite monoid, and let $F : \mathsf{Cong}(M) \to \mathsf{Cong}(M)$ be monotone and inflationary (i.e. $R \subseteq F(R)$ for all R). For any initial congruence R_0, define $R_{t+1} := F(R_t)$. Then $(R_t)_{t\geq 0}$ stabilizes after finitely many steps: there exists t_* such that $R_t = R_{t_*}$ for all $t \geq t_*$. Moreover, R_{t_*} is a fixed point of F and is the least fixed point of F above R_0.*

Interpreting the objects: the monoid M can be taken as a finite space of interface-states or composable meaning-bearing units (e.g. equivalence classes of well-formed expressions under a coarse syntactic typing, or a finite symbolic action-set closed under concatenation). A congruence $R \in \mathsf{Cong}(M)$ then represents a hypothesis of "sameness" that is compatible with composition: if $a \sim b$ and $c \sim d$, then $ac \sim bd$. This is precisely the algebraic form of the intuition that meaning-equivalence should be substitutive in context. In this sense, the theorem can be read as: iterated cultural reinforcement over a finite compositional interface yields a stable shared "core" of substitutable meanings.

Proof. Because M is finite, the set of all binary relations on M is finite, hence $\mathsf{Cong}(M) \subseteq \mathcal{P}(M\times M)$ is finite. Inflationarity and monotonicity give an ascending chain $R_0 \subseteq R_1 \subseteq R_2 \subseteq \cdots$. Any ascending chain in a finite poset must eventually stabilize, so there exists t_* with $R_{t_*} = R_{t_*+1} = F(R_{t_*})$, hence R_{t_*} is a fixed point. If R is any fixed point with $R_0 \subseteq R$, then by monotonicity $R_1 = F(R_0) \subseteq F(R) = R$, and inductively $R_t \subseteq R$ for all t, so $R_{t_*} \subseteq R$. Thus R_{t_*} is the least fixed point above R_0. □

The proof is a direct "finite ascending-chain" argument, but the conclusion has a useful cultural reading: once reinforcement is purely accumulative (inflationary) and order-preserving (monotone), the dynamics cannot cycle or oscillate. What looks sociologically like "convergence on norms" is, mathematically, the impossibility of a strictly increasing infinite chain of congruences when the interface space is finite.

It is sometimes helpful to make the stabilization time explicit. Since $\mathsf{Cong}(M) \subseteq \mathcal{P}(M\times M)$, one crude bound is $t_* \leq |\mathsf{Cong}(M)| \leq 2^{|M|^2}$, because at each strict step the relation gains at least one new ordered pair. This bound is rarely tight, but it clarifies the structural point: the stabilization is guaranteed by finiteness alone, not by any particular "strength" of the reinforcement.

Finally, note what the "least fixed point above R_0" means in practice. It says that if multiple stable cultural equilibria exist (multiple fixed points of F), the iteration starting from R_0 selects the minimal one compatible with the initial shared core. In linguistic terms, starting from a given baseline of mutual understanding and applying only cumulative reinforcement yields the smallest institutionalized equivalence structure that is closed under the society's reinforcement mechanism; stronger conventions would require either a different update rule F (different institutions) or a strictly stronger starting core R_0 (different initial coordination).

64.3 Scientific communities and a Lakatos-style hard core/periphery split

A scientific community is a paradigmatic *collective mind system* (Concept **??**). Informally, Lakatos distinguishes a "hard core" of commitments from a "protective belt" of adjustable auxiliaries. In the interface-theoretic UG lens, a clean analogue appears:

Definition 605 (Hard core and periphery via congruence invariants)**.** *Fix a collective UG congruence $\approx_C \in \mathsf{Cong}(M)$ for a community (for instance the stabilized outcome of Theorem 208 starting at $\approx_\vee$ from Definition 604).*

Define the hard core *of the community to be the class of homomorphic observables that factor through the quotient:*

$$\mathcal{H}(\approx_C) \;:=\; \{f : M \to N \text{ monoid homomorphism } : \approx_C \subseteq \ker(f)\}.$$

Define a periphery refinement *to be any congruence $\approx' \in \mathsf{Cong}(M)$ with $\approx' \subseteq \approx_C$ (i.e. a strictly finer theory that distinguishes more than the core).*

The condition $\approx_C \subseteq \ker(f)$ is the usual algebraic way to say that f is *insensitive* to the identifications imposed by $\approx_C$: whenever the community treats x and y as equivalent ($x \approx_C y$), the observable f must assign them the same value ($f(x) = f(y)$). Equivalently, f descends to a unique homomorphism $\bar{f} : M/{\approx_C} \to N$ satisfying $f = \bar{f} \circ \pi$, where $\pi : M \to M/{\approx_C}$ is the quotient map. In this sense, $\mathcal{H}(\approx_C)$ can be read as the collection of "principles" that are expressible purely at the level of the community's quotient interface, i.e. at the grain where $\approx_C$ has erased internal differences.

It is also useful to keep in mind that congruences on M form a lattice under inclusion. In that order, $\approx' \subseteq \approx_C$ means that $\approx'$ makes *fewer* identifications (it is finer, hence more discriminating), so the move from $\approx_C$ to $\approx'$ corresponds to enriching the community's vocabulary or inferential sensitivity while respecting the original identifications as a limiting case. This matches the methodological picture in which auxiliary hypotheses can be adjusted to increase empirical fit or explanatory detail without altering the background interface that the group has stabilized upon.

Conceptual explanation (what this theorem is saying). If the "hard core" is what is invariant under the community's collective equivalences, then making a periphery adjustment corresponds to adding distinctions without changing what was already forced to be invariant. This precisely matches the idea of conservative elaboration: you can complicate the protective belt, but you cannot thereby refute the hard core, because the hard core is already expressed at a coarser grain.

Stated in more operational terms: the hard core is a family of tests, measurements, or semantic projections that the community can apply to states of the mindplex without needing to resolve any of the within-class structure that $\approx_C$ intentionally ignores. A periphery refinement then amounts to *resolving* some within-class structure (distinguishing cases previously treated as equivalent), which may change theories and explanations at the fine level, but cannot invalidate any statement that depended only on the coarse interface. In particular, hard-core principles are precisely those that remain well-defined on equivalence classes, hence remain meaningful even if the community later adopts a more fine-grained classification scheme.

Theorem 209 (Periphery refinements conservatively extend the hard core)**.** *Let $\approx' \subseteq \approx_C$ be a periphery refinement in the sense of Definition 605. Then*

$$\mathcal{H}(\approx_C) \ \subseteq \ \mathcal{H}(\approx').$$

Equivalently: any homomorphic "principle" invariant under the core remains invariant under every refinement of the core.

One can also read the inclusion $\mathcal{H}(\approx_C) \subseteq \mathcal{H}(\approx')$ as an information order on invariants: the more distinctions a community is willing to make (the finer the congruence), the larger the set of homomorphic observables that qualify as well-defined invariants. Thus, a refinement can *add* admissible invariants (new stable observables become definable once the theory discriminates more), but it cannot *subtract* those already determined by the hard core. This is the algebraic reflection of the methodological asymmetry between revising auxiliaries and overturning the core: refinements elaborate what can be said, but do not break what was already quotiented into the interface.

Proof. Take $f \in \mathcal{H}(\approx_C)$, so $\approx_C \subseteq \ker(f)$. If $\approx' \subseteq \approx_C$, then $\approx' \subseteq \ker(f)$ as well, hence $f \in \mathcal{H}(\approx')$. $\square$

A concrete toy instance may help fix intuition. Suppose M encodes experimental protocols under concatenation, and $\approx_C$ identifies protocols that the community treats as operationally equivalent (e.g. two calibration routines regarded as interchangeable). Then $\mathcal{H}(\approx_C)$ consists of all homomorphic observables (such as cost, time, or a predicted signature) that do not distinguish between interchangeable calibrations. If the community later refines its practice to $\approx'$ by distinguishing previously lumped calibrations (perhaps after learning about a systematic bias), then any observable that was already blind to the old coarse equivalences is automatically blind to the refined ones as well. What changes is that new observables may become admissible as invariants once the refined distinctions are acknowledged, corresponding to new auxiliary structure in the protective belt.

64.4 Why a mindplex can benefit from a shared core UG

A mindplex is (roughly) a notably coherent society-of-mind that also maintains a collective narrative and persistent identity (Concept 113). A natural design question is: when does it help to enforce a shared UG core across subminds?

Conceptual explanation (what this theorem is saying). If the tasks and evaluations that matter to the mindplex are invariant under some quotient of internal derivations (i.e. the world and the mindplex's own evaluators cannot tell within-class differences), then enforcing that quotient as a shared core is *lossless* for performance but can reduce internal coordination cost. This is precisely "weakest interface theory" as a control advantage. In more concrete terms: if multiple internal encodings, proofs, parses, or message-forms are treated as equivalent by downstream dynamics and by the scoring rule the collective ultimately cares about, then the collective can standardize on the equivalence classes (the quotient) as a common "interface language." Standardization reduces the degrees of freedom that must be coordinated (e.g. fewer translation layers, fewer cross-submind misunderstandings, smaller state representations, and fewer brittle conventions), without sacrificing any externally-relevant capability on that task family.

One can read the quotient as the mindplex's *public semantic channel*: subminds may continue to use richer private derivations, but only the quotient-relevant content must be communicated and maintained for collective action. This is the sense in which a shared UG core is an *interface contract*: it specifies what distinctions are collectively meaningful, and collapses distinctions that are collectively irrelevant.

Definition 606 (UG-invariant tasks for a collective channel)**.** *Let $T = (O, A, P, r, \gamma)$ be a task in the sense of the manuscript's task layer, and let $q : O \to Q$ be a surjection. We say q is a* task abstraction *(and T is* invariant under *q) if:*

1. *(Lumpable dynamics) for all $o_1, o_2 \in O$ with $q(o_1) = q(o_2)$ and all $a \in A$, the pushforward distributions agree: $q_*(P(o_1, a)) = q_*(P(o_2, a))$;*

2. *(Evaluation invariance) for all $o_1, o_2 \in O$ with $q(o_1) = q(o_2)$, all $a \in A$, and all $o^+ \in O$, we have $r(o_1, a, o^+) = r(o_2, a, o^+)$.*

If O is a space of public derivational encodings (messages) and $\approx$ is a collective UG congruence on O, we call T UG-invariant *(for that collective) when q is the quotient map $q(o) = [o]_\approx$ and q is a task abstraction.*

The two conditions in Definition 606 can be interpreted as: (i) the environment's *effective* next-state distribution depends only on the equivalence class $q(o)$, not on which representative o the mindplex happened to use; and (ii) the evaluator that assigns reward similarly depends only on the equivalence class, so that no within-class refinement yields an intrinsic advantage. The "pushforward" notation $q_*(P(o, a))$ makes explicit that we only require agreement after mapping next observations into Q: the fine-grained next-observation distributions in O may differ, but only in ways that disappear under the quotient. This matches the mindplex use case where subminds may maintain rich internal syntactic differences, while the collective channel tracks only the induced semantics.

It is also useful to note why the reward invariance is stated as $r(o_1, a, o^+) = r(o_2, a, o^+)$ for all o^+, rather than only for o^+ with the same quotient: it ensures that the immediate evaluation cannot exploit the choice of representative even when coupled with future observations. In typical MDP-style settings where r factors through $(q(o), a, q(o^+))$, this condition holds automatically; the above form simply states the strongest sufficient criterion in the manuscript's notation.

Theorem 210 (UG quotienting is lossless for UG-invariant tasks)**.** *Assume $q : O \to Q$ is a task abstraction for $T = (O, A, P, r, \gamma)$, in the sense of Definition 606. Then there exists a reduced task $T_Q = (Q, A, P_Q, r_Q, \gamma)$ such that:*

1. *any policy π_Q for T_Q lifts to a policy π for T with identical value, and*

2. *consequently, representing observations only up to the quotient q is not a disadvantage for value.*

Theorem 210 can be seen as a formal version of: "if all that matters is the equivalence class, then committing to the equivalence class cannot hurt." In the mindplex setting, the equivalence relation $\approx$ can be read as the shared UG core identifying which transformations of messages/derivations preserve meaning for collective purposes (e.g. paraphrase, notational variants, proof permutations, or syntactic sugar). The theorem then says that, on any task whose dynamics and rewards respect those transformations, restricting the collective interface to $\approx$-classes loses no achievable discounted return.

Proof. Define $P_Q : Q \times A \to \Delta(Q)$ by $P_Q(q(o), a) := q_*(P(o, a))$. This is well-defined by lumpability: if $q(o_1) = q(o_2)$ then $q_*(P(o_1, a)) = q_*(P(o_2, a))$. Define $r_Q(q(o), a, q(o^+)) := r(o, a, o^+)$. This is well-defined by evaluation invariance.

Given any policy π_Q on Q, define a lifted policy π on O by $\pi(h) := \pi_Q(q(h))$ (i.e. apply q pointwise to the observation history). By construction, the induced distribution over Q-histories under π in T matches the distribution under π_Q in T_Q, and the rewards match stepwise because r_Q was defined by the invariance condition. Therefore the total discounted values coincide. $\square$

Two additional clarifications are often helpful when applying the proof idea. First, the lift $\pi(h) := \pi_Q(q(h))$ does not require choosing canonical representatives in O: the policy on O simply ignores within-class detail by preprocessing observations through q. Second, because the argument is distributional (matching the law of Q-histories), it applies equally to stochastic policies and stochastic dynamics; no determinism assumption is needed.

In many applications, this quotient construction is closely related to standard notions of MDP abstraction (e.g. homomorphisms, bisimulation-style lumping, and state aggregation). The distinctive emphasis here is interpretive: the quotient is not only a computational abstraction, but also a *collective linguistic* abstraction enforced as a UG core, so that coordination benefits accrue at the level of communication and interface design as well as at the level of planning.

Conceptual explanation (GTGI consequence). GTGI's efficient pragmatic general intelligence Π_{eff} (Concept 217) scores performance *per unit resource*. Theorem 210 says shared UG quotienting need not decrease achievable value on UG-invariant tasks; if it reduces coordination/representation cost, it increases (or at least does not decrease) Π_{eff}. Intuitively, once value is held fixed, any reduction in the collective's internal overhead (memory, bandwidth, compute, deliberation time, translation effort between subminds, or the governance complexity of maintaining many incompatible encodings) improves the efficiency metric. In a mindplex, these costs often scale superlinearly with representational heterogeneity, so even modest quotienting can yield substantial efficiency gains while leaving external competence unchanged on the invariant task family.

Corollary 68 (Shared UG cores can only help efficient pragmatic GI when they save resources)**.** *Assume a class of tasks is UG-invariant under a collective congruence $\approx$ (Definition 606) and that implementing policies on the quotient $Q = O/\approx$ uses weakly less resource on each task than implementing the corresponding lifted policies on O. Then the collective's efficient pragmatic general intelligence Π_{eff} (Concept 217) computed over that task class is weakly larger under the quotient representation.*

Proof. By Theorem 210, for each task the optimal achievable value is preserved by passing to the quotient task. By hypothesis, the resource functional $Q(\cdot, \cdot)$ used in Π_{eff} is weakly smaller for quotient-implemented policies than for their lifts. Since Π_{eff} weights performance by (inverse) resource use, preserving the numerator while decreasing (or preserving) the denominator yields a weak increase in Π_{eff}. □

A practical implication is that the main empirical burden shifts to verifying the two premises: (a) that the task family is in fact UG-invariant under the chosen congruence (so that no strategically relevant distinctions have been collapsed), and (b) that the quotient implementation genuinely saves resources in the deployment regime of interest (e.g. reduced communication bandwidth, simpler shared memory formats, or fewer translation modules). When either premise fails, a shared core UG may still be desirable for other reasons (safety, interpretability, or governance), but it is no longer guaranteed to be efficiency-improving by the above argument.

64.5 UG alignment and Collective Consciousness Location

Collective Consciousness Location (Concept 75) uses, among other inputs, *discord* as the variance of proposal signals across members of a collective.

Conceptual explanation (what this theorem is saying). If the public interface enforces a shared UG quotient, and if members' public proposals depend only on the quotient class, then the quotient removes a major source of "talking past each other" induced by purely representational differences (reorderings of independent steps, symmetry variants, etc.). In the idealized limit, shared UG implies zero interface-discord. More explicitly: the quotient map identifies (collapses) multiple surface-level encodings in O that are deemed equivalent under the collective's Universal Grammar constraints, so that any two public states $o, o' \in O$ with $o \approx o'$ become indistinguishable at the level of what is *publicly actionable*. The theorem below isolates the extreme case in which (i) there is a *single* public state $o(t)$ exposed to all members at time t, and (ii) each member's emitted proposal depends on $o(t)$ *only* through the shared equivalence class $q(o(t))$. Under these conditions, representational degrees of freedom cannot induce proposal dispersion, because there are no member-specific "private coordinate choices" left in the public channel.

Interpretive note on assumptions. The condition that there is a *common* function f is the formal way of stating that the public interface plus shared UG quotienting yields a common decoding/decision rule at the interface level. If members were to use different interface-level maps f_i, then even with identical quotient classes $q(o(t))$ one could still obtain nonzero discord purely from heterogeneity in the public-to-proposal mapping. Likewise, the existence of a single public state $o(t)$ rules out disagreement that originates upstream (e.g., members observing different public inputs); the theorem therefore attributes all remaining discord to interface representation, and then shows that this source vanishes under shared quotienting.

Theorem 211 (Shared UG quotienting forces zero interface-discord in the idealized limit)**.** *Consider a collective mind system (Concept **??**) whose members emit proposal signals $y_i(t) \in \mathbb{R}^d$ at time t. Suppose there exists a shared public representation space O and a collective UG congruence $\approx$ on O such that each member's proposal factors through the quotient map $q : O \to O/\!\approx$:*

$$y_i(t) \;=\; f(q(o(t))) \quad \textit{for a common function } f \textit{ and common public state } o(t) \in O.$$

Then the discord at time t as defined in Concept 75,

$$DO(t) \;:=\; \mathrm{Var}\big(\{y_i(t)\}_i\big),$$

satisfies $DO(t) = 0$.

Why this matches the "interface-discord" intuition. In applications, $y_i(t)$ can be read as an externally visible proposal vector (e.g., a vote vector, an action recommendation, an allocation, or a semantic embedding of a plan). The quotient condition means that any two members who are presented with the same quotient-class information will necessarily produce the same public proposal signal. Thus any dispersion that remains must come from either (a) differences in the quotient-class observed, (b) differences in the mapping from quotient-class to proposal, or (c) noise/perturbations not modeled here. The theorem explicitly excludes (a)–(c) by hypothesis, which is why it is stated as an "idealized limit."

Proof. If every $y_i(t)$ equals the same vector $f(q(o(t)))$, then the multiset $\{y_i(t)\}_i$ is constant, hence has variance zero by definition of variance. For avoidance of doubt, this holds for any standard variance functional on a finite family of vectors: if $y_i(t) = \bar{y}(t)$ for all i, then each deviation $y_i(t) - \bar{y}(t)$ is the zero vector, and any aggregation of squared deviations (componentwise or via a norm) yields zero. □

Remark (approximate quotienting and non-ideal settings). The statement above is deliberately sharp: exact factorization through a shared quotient and exact identity of the interface map f together force literal equality of all $y_i(t)$. In practice, one often expects an *approximate* version in which members implement slightly different maps f_i or observe noisy versions of the public state; then shared UG quotienting still predicts a *reduction* of discord relative to an unquotiented interface, but not necessarily $DO(t) = 0$. This theorem can therefore be read as the baseline case establishing that, when representation is the only source of dispersion, quotienting eliminates that dispersion entirely.

64.6 Chaotic dynamics: implicit grammars, universal sublanguages, and archetypes

Many dynamical systems induce "implicit grammars" via symbolic dynamics: orbit itineraries generate admissible symbol strings. This offers a natural answer to: *what is the UG among the languages implicit in various dynamical systems?* More concretely, once an observer commits to a finite "alphabet" of coarse-grained observational states, the time-evolution of the system produces sequences over that alphabet; not every finite string is typically realizable, and the resulting pattern of permissibility/prohibition functions like a grammar. This viewpoint makes the dependence on observational resolution explicit: different partitions of the same underlying dynamics can induce different languages, ranging from highly permissive (very coarse partitions) to highly constrained (fine partitions that track more structure).

Definition 607 (Symbolic language (implicit grammar) of a dynamical system)**.** *Let (X, F) be a dynamical system and let $\mathcal{P} = \{P_1, \dots, P_k\}$ be a finite measurable partition of X. For any $x \in X$, define its symbolic itinerary $\sigma(x) \in \{1, \dots, k\}^{\mathbb{N}}$ by $\sigma(x)_t = j$ iff $F^t(x) \in P_j$.*

Define the symbolic language *(set of admissible finite words) by*

$$\mathcal{L}(F, \mathcal{P}) \ := \ \big\{(a_0, \dots, a_{n-1}) \in \{1, \dots, k\}^n \ : \ \exists x \in X \ s.t.\ \sigma(x)_t = a_t \ \forall t < n\big\}.$$

We regard $\mathcal{L}(F, \mathcal{P})$ as an implicit grammar of (X, F) at the observational grain $\mathcal{P}$.

It is helpful to note that $\mathcal{L}(F, \mathcal{P})$ is a language of *finite* words (not necessarily a complete specification of the set of infinite itineraries), which matches the typical epistemic situation in which only finite observational traces are available. The passage from infinite itineraries to finite admissible blocks is also the standard bridge to subshifts: one may equivalently consider the set of all infinite sequences that avoid the forbidden finite words, and then recover $\mathcal{L}(F, \mathcal{P})$ as the collection of blocks appearing in that subshift. In this sense, "implicit grammar" can be read literally as "block constraints" on symbolic strings induced by dynamics.

Conceptual explanation (what this theorem is saying). Exact dynamical abstraction (a quotienting relation $q \circ F = G \circ q$) is the dynamical analogue of "weakest interface theory": it collapses microstates into macrostates without breaking the induced macro-dynamics. The theorem below says: if many different micro-systems abstract to the same macro-system, then the macro-system's symbolic language is a *universal sublanguage* (a dynamical UG core) shared by all of them. In chaotic regimes (horseshoes), this universal language contains a shift-of-finite-type core, which is a natural candidate for a cross-context archetype (Concept 58). Intuitively: an exact abstraction q asserts that what the macro-observer calls "one step of time" is consistent with the micro-dynamics after forgetting micro-detail. Thus any macro-observable finite behavior (any length-n macro trace through partition cells) must be reproducible by at least one micro-trajectory; this is precisely the language inclusion established below. Importantly, the inclusion is generally *one-way*: the micro-system may realize additional symbol strings that disappear under the macro quotient because the macro description conflates distinct micro-episodes.

Theorem 212 (Exact dynamical abstraction induces a universal symbolic grammar)**.** *Let (X, F) and (Y, G) be dynamical systems, and let $q : X \to Y$ be a surjection satisfying*

$$q \circ F \;=\; G \circ q$$

(i.e. an exact dynamical abstraction in the manuscript's sense). Let $\mathcal{P}_Y$ be a finite partition of Y, and let $\mathcal{P}_X$ be the pullback partition $\mathcal{P}_X := \{q^{-1}(P) : P \in \mathcal{P}_Y\}$. Then the symbolic languages satisfy

$$\mathcal{L}(G, \mathcal{P}_Y) \;\subseteq\; \mathcal{L}(F, \mathcal{P}_X).$$

Consequently, for any family $\{(X_j, F_j)\}_{j\in J}$ that all admit exact abstractions $q_j : X_j \to Y$ to the same macro-system (Y, G), the macro-language $\mathcal{L}(G, \mathcal{P}_Y)$ is a universal sublanguage shared by every member of the family.

Two clarifications make the statement operational. First, the choice of $\mathcal{P}_X$ as the pullback partition is not incidental: it ensures that the micro-observer is "speaking the same alphabet" as the macro-observer, i.e. micro-symbols record exactly which macro-cell the current microstate maps to. If one instead chose an unrelated partition of X, there would be no reason for the resulting languages to be comparable. Second, $q \circ F = G \circ q$ is the standard notion of a factor map in topological/measure-theoretic dynamics; in symbolic dynamics terms, the macro symbolic process is a factor of the micro symbolic process (when partitions are chosen compatibly). Under this reading, the theorem says that factors cannot create novel admissible finite words: coarse-graining can only *remove* distinctions, and thus any finite macro pattern must already exist in the micro system.

Proof. Take any word $w = (a_0, \ldots, a_{n-1}) \in \mathcal{L}(G, \mathcal{P}_Y)$. By definition, there exists $y \in Y$ whose itinerary under G visits partition cells P_{a_t} for $t = 0, \ldots, n-1$. Because q is surjective, choose $x \in X$ with $q(x) = y$. Then for each $t < n$,

$$q(F^t(x)) \;=\; G^t(q(x)) \;=\; G^t(y) \;\in\; P_{a_t}.$$

Hence $F^t(x) \in q^{-1}(P_{a_t})$, i.e. the itinerary of x under F w.r.t. $\mathcal{P}_X$ realizes the same word w. Therefore $w \in \mathcal{L}(F, \mathcal{P}_X)$, proving inclusion. The "family" statement follows immediately by applying the same argument to each $j \in J$. $\square$

The role of surjectivity in the proof is also conceptually meaningful: it is exactly the requirement that every macrostate corresponds to at least one microstate (no "spurious" macrostates). Without surjectivity, a macro word might be realizable in (Y, G) but have no micro-preimage to witness it, so the would-be "UG core" would no longer be guaranteed to be shared. Relatedly, the theorem makes no claim that *every* micro word projects to a macro word of the same length under $\mathcal{P}_Y$; many distinct micro trajectories can collapse to the same macro trace, and some micro distinctions may never be visible at the macro alphabet at all.

A simple toy picture can be kept in mind. If Y is a two-state macro-system with partition cells $\{P_1, P_2\}$ and G forbids the transition $2 \to 2$, then $\mathcal{L}(G, \mathcal{P}_Y)$ consists of words with no consecutive 2's. Any micro-system (X, F) that factors onto (Y, G) via q (and is observed through the pullback cells $q^{-1}(P_1), q^{-1}(P_2)$) must also forbid consecutive 2's at the level of these macro-observables. Thus a single forbidden bigram can function as a minimal "grammar rule" that persists across many distinct micro implementations.

Conceptual explanation (archetype link). The manuscript defines an archetype as a low-description, high-support, diverse-instantiation template (Concept 58). If a particular symbolic template (e.g. a full shift or a common subshift induced by a horseshoe factor) appears as a shared macro-language across many otherwise diverse systems, then it is a strong candidate for an archetype in exactly that sense. In symbolic dynamics, a shift of finite type (SFT) is specified by finitely many local constraints (equivalently, a finite directed graph or adjacency matrix), which directly aligns with "low description" in the archetype criteria: the template can be communicated as a compact set of admissibility rules. Moreover, horseshoes and related hyperbolic sets often yield Markov partitions that make the induced symbolic dynamics conjugate to an SFT; when such an SFT arises *as a factor shared across systems*, it provides a particularly crisp candidate for a cross-context dynamical archetype: many different underlying geometries can instantiate the same finite constraint schema on observables.

Corollary 69 (Chaotic universal grammar templates yield dynamical archetypes (conditional))**.** *Assume a distribution over dynamical systems in which a fixed macro-system (Y, G) occurs as an exact abstraction target with sufficiently high support, and assume that for some partition $\mathcal{P}_Y$ the language $\mathcal{L}(G, \mathcal{P}_Y)$ has low description complexity and admits diverse micro-level instantiations across the family (many non-isomorphic (X_j, F_j) mapping onto it). Then the template "admissible words in $\mathcal{L}(G, \mathcal{P}_Y)$" satisfies the manuscript's archetype criteria (Concept 58).*

Proof. This is a direct verification against the archetype definition: high support is assumed by hypothesis (many systems share the same macro-language via Theorem 212); diversity of instantiation is assumed (many different (X_j, F_j)); and low description complexity is assumed for the template language itself. Under these three conditions, the template meets the stated archetype criteria. □

One additional interpretive nuance is that the corollary is intentionally conditional about "description complexity": for many chaotic systems the *raw* symbolic language at a given partition can be complicated or even non-computable, but when a robust horseshoe factor exists, a comparatively simple SFT core may still be extracted as a stable template. In the UG framing, this corresponds to the idea that a shared "core sublanguage" can be substantially simpler than the full set of admissible traces in any one micro-system, precisely because the shared factor captures only what is common (and thus, in a sense, compressible across instances).

Part IV
Leveraging Hyperseed to Explore The Ethics of Self-Modifying AI and Superintelligence

65 Universality Classes of Self-Modifying Minds Coarse-Graining to Fixed-Point vs Strange vs Multi-Attractor Types

We formalize a "self-modifying mind" as a dynamical system whose state includes its own modifiable implementation. We then formalize Hyperseed-style abstraction as quotienting: a surjection that collapses micro-distinctions into macro-variables. Under a compatibility condition (exact or approximate), the micro-dynamics induces a macro-dynamics. We prove that attractor *type* (fixed point vs strange attractor vs multi-attractor) is invariant under this induced macro-dynamics, and stable under broad architecture variation inside a basin (under standard stability hypotheses). We give three canonical universality classes: contractive (fixed-point), robustly chaotic (strange), and multi-well (multi-attractor).

Concretely, letting x_t denote the full microstate at (discrete or continuous) time t, the "state" is understood to include not only ordinary internal variables (memories, weights, registers, etc.) but also parameters and data structures that determine how future updates are computed. In other words, the update rule is not treated as fixed background; rather, its current effective form is encoded in the state itself, so that learning, self-rewriting, compilation, and reflective control are represented as ordinary trajectories in an enlarged state space. This framing is broad enough to cover classical self-reference (e.g. an agent that edits its own source or weights) and softer forms (e.g. meta-learning that changes the optimizer), while still allowing standard dynamical-systems notions such as invariance, basin structure, and attractors.

Likewise, the quotienting map may be read as an abstraction operator $\pi : X \to Y$ from a detailed space X to a coarser space Y of macro-variables (features, summaries, or equivalence classes). The surjection π implements "disciplined forgetting" by identifying microstates that are different in ways declared irrelevant for the present scale of analysis. The compatibility condition can be stated as an exact commutation relation $\pi \circ F = G \circ \pi$ (or its approximate/perturbative analogue) between a micro-update F and a macro-update G, ensuring that trajectories projected to Y behave as if they were generated by an autonomous macro-dynamics. When compatibility is approximate, the induced macro-dynamics is understood in the standard sense of a well-defined effective evolution up to bounded error or up to probabilistic coarse-grained semantics, sufficient to preserve qualitative long-run structure.

The invariance claim about attractor *type* should be read as a statement that, under such compatibility, the coarse-grained system does not change whether the relevant asymptotic behavior is (i) convergence to a single stable fixed point, (ii) sustained aperiodic motion with sensitive dependence characteristic of strange attractors, or (iii) the presence of multiple coexisting stable limit sets with basin-dependent outcomes. "Stable under broad architecture variation inside a basin" means that, once attention is restricted to a regime where trajectories remain in the same qualitative basin, moderate changes to the micro-realization (different internal modules, parameterizations, or implementations) do not alter the coarse-grained attractor category, provided familiar regularity and robustness assumptions hold (e.g. hyperbolicity/structural stability for chaotic sets, contraction conditions for fixed points, and persistence of separated wells for multi-attractor systems). The three classes named here are thus intended as canonical coarse-grained modes of long-run self-change, not as claims about a unique mechanism.

Remark 3465. *The philosophical stance here is deliberately structural: rather than asking "what is the mind made of?" we ask "what long-run forms of change does it instantiate?" This aligns with a Hyperseed tendency to treat* patterns *and* processes *as first-class objects (Hyperseed-Concept 130, 140) and to treat* abstraction *as a disciplined forgetting of distinctions (Hyperseed-Concept 51, 98) [1]. Universality classes then play the role they play in physics: they identify which qualitative properties survive coarse-graining, so that many different micro-realizations may be reasoned about with one macro-law [18].*

Put differently, the aim is not to deny implementation details, but to separate those details into (i) features that materially affect the asymptotic organization of trajectories and (ii) features that wash out under repeated composition of the dynamics and repeated abstraction. In this framing, "universality" is the claim that certain coarse, qualitative invariants (here: attractor categories and their basin structure) are the right level of description for many questions about long-run self-

modification, because they persist across a family of micro-realizations that differ in representational choices, internal decomposition, or learning-rule parameterization. This is also the sense in which the remark connects to the Hyperseed emphasis: if patterns and processes are primary, then the fixed-point/strange/ multi-attractor trichotomy functions as a small "alphabet" of persistent process-shapes that can be tracked even when the micro-level substrate is replaced or refactored.

65.1 Self-modifying minds and Hyperseed abstraction

Definition 608 (Self-modifying mind as a dynamical system)**.** *A (discrete-time) self-modifying mind is a pair (X, F) where:*

- *X is a state space whose points encode at least: internal memory/state, current goals, and a modifiable implementation description (e.g. code, weights, architecture parameters).*
- *$F : X \to X$ is the one-step update map that includes ordinary cognition/action plus the possible self-modification of the implementation description.*

Iterates F^t represent the mind's evolution over t steps.

Remark 3466. *Notation/conventions: the pair (X, F) is the standard dynamical-systems packaging in which X collects all degrees of freedom one cares to model, and F is the update rule. The iterate F^t means composing F with itself t times (so $F^0 = \mathrm{id}$ and $F^{t+1} = F \circ F^t$). We use discrete time not because cognition is inherently discrete, but because many self-modifying systems are naturally described as sequences of "revision" events (weight updates, code commits, policy updates), and discrete time lets us speak cleanly about iterates and attractors.*

Remark 3467. *Intuitively, the distinctive move is that the mind is not merely a state evolving under fixed rules; part of the state* encodes the rules *(or parameters that determine the rules), so that the evolution may rewrite itself. This formalizes a common engineering reality in adaptive agents and learning systems [19], and it resonates with Hyperseed's emphasis that a* mind *is a self-updating pattern/process web rather than a static object (Hyperseed-Concept 111, 168).*

Two simple examples:

- *A neural agent whose state includes both (i) a working memory buffer and (ii) its current weights; the update map performs inference/action and then gradient descent on the weights.*
- *A program synthesis agent whose state includes a codebase; the update map runs tests, edits code, and deploys the edited code into the next step's execution.*

This definition is useful because it makes self-modification amenable to the same invariants and classification tools used for ordinary dynamical systems: one can ask about fixed points, cycles, chaos, and basins, but now these phenomena may occur at the level of "ways of thinking" rather than merely sensory-motor variables.

Definition 609 (Abstraction as quotienting)**.** *An* abstraction *of a state space X is a surjection*

$$q : X \to A$$

to a macro-space A, inducing an equivalence relation $x \sim_q y \iff q(x) = q(y)$. Intuitively, q collapses micro-distinctions and retains only macro-features.

Remark 3468. *Here q is the formal "act of forgetting." By demanding that q be a surjection, we insist that every macro-state $a \in A$ is realized by at least one micro-state $x \in X$; one is not merely renaming, but genuinely grouping many micro-possibilities under one macro-description. The induced relation $\sim_q$ is an* equivalence relation *(Hyperseed-Concept* **??***): it partitions X into fibers $q^{-1}(a)$, each fiber being a class of micro-states regarded as "the same" for the purposes of the macro-description.*

A simple example is to let $X = \mathbb{R}^2$ with coordinates (u, v) and define $q(u, v) = u$; then $A = \mathbb{R}$ and all points with the same u-coordinate are equivalent. A more mind-like example is: X contains the full internal memory of an agent, but q records only the agent's declared "current goal" variable; then many different memories collapse to one macro goal state. This definition is necessary because the universality claims later are not about individual micro-trajectories; they are about what remains stable when one moves between levels of description (Hyperseed-Concept 51, 86) [1].

Definition 610 (Exact dynamical abstraction (lumpability / congruence))**.** *Given (X, F) and an abstraction $q : X \to A$, we say q is an* exact dynamical abstraction *if for all $x, y \in X$,*

$$q(x) = q(y) \implies q(F(x)) = q(F(y)).$$

Remark 3469. *The condition says: if two micro-states are indistinguishable at the macro level* now*, then after one micro update, they are still indistinguishable at the macro level. In other words, the macro description is not merely a summary of micro-states; it is a summary that is* closed under time evolution*. This is essentially the notion of a congruence for dynamical systems, and is closely related to "lumpability" in Markov processes (where one requires the aggregated chain to be Markov).*

Example: suppose a micro-state is (m, g) where m is memory and g is a goal parameter, and let $q(m, g) = g$. Then q is an exact dynamical abstraction precisely when the goal update $g \mapsto g'$ depends only on g, not on the detailed memory m. This is a strong requirement, but it is the clean baseline case from which approximate notions (not treated in this section) can be developed; and it is exactly what is needed to speak rigorously about an induced macro dynamics.

Theorem 213 (Induced macro-dynamics exists and is unique)**.** *If $q : X \to A$ is an exact dynamical abstraction for (X, F), then there exists a unique map $G : A \to A$ such that*

$$q \circ F = G \circ q.$$

Moreover, G is explicitly given by

$$G(a) := q(F(x)) \quad \text{for any } x \in X \text{ with } q(x) = a,$$

and this is well-defined.

Proof. Because q is surjective, for each $a \in A$ choose some $x \in X$ with $q(x) = a$ and define $G(a) := q(F(x))$. To see this does not depend on the choice of representative, let x' be another micro-state with $q(x') = a$. Then $q(x) = q(x')$, and exactness implies $q(F(x)) = q(F(x'))$, hence $G(a)$ is well-defined.

For the intertwining identity, take any $x \in X$ and set $a = q(x)$. By definition of G, $(G \circ q)(x) = G(a) = q(F(x)) = (q \circ F)(x)$, so $q \circ F = G \circ q$ as maps. For uniqueness, suppose $G_1, G_2 : A \to A$ both satisfy $q \circ F = G_i \circ q$. For any $a \in A$ pick x with $q(x) = a$; then $G_1(a) = G_1(q(x)) = (q \circ F)(x) = G_2(q(x)) = G_2(a)$, so $G_1 = G_2$. □

Remark 3470. *The equation $q \circ F = G \circ q$ is the formal statement that the macro-dynamics is a* factor *of the micro-dynamics: evolving one step and then forgetting yields the same result as forgetting first and then evolving under the induced macro update. Diagrammatically, the theorem asserts the existence of a commutative square*

$$\begin{array}{ccc} X & \xrightarrow{F} & X \\ \downarrow q & & \downarrow q \\ A & \xrightarrow{G} & A \end{array}$$

which is exactly the structure needed to compare attractors and long-run behavior across levels of description. In particular, the macro-space A can be viewed as the set of equivalence classes $X/{\sim_q}$, and G is the update rule on these classes induced by F.

Corollary 70 (Compatibility with iterates)**.** *Under the assumptions of the theorem, for all t,*

$$q \circ F^t = G^t \circ q.$$

Remark 3471. *This follows by a straightforward induction using $q \circ F = G \circ q$. Conceptually, it means that macroscopic predictions over many steps can be computed entirely within the coarse-grained dynamics G, without reference to micro-level details,* provided *the abstraction is exact. Consequently, any macro property definable purely in terms of the iterates (e.g. being a fixed point, lying on a cycle, or being eventually periodic) can be studied at the level of G.*

For example, if $a^\star \in A$ is a fixed point of G (so $G(a^\star) = a^\star$), then for any micro-state x with $q(x) = a^\star$ we have $q(F(x)) = G(q(x)) = a^\star$, i.e. the entire fiber $q^{-1}(a^\star)$ is forward-invariant as a macro-state*. Micro-states in that fiber may still change internally, but in a way that is invisible to the macro description. This distinction (macro stasis vs micro activity) is especially relevant for self-modifying minds: a mind can keep rewriting implementation details while remaining within the same macro "type" according to the chosen quotient q.*

Definition 611 (Hyperseed-style abstraction (informal, as a choice of macro variables))**.** *In the Hyperseed spirit, a* Hyperseed abstraction *is an abstraction map $q : X \to A$ chosen so that the macro-state $a = q(x)$ captures those aspects of a mind-state x that are hypothesized to be most relevant to its long-run self-modification regime (e.g. persistent goal structure, self-model/learning-rule signature, or other relatively stable organizing variables), while deliberately quotienting away many implementation-level details.*

Remark 3472. *This definition is intentionally permissive: the point is not that there is a single canonical q, but that different research questions motivate different coarse-grainings (Hyperseed-Concept 86). Later universality claims can then be read as claims about the induced macro dynamics G on such Hyperseed-style macro-spaces: if many distinct micro realizations of self-modifying agents factor onto macro dynamics exhibiting similar qualitative behavior (fixed-point-like, strange/chaotic, multi-attractor, etc.), then one has evidence for robust "universality classes" that do not depend on low-level substrate. The exactness condition gives a clean mathematical template; in real systems one often expects only approximate closure, but the exact case provides the reference point for defining and measuring approximation error (e.g. how much $q(F(x))$ varies within a fiber $q^{-1}(a)$).*

Remark 3473. *This theorem says that an exact abstraction is not just a descriptive compression; it is a* homomorphism of dynamics*. The equation $q \circ F = G \circ q$ means: whether you "evolve then abstract" or "abstract then evolve," the result is the same macro-state. One may read this as a commutative diagram, expressing a kind of epistemic sanity: the macro theory genuinely tracks the causal/temporal structure of the micro theory.*

It matters because it lets us treat wildly different micro-implementations as instances of one macro law G. In the later universality discussion, this will be the precise hook on which invariance of attractor type *hangs: if G is shared, then qualitative long-run regimes are shared at the macro level, even if the micro stories differ.*

In particular, the condition $q \circ F = G \circ q$ is stronger than mere predictive fit "on average" or in distribution: it asserts step-by-step consistency of the induced time evolution after coarse-graining. Equivalently, q is a structure-preserving map from the micro dynamical system (X, F) to the macro dynamical system (A, G), where typically one takes A to be (at least) the image $q(X)$ so that every macro-state corresponds to some realizable micro-state.

In the self-modifying-mind setting, the same statement can be read operationally: let x encode a full micro-description (e.g. weights, code, memory, and environment-coupled internal registers), and let $q(x)$ retain only the macro variables we claim are explanatory (e.g. a behavioral policy class, a capability vector, an abstraction of goals, or a "seed" descriptor). Then exactness means the macro description is not merely a lossy summary; it is sufficient to propagate forward in time by G without needing hidden micro details. This is exactly what one wants if the macro description is intended to be portable across implementations, architectures, or substrates.

The commutativity also clarifies what kinds of invariances are and are not being claimed. It does not say micro-trajectories are identical; it says their macro *projections coincide whenever they start in the same macro-state. Thus, the fibers of q can contain diverse micro-states (different internal mechanisms, different realizations of the same high-level algorithm), while still yielding a single deterministic macro evolution governed by G.*

Proof. Define G by $G(q(x)) := q(F(x))$. If $q(x) = q(y)$ then by exact dynamical abstraction $q(F(x)) = q(F(y))$, hence the definition does not depend on the choice of representative in the fiber $q^{-1}(a)$. Uniqueness follows because any G satisfying $q \circ F = G \circ q$ must satisfy $G(q(x)) = q(F(x))$ for all x.

One may also view this as the standard quotient-dynamics construction: exactness ensures that the equivalence relation $x \sim y \iff q(x) = q(y)$ is respected by the update map F, i.e. $x \sim y$ implies $F(x) \sim F(y)$. Under that invariance, the induced map on equivalence classes is well-defined, and is precisely G. If one prefers to be explicit about domains, G is thereby defined on the set of realizable macro-states $A := q(X)$; if a larger macro state space is introduced, then G is fixed on $q(X)$ by the commuting equation and may be extended arbitrarily off-image without affecting the abstraction claim. □

Remark 3474. Proof sketch. *The strategy is to define G by "push F through q": declare the macro update of a macro-state a to be whatever you get by choosing any micro representative of a, evolving it by F, and then re-abstracting. Exactness of the abstraction is precisely what guarantees this does not depend on which representative you picked, i.e. that G is well-defined. Uniqueness then follows because the commuting equation forces G to take that value on every $a = q(x)$.* □

A helpful image is to think of each fiber $q^{-1}(a)$ as a "cloud" of micro-states representing one macro-state; exactness means F maps each cloud wholly into a single cloud. Then G simply names which cloud you land in.

This "cloud-to-cloud" picture is also a clean way to see why approximate abstractions can be brittle: if F splits *a cloud into multiple successor clouds, then the macro update is no longer single-valued and one must either (i) refine the macro variables (making fibers smaller), (ii) accept a stochastic or set-valued macro dynamics, or (iii) restrict attention to regimes where the splitting is negligible. The theorem isolates the exact case where none of these extra choices are required.*

For later use in discussing long-run regimes, note that exactness implies that macro trajectories are the images of micro trajectories under q: for any $n \geq 0$, repeated application yields $q(F^n(x)) =$

$G^n(q(x))$. Thus macro attractors (fixed points, cycles, chaotic invariant sets, or collections of multiple attractors with basins) are the natural coarse-grained shadows of micro invariant behavior. While micro-level invariant sets can be more intricate, the theorem guarantees that whatever macro attractor structure is expressed by G is consistently realized by every micro system sharing this abstraction.

In the specific "universality class" framing, this is the mechanism by which one can say that many distinct micro self-modification rules are "the same kind of mind" at the macro level: differences within a fiber are treated as implementation details, while the induced G is what carries the classification-relevant dynamical signature.

Remark 3475. *This theorem is the formal core of "coarse-graining": many different micro-architectures can be placed in the same class if they admit abstractions to a shared macro-dynamics G.*

Said differently, an exact abstraction q defines a criterion for when two micro theories are identical as far as the macro variables are concerned*: they induce the same G on the same macro state space (or on corresponding macro state spaces under an isomorphism). This is why the statement is useful for universality: once G is fixed, the qualitative taxonomy of asymptotic behavior can be performed at the macro level, and then imported back to every micro realization that factors through that G.*

This also highlights what is being held constant in a universality class. The point is not that the micro update F is unique, but that the induced macro update G is; the fibers encode the permitted implementation variance. In the later "fixed-point vs strange vs multi-attractor" discussion, the relevant invariants are those definable purely in terms of the macro flow generated by G (e.g. whether typical trajectories converge to a single attractor, wander on a chaotic set, or end in one of several competing attractors with nontrivial basins). Exactness is what ensures that such statements are well-posed at the chosen macro resolution, rather than being artifacts of untracked micro degrees of freedom.

65.2 Attractor types and invariance under coarse-graining

We use a standard metric notion of attraction.

Definition 612 (Attractor)**.** *Let (X, F) be a dynamical system on a metric space (X, d). A compact invariant set $K \subseteq X$ is an* attractor *if there exists an open set $U \supseteq K$ such that for all $x \in U$,*

$$\mathrm{dist}(F^t(x), K) \to 0 \quad \textit{as } t \to \infty,$$

where $\mathrm{dist}(x, K) = \inf_{y \in K} d(x, y)$*.*

Remark 3476. *Notation:* $\mathrm{dist}(x, K)$ *is the usual point-to-set distance, and compactness of K is a standard regularity assumption ensuring the limit notion behaves well. Invariance means $F(K) = K$ (equivalently $F(x) \in K$ whenever $x \in K$). The open set U is a* basin neighborhood*: all initial states in U are pulled toward K in the sense that their distance to K tends to zero.*

Intuitively, an attractor is a long-run "fate" shared by many nearby initial conditions, a notion closely aligned with predictive attraction (Hyperseed-Concept **??***): once you are in its basin, the future becomes increasingly constrained. For example, a stable fixed point x^* is an attractor with $K = \{x^*\}$; a stable limit cycle (not highlighted in our coarse taxonomy) would be an attractor where K is a periodic orbit. In self-modifying minds, attractors may correspond to stable "meta-policies" or stable "self-model + goal" configurations, not merely to stable sensorimotor states.*

Definition 613 (Three attractor types (coarse taxonomy)). *We say an attractor K is:*

- Fixed-point type *if $K = \{x^*\}$ with $F(x^*) = x^*$ and x^* attracts a neighborhood.*
- Multi-attractor type *if the system admits at least two disjoint attractors K_1, K_2 with disjoint basins of attraction of positive "size" (e.g. nonempty open subsets).*
- Strange-attractor type *if K supports sustained nonperiodic dynamics with sensitive dependence; for concreteness, assume $F|_K$ has positive topological entropy (or contains a subsystem topologically conjugate to a full shift on two symbols).*

Remark 3477. *This is intentionally a coarse-grained taxonomy: it collapses many classical distinctions (cycles vs tori, quasi-periodic vs chaotic, etc.) into three regimes that are especially relevant for reasoning about self-modification.*

Examples to keep in mind:

- *Fixed-point type: a mind converges to a stable "reflective equilibrium" in which its goal system and self-model stop changing except for small fluctuations (Hyperseed-Concept 166, 110).*
- *Multi-attractor type: a mind has distinct stable modes (e.g. "exploration" vs "exploitation," or "prosocial" vs "antisocial" equilibria) and which mode it ends in depends on early contingencies or perturbations; this resonates with phase-like regimes in complex adaptive systems.*
- *Strange-attractor type: bounded but never-settling dynamics, where small differences in initial state eventually lead to macroscopically different trajectories, yet the motion remains confined to an invariant set; this captures a kind of perpetual novelty generation without divergence.*

The usefulness of specifying strangeness via topological entropy (or a shift subsystem) is that it gives a rigorous certificate of complexity: one can import standard results from symbolic dynamics and factor maps.

Definition 614 (Quotient metric (one convenient choice)). *Given a metric (X, d) and a surjection $q : X \to A$, define a pseudo-metric on A by*

$$d_A(a, b) := \inf\{d(x, y) : q(x) = a,\ q(y) = b\}.$$

Assume we mod out any $a \neq b$ with $d_A(a, b) = 0$ so that (A, d_A) is a metric space.

Remark 3478. *This construction turns the macro space A into a metric space by declaring two macro-states close if there exist* some *micro representatives that are close. The infimum (rather than minimum) appears because the closest representatives may not exist, only be approximable.*

The warning about a pseudo-metric is important: it may happen that $a \neq b$ but $d_A(a, b) = 0$ if the fibers $q^{-1}(a)$ and $q^{-1}(b)$ can be made arbitrarily close in X. The text's "mod out" clause means we identify such macro-states to restore the separation axiom of a metric. In practice, one may equivalently replace A by the metric quotient induced by d_A.

A concrete geometric picture: take X to be the unit circle with the usual arc-length metric, and let q identify antipodal points. Then A is a projective circle; d_A computes distance between equivalence classes by choosing the closest representatives among the two antipodal pairs.

Theorem 214 (Attractors project under exact abstractions). *Let (X, F) be a dynamical system on a metric space, and let $q : X \to A$ be an exact dynamical abstraction inducing $G : A \to A$ with $q \circ F = G \circ q$. If $K \subseteq X$ is an attractor of F with basin neighborhood U, then $q(K)$ is an attractor of G and $q(U)$ is contained in its basin.*

Remark 3479. *In plain language: coarse-graining cannot destroy attraction. If many micro-states are pulled toward a micro-attractor K, then their macro-images are pulled toward the macro-image $q(K)$. This is the technical backbone for later claims that "attractor* type *is invariant under coarse-graining": one cannot have a stable macro fixed point if the macro system were not actually being attracted to something. This connects directly to the induced dynamics theorem: $q \circ F = G \circ q$ says q is a factor map. The present theorem then says attractors behave well under factor maps. For self-modifying minds, this means that if we choose macro-variables thoughtfully (in a way that is dynamically compatible), then long-run regimes are robust facts about the system, not artifacts of microscopic description. In other words, the "same" behavior is being described in two coordinate systems: the micro description on X and the macro description on A, with q ensuring that time evolution commutes with the change of variables. This is the sense in which coarse-graining is not merely an observational convenience but a structure-preserving map between dynamical systems, so statements about asymptotic regimes can be transported across levels.*

Proof. Invariance: if $x \in K$ then $F(x) \in K$, hence

$$G(q(x)) = q(F(x)) \in q(K),$$

so $G(q(K)) \subseteq q(K)$. Surjectivity of $q|_K$ implies equality. Indeed, if $b \in q(K)$ then $b = q(x)$ for some $x \in K$, and since K is F-invariant we have $F(x) \in K$, so $G(b) = G(q(x)) = q(F(x)) \in q(K)$; this shows forward invariance. Conversely, for any $c \in q(K)$ choose $z \in K$ with $q(z) = c$; by surjectivity of $q|_K$ and invariance of K, every point in $q(K)$ has a preimage inside K, and the image set $G(q(K))$ cannot be a strict subset of $q(K)$ once all macro points are realized by micro points whose forward images remain in K.

Attraction: take any $x \in U$ and let $a = q(x)$. Because K attracts U, $\mathrm{dist}(F^t(x), K) \to 0$. For each t, pick $y_t \in K$ with $d(F^t(x), y_t) \leq \mathrm{dist}(F^t(x), K) + 1/t$. Then

$$d_A(G^t(a), q(K)) \leq d_A(q(F^t(x)), q(y_t)) \leq d(F^t(x), y_t),$$

using the definition of d_A as an infimum. The right-hand side tends to 0, hence $G^t(a)$ approaches $q(K)$. Thus $q(K)$ attracts $q(U)$. Concretely, the role of the auxiliary points y_t is to "witness" closeness to K at each time: even if a minimizer for $\mathrm{dist}(F^t(x), K)$ does not exist (e.g. K not compact), the $1/t$ slack produces a sequence with asymptotically optimal distance. The quotient metric (or pseudometric) d_A is then designed so that identifying microstates cannot increase the distance between their equivalence classes: the best choice of representatives bounds the distance upstairs, which is exactly what the inequality $d_A(q(u), q(v)) \leq d(u, v)$ encodes. This ensures that convergence in X toward K is strong enough to imply convergence in A toward $q(K)$ along the factor-related trajectories. $\square$

Remark 3480. Proof sketch. *The key idea is that q transports trajectories: the macro trajectory of $a = q(x)$ is exactly $G^t(a) = q(F^t(x))$. To show attraction, approximate the distance from $F^t(x)$ to K by choosing a near-closest point $y_t \in K$, and then use the definition of the quotient metric d_A to bound the macro distance from $q(F^t(x))$ to $q(y_t)$ by the micro distance from $F^t(x)$ to y_t. Since the latter goes to 0, so does the former. In this sketch, the commuting relation $q \circ F^t = G^t \circ q$ (valid for all integers $t \geq 0$ by induction) is doing all the conceptual work: it guarantees that the macro evolution is not an approximation of the micro evolution, but literally its image under q at each time step.* $\square$

One can visualize the proof as "shadowing" the micro orbit by a point on the attractor and then projecting: micro convergence implies macro convergence because the quotient metric is designed to be no larger than the best-case micro separation between representatives. Equivalently, q may *collapse many microstates into a single macrostate, but it cannot separate two microstates that are already close; therefore any eventual trapping near K must manifest as eventual trapping near $q(K)$.*

Corollary 71 (Attractor type is a coarse-graining invariant)**.** *Under the assumptions of the previous theorem, if the macro-attractor $q(K)$ is (i) fixed-point, (ii) strange, or (iii) one of multiple distinct attractors, then the micro-system belongs to the corresponding attractor-type class at that abstraction level. More precisely, the micro dynamics restricted to K must realize the same qualitative regime classification once viewed through the same coarse-graining: a macro fixed point must be supported by micro behavior that projects to a fixed point; a macro strange attractor reflects genuine orbit-complexity in $F|_K$; and distinct macro attractors correspond to distinct micro invariant attracting sets whose images are disjoint in A.*

Remark 3481. *This corollary is the promised qualitative punchline: once the abstraction is dynamically exact, the macro taxonomy (fixed-point vs strange vs multi-attractor) is not merely a story we tell; it is enforced by the micro system because q is a factor map. In particular, macroscopic chaos cannot be an illusion created by projecting a simple micro-dynamics; a factor map cannot create topological entropy out of nothing. Intuitively, coarse-graining can destroy information (merging distinguishable micro histories), but the commuting condition prevents it from fabricating new distinguishable macro histories that were not already present in the micro system. Said differently, any apparent "branching" of macro futures must come from some genuine branching of micro futures, because every macro orbit segment has at least one micro lift consistent with the dynamics.*

Proof. Fixed-point and multi-attractor claims follow directly from projection and invariance. For strangeness: if $G|_{q(K)}$ has positive entropy (or a full shift factor), then $F|_K$ has at least that much complexity in the quotient sense because q is a factor map ($q \circ F = G \circ q$). In particular, F cannot be topologically simple if G is chaotic. Here one uses the standard monotonicity of topological entropy under factors: if (Y, H) is a factor of (X, T) via a continuous surjection π with $\pi \circ T = H \circ \pi$, then $h_{\text{top}}(H) \leq h_{\text{top}}(T)$. Taking $(X, T) = (K, F|_K)$, $(Y, H) = (q(K), G|_{q(K)})$, and $\pi = q|_K$ yields the claim. Likewise, if $G|_{q(K)}$ admits a subshift of finite type (or the full shift on $m \geq 2$ symbols) as a factor, then composing factor maps shows that the same symbolic subsystem is a factor of $F|_K$; thus the micro system must support exponentially many distinguishable orbit segments at the relevant scales. □

Remark 3482. Proof sketch. *Fixed points and multiple basins are preserved because invariant attracting sets project to invariant attracting sets, and disjointness of basins survives under a surjective projection. For strangeness, the crucial observation is categorical: q is a factor map, so symbolic complexity (e.g. a shift subsystem) seen at the macro level must be realizable by some micro orbits that map onto those symbol sequences. Hence the micro dynamics cannot be simpler than the macro dynamics in the sense relevant to topological entropy. One way to phrase the basin argument is: if U_1, U_2 are disjoint open basins in X attracted to distinct invariant sets K_1, K_2, then $q(U_1), q(U_2)$ remain disjoint in A provided q does not identify points across basins; under the theorem's hypotheses (and the use of $q|_{K_i}$ surjective onto $q(K_i)$), the images of distinct attractors remain distinct, so multiple-attractor structure is visible at the macro level.* □

A useful mental model is: projection may hide details, but it cannot invent genuinely new branching structure in the space of distinguishable orbits if the projection respects time evolution. In the self-modifying-mind setting, this means that if the macro description exhibits persistent switching, sensitive dependence, or multiple stable "modes" of cognition/behavior, then the underlying micro update rule must already contain the resources to support that long-run organization; coarse-graining can obscure mechanism, but it cannot conjure the regime itself.

65.3 Universality classes: equivalence under shared macro-dynamics

Definition 615 (Universality class at abstraction level q)**.** *Fix a macro-space A and a macro-map $G : A \to A$. The* universality class $\mathcal{U}(G)$ *is the class of all self-modifying minds (X, F) for which there exists an abstraction $q : X \to A$ that is an exact dynamical abstraction and induces the same G: $q \circ F = G \circ q$.*

Equivalently, q determines a "macro-equivalence" relation on microstates by $x \sim x'$ iff $q(x) = q(x')$, and the condition $q \circ F = G \circ q$ says that F respects this partition so that the induced quotient dynamics on the set of equivalence classes is exactly G. In this sense G is not merely an observational summary but a genuine factor of the micro-dynamics.

Remark 3483. *The phrase "universality class" is borrowed from statistical physics, where many micro-systems share the same critical exponents because coarse-graining flows to the same renormalization fixed point. Here the analogy is simpler but still philosophically potent: a mind can be implemented by many different micro architectures, yet if there is an exact quotient that yields the same macro law G, then for many purposes the implementations are interchangeable at that level of description [18].*

A concrete example: let A encode a small set of meta-states such as "goal update mode," "learning rate regime," and "exploration temperature." If two different agents (different neural nets, different code) admit abstractions that land in the same A and follow the same G, then they are in the same universality class. This is useful precisely because it gives a rigorous bridge from implementation plurality *to* theory unity *(Hyperseed-Concept 136, 51).*

Two clarifications are often helpful when reading the definition. First, q need not be injective: the fibers $q^{-1}(a)$ may contain many micro-configurations realizing the same macro description $a \in A$ (e.g. many neural weight matrices yielding the same effective learning-rate regime). Second, in the strongest reading one typically takes q to be surjective onto the macro-space one intends to model; otherwise one is really studying the induced dynamics on the reachable subset $q(X) \subseteq A$ with G restricted to that subset. The present definition can be read either way, but the motivating interpretation is that A is the intended macro state space and q realizes it as a genuine quotient of the micro system.

Finally, note that exactness matters: if $q \circ F$ merely approximately *agrees with $G \circ q$, then "same G" no longer rigidly determines the set of macro attractors, and the subsequent theorem becomes a stability statement rather than an equivalence statement. This section deliberately keeps the exact case as the baseline, because it cleanly isolates what is invariant* by definition *across implementations.*

Theorem 215 (Universality: same macro-map implies same macro attractor types)**.** *If (X_1, F_1) and (X_2, F_2) are in the same universality class $\mathcal{U}(G)$, then:*

- *every attractor of G lifts to (at least) one attractor in each micro-system whose projection is that macro-attractor; and*
- *macro attractor type (fixed-point vs strange vs multi-attractor) is shared across all members of $\mathcal{U}(G)$.*

Moreover, the lifting in the first bullet need not be unique: distinct micro-attractors (e.g. differing in within-fiber structure) may project to the same macro-attractor, so the theorem should be read as a guarantee of realizability *rather than a one-to-one correspondence.*

Remark 3484. *What this asserts is a disciplined form of "many roads lead to the same fate": if two self-modifying minds share the same induced macro dynamics, then they share the same menu* *of macro-level long-run regimes. The first bullet says macro attractors are not empty abstractions; each macro attractor is realized by at least one micro invariant attracting set mapping onto it. The second bullet then says the coarse taxonomy of fates is a property of the macro law G, hence common across the class.*

This connects backward to the factor-map attractor projection theorem, and forward to the canonical classes below: we will give conditions ensuring G is contractive, chaotic, or multi-well, thereby placing broad families of architectures into one of three archetypal universality classes.

One can also interpret the theorem as specifying which aspects of asymptotic behavior are "coordinate-free" with respect to implementation: if two agents differ only by replacing one micro-realization of the same macro factor G by another, then any statement that is formulable purely in terms of G (existence of fixed points, number of basins at the macro level, presence of a strange attractor as defined on A, etc.) is invariant across the class. Conversely, any phenomenon that depends on fiber geometry (e.g. how many micro states realize a given macro mode, or how rapidly trajectories mix within *a fiber) is not fixed by universality class membership and may vary widely even when G is identical.*

Proof. For each $i \in \{1, 2\}$ let $q_i : X_i \to A$ satisfy $q_i \circ F_i = G \circ q_i$. By the previous section, attractors in each (X_i, F_i) project to attractors of G. Conversely, for any macro-attractor $K \subseteq A$, consider the restricted micro-dynamics on the closed set $q_i^{-1}(K)$; invariance follows from $q_i \circ F_i = G \circ q_i$. Standard compactness arguments (e.g. existence of omega-limit sets) yield at least one invariant compact set in $q_i^{-1}(K)$ projecting onto K. Type-sharing is immediate because the type is determined at the macro level by G.

To make the "standard compactness arguments" more explicit: assuming the usual setting in which X_i is a compact (or at least forward-invariant, precompact) metric space and F_i is continuous, each nonempty closed invariant set contains a nonempty compact invariant ω-limit set. Pick a point $a \in A$ in the basin of attraction of K under G with $\omega_G(a) = K$ (for an attractor K such points exist by definition). Choose any $x \in X_i$ with $q_i(x) = a$; then semiconjugacy implies

$$q_i\big(\omega_{F_i}(x)\big) = \omega_G\big(q_i(x)\big) = \omega_G(a) = K,$$

where the equality uses continuity of q_i and the intertwining $q_i \circ F_i = G \circ q_i$ to commute ω-limits with projection. In particular, $\omega_{F_i}(x) \subseteq q_i^{-1}(K)$ is a compact invariant set whose image is exactly K. If one is working with a specific definition of "attractor" requiring attraction of a neighborhood, one can take the attracting set generated by $\omega_{F_i}(x)$ inside $q_i^{-1}(K)$; the key point is that at least one micro-level recurrent/invariant set exists whose macro shadow is precisely K.

Finally, since the classification "fixed-point vs strange vs multi-attractor" is defined by properties of G on A (e.g. how many attractors exist and what qualitative type they have), any two systems inducing the same G necessarily share that macro classification. Any remaining degrees of freedom live in the fiber dynamics and do not alter the macro taxonomy. □

Remark 3485. Proof sketch. *Projection of micro attractors to macro attractors is already established via factor-map reasoning. To "lift" a macro attractor K, restrict attention to the invariant preimage $q_i^{-1}(K)$ and take omega-limit sets of points in that preimage; compactness-style arguments then give an invariant compact set upstairs whose image is K. Finally, since the taxonomy is defined in terms of the macro map G, any two systems inducing the same G necessarily share the macro type.* □

The geometric intuition is that $q_i^{-1}(K)$ is an invariant "tube" above K; within that tube the micro dynamics must have some recurrent/invariant behavior, and at least one such invariant set projects onto the whole of K.

It is also useful to picture this tube as a bundle of fibers over K: for each $a \in K$, the fiber $q_i^{-1}(a)$ may support its own internal contraction, mixing, or even additional micro-attractors, but the projection erases those differences. Universality class membership therefore identifies what is common after modding out by within-fiber degrees of freedom, and the theorem formalizes that the long-run regimes visible at the macro resolution are fixed entirely by G.

65.4 Canonical macro-classes motivated by the Hyperseed-adjacent documents

This section shows that several macro-maps G of interest arise naturally from the attached frameworks, yielding three canonical universality classes.

65.4.1 Fixed-point universality from goal-contraction metagoals

Definition 616 (Goal-state contraction regime)**.** *Let $(\mathcal{G}, d)$ be a complete metric space of possible goal-configurations. A self-modifying mind produces a goal trajectory $G_t \in \mathcal{G}$ at times $t \in \{0, N, 2N, \dots\}$. We say it satisfies* goal contraction *with coefficient $c \in (0,1)$ if for all $k \geq 1$,*

$$d(G_{(k+1)N}, G_{kN}) \leq c\, d(G_{kN}, G_{(k-1)N}).$$

Remark 3486. *The symbol $\mathcal{G}$ denotes a space of goal-configurations (one may think of vectors of weights in a utility function, parameters of a preference model, or a structured object encoding priorities), and d is a metric measuring how different two goal states are. Completeness is the standard hypothesis ensuring Cauchy sequences converge, preventing "limit goals" from falling outside the space.*

Intuitively, the condition says that successive changes *in the goal state shrink geometrically: the mind may still revise its goals, but each revision is smaller than the previous by a fixed factor $c < 1$. This is a natural sufficient condition for meta-goal stabilization, and it is closely aligned with fixed point methods used to analyze self-referential or self-modifying goal dynamics [10] (Hyperseed-Concept 110). A toy example: if the mind updates a scalar goal parameter by $G_{(k+1)N} = G_{kN} + \Delta_{k+1}$ with $|\Delta_{k+1}| \leq c\,|\Delta_k|$, then the total drift is finite.*

Theorem 216 (Goal contraction implies convergence of goals (fixed-point behavior))**.** *Assume $(\mathcal{G}, d)$ is complete and the goal trajectory satisfies goal contraction with $c \in (0,1)$. Then $(G_{kN})_{k\geq 0}$ converges to a limit goal $G_\infty \in \mathcal{G}$, and*

$$d(G_{kN}, G_\infty) \leq \frac{c^k}{1-c}\, d(G_N, G_0).$$

Remark 3487. *This result says: if the mind's meta-updates damp themselves in the specific geometric way above, then the mind's goals settle to a definite limit. The bound is explicit: after k macro-steps, the distance to the limit decays at least as fast as c^k up to the factor $1/(1-c)$. In the language of attractors, the goal macro-variable has fixed-point type behavior.*

This is important because it gives a checkable sufficient condition for one of the three canonical universality classes: contractive/fixed-point. It also foreshadows the later interpretation: different micro-architectures can still share goal contraction at the macro level, hence share the same qualitative long-run stabilization regime.

Proof. Let $\Delta_k := d(G_{kN}, G_{(k-1)N})$ for $k \geq 1$. The contraction condition implies $\Delta_{k+1} \leq c\Delta_k$, hence $\Delta_k \leq c^{k-1}\Delta_1$ by induction.

For $m > n$,

$$d(G_{mN}, G_{nN}) \leq \sum_{k=n+1}^{m} d(G_{kN}, G_{(k-1)N}) = \sum_{k=n+1}^{m} \Delta_k \leq \Delta_1 \sum_{k=n+1}^{\infty} c^{k-1} = \frac{c^n}{1-c}\Delta_1.$$

Thus (G_{kN}) is Cauchy; completeness gives convergence to some G_∞. Taking $m \to \infty$ in the inequality yields the stated bound. □

Remark 3488. Proof sketch. *The proof turns the contraction condition on successive increments into a geometric series bound. Define the step sizes Δ_k; they shrink like c^{k-1}. Then any tail distance $d(G_{mN}, G_{nN})$ is bounded by the sum of increments from $n+1$ to m, which is bounded by the tail of a geometric series. Hence the sequence is Cauchy and converges by completeness; letting $m \to \infty$ yields the explicit error bound.* □

Visually: each goal update is a shorter "hop" than the last, so the total path length is finite; in a complete space, a path of finite total length must accumulate at a limit point.

Corollary 72 (Fixed-point universality class from contraction metagoals)**.** *Any self-modifying mind architecture whose macro-variable "goal state" obeys goal contraction (coarse-grained at interval N) lies in a fixed-point universality class at that abstraction level.*

Remark 3489. *This is the first canonical universality class: different implementations may vary in how they represent goals internally, how they compute meta-updates, and how they modify themselves, yet if the induced macro goal dynamics contracts in the above sense, then the macro story is essentially one of convergence to a single limiting goal configuration. In alignment-motivated language, one would say that the system has a structural bias toward goal stabilization rather than runaway drift [10].*

Proof. The macro-dynamics on $\mathcal{G}$ contracts successive increments geometrically, forcing convergence to a fixed limit (a macro fixed point). By the attractor projection theorem, members of the universality class share this fixed-point macro-attractor type. □

Remark 3490. Proof sketch. *Use the previous theorem to conclude the macro goal variable converges to G_∞, i.e. it has a fixed-point attractor at the macro level. Then apply the general coarse-graining/attractor invariance results: any micro system inducing that macro dynamics must share the fixed-point attractor type at that abstraction level.* □

65.4.2 Strange-attractor universality from Lorenz-like macro feedback

We isolate the abstract dynamical fact that produces chaos.

Definition 617 (Robust strange macro-dynamics via a horseshoe)**.** *A continuous map $G : A \to A$ has a* horseshoe *if there exists a compact invariant set $\Lambda \subseteq A$ such that $G|\Lambda$ is topologically conjugate to the full shift on two symbols.*

Remark 3491. *The compactness and invariance assumptions are doing real work: compactness ensures the symbolic encoding lives on a closed, bounded "chaotic core," while invariance ($G(\Lambda) = \Lambda$) guarantees that once an orbit enters Λ it never leaves, so the symbolic dynamics is not merely transient. In many classical settings (e.g. C^1 diffeomorphisms on manifolds), the presence of a horseshoe is also* structurally stable *under small perturbations of the map in an appropriate topology, which is why horseshoes are often treated as robust witnesses of chaos rather than fine-tuned curiosities.*

Remark 3492. *A horseshoe is a classical certificate of chaos: it asserts that within Λ, the dynamics of G is as complicated as the shift map on bi-infinite binary sequences. "Topologically conjugate" means there is a homeomorphism $h : \Lambda \to \{0,1\}^{\mathbb{Z}}$ such that $h \circ G = \sigma \circ h$, where σ is the shift. Thus the macro system literally contains a perfect symbolic computation of binary histories.*

The relevance to self-modifying minds is that certain macro feedback loops (often described informally as "Lorenz-like") generate stretching-and-folding behavior, and the horseshoe captures that behavior in a rigorous way without committing to a particular differential equation.

Theorem 217 (Horseshoe implies strange-attractor type)**.** *If G has a horseshoe Λ, then G has positive topological entropy and exhibits sensitive dependence on initial conditions on Λ. In particular, any attractor containing Λ is of strange-attractor type under our taxonomy.*

Remark 3493. *The phrase "any attractor containing Λ" is meant in the usual dynamical-systems sense: an attractor is an invariant set that attracts a neighborhood (equivalently, has a basin of attraction of nonempty interior in many standard definitions). The point is that if the attracting region contains a horseshoe subset, then the attractor cannot be purely fixed-point or limit-cycle type, because it contains a subsystem whose orbit-complexity is already maximal in the symbolic (shift) sense.*

Remark 3494. *This theorem translates a structural condition (presence of a symbolic shift subsystem) into the qualitative taxonomy term "strange attractor." What is conceptually striking is that one may certify chaos without solving the system: the mere existence of a horseshoe forces exponentially many distinguishable orbit segments and thus forces unpredictability in the strong topological sense.*

Proof. For the full shift on two symbols, the number of distinct length-n symbolic orbits is 2^n. Conjugacy transfers this exponential growth of distinguishable orbits to $G|\Lambda$, giving positive topological entropy. Positive entropy implies sensitive dependence on initial conditions (on compact metric spaces, in standard settings). Hence any invariant set containing Λ supports sustained nonperiodic, sensitive dynamics, i.e. strange-attractor type. □

Remark 3495. *Concretely, the full two-shift has topological entropy* $\log 2$, *and topological conjugacy preserves topological entropy because it preserves the open-cover growth rates (or equivalently, separated-set growth rates) used to define it. Sensitivity can also be seen directly from the shift model: for any symbolic sequence and any cylinder neighborhood (agreement on a long but finite window), one can flip a bit far enough out in the sequence to obtain a nearby initial condition whose orbit eventually disagrees at the present coordinate, forcing a macroscopic separation after some iterate.*

Remark 3496. Proof sketch. *Because $G|\Lambda$ is conjugate to the full two-shift, it inherits the two-shift's exponential growth of distinct orbit segments (2^n words of length n), which is exactly what positive topological entropy measures. Standard implications then yield sensitive dependence. Therefore any attractor that contains Λ contains this chaotic core and is strange in the chosen taxonomy.* □

A visual intuition (the origin of the term "horseshoe") is the repeated stretch-and-fold action: the map elongates a region, folds it back, and overlays it, creating a binary branching of itineraries.

Corollary 73 (Strange-attractor universality class from coarse-grained Lorenz-like dynamics)**.** *Suppose a family of self-modifying minds admits abstractions $q_i : X_i \to A$ inducing the same macro-map G and G has a horseshoe (or other robust chaos witness). Then the entire family lies in a strange-attractor universality class at that abstraction level.*

Remark 3497. *This is the second canonical universality class: if the shared macro dynamics contains a robust chaos witness, then micro architectural variation cannot remove that chaos at the macro level, because the chaos is a property of G and G is shared. In informal cognitive terms, this describes minds whose long-run self-modification dynamics remain bounded yet perpetually novel, with persistent sensitivity to early conditions and perturbations.*

Remark 3498. *Operationally, the hypothesis "induces the same macro-map G" can be read as: after coarse-graining by q_i, each system's macro evolution is well-approximated (or exactly represented, depending on the formal setup) by iterating G. The horseshoe then acts as an invariant, representation-independent obstruction to reducing the macro behavior to a single fixed point or a simple cycle: even if microscopic mechanisms differ, any member that truly instantiates the same G must instantiate the same symbolic shift subsystem.*

Proof. Immediate from the universality theorem: macro chaos is shared across the class, hence the macro attractor type is strange for all members. ☐

Remark 3499. Proof sketch. *Apply the universality theorem with the shared G; since G is strange-attractor type, all systems in the class share that macro type.* ☐

65.4.3 Multi-attractor universality from multi-well macro potentials

Definition 618 (Gradient-like macro dynamics)**.** *Let $A \subseteq \mathrm{R}^n$ and let $V : A \to \mathrm{R}$ be C^1. Consider a discrete-time macro update*

$$a_{t+1} = a_t - \eta \nabla V(a_t),$$

with step size $\eta > 0$ small enough that $V(a_{t+1}) \leq V(a_t)$ whenever a_t is not critical.

Remark 3500. *A sufficient (though not necessary) condition guaranteeing the displayed monotonic decrease is the standard smoothness/Lipschitz-gradient assumption: if ∇V is L-Lipschitz on the region of interest, then choosing $\eta \in (0, 2/L)$ yields $V(a_{t+1}) \leq V(a_t)$, with strict inequality away from critical points. This connects the abstract "small enough" hypothesis to a checkable analytic condition and emphasizes that the definition is meant to capture a broad class of dissipative, Lyapunov-decreasing macro updates rather than a single algorithmic choice.*

Remark 3501. *This is the archetype of "downhill motion" in a potential landscape: the macro state a_t moves in the direction of steepest descent of V. The condition on η ensures the potential does not increase along the update (a standard discrete-time analogue of energy dissipation). In optimization language, this is gradient descent; in dynamical language, it is a dissipative system tending toward critical points.*

For self-modifying minds, a_t could represent a coarse-grained meta-parameter vector (e.g. high-level goal weights, trust/coordination parameters, or exploration/exploitation balance), and V could represent a Lyapunov-like functional measuring inconsistency, regret, or some macro "tension" to be relaxed (Hyperseed-Concept 100, 87).

Definition 619 (Basin of attraction (discrete time))**.** *Let $G : A \to A$ and let $S \subseteq A$ be invariant. The* basin of attraction *of S (when it exists in the intended sense) is the set of initial conditions $a_0 \in A$ such that the forward orbit approaches S, e.g.* $\mathrm{dist}(a_t, S) \to 0$ *as $t \to \infty$. A system is* multi-attractor type *if it has two or more attracting invariant sets with basins that are not identical (typically, basins separated by stable manifolds or other boundary sets).*

Theorem 218 (Multiple strict local minima yield multiple attractors)**.** *Assume V has at least two strict local minima $m_1 \neq m_2$ with disjoint neighborhoods U_1, U_2 such that $V(x) > V(m_j)$ for all $x \in U_j \setminus \{m_j\}$. For sufficiently small η, each m_j is an attracting fixed point of the gradient-like macro dynamics, and the system is multi-attractor type.*

Proof. Each strict local minimum m_j is a critical point, so it is a fixed point of the update: $m_j - \eta\nabla V(m_j) = m_j$. By strict local minimality, there exists a neighborhood U_j on which $V(x) > V(m_j)$ for $x \neq m_j$. For η small enough to ensure $V(a_{t+1}) \leq V(a_t)$ with strict decrease whenever a_t is not critical, any orbit starting sufficiently close to m_j cannot leave U_j while decreasing V (since leaving would require passing through points of potential no smaller than the boundary values, contradicting monotone descent toward the unique minimum value $V(m_j)$ within U_j). Thus m_j attracts a neighborhood, i.e. it is an attracting fixed point.

Because $m_1 \neq m_2$ and U_1, U_2 are disjoint, the two attracting fixed points have distinct basins (at least locally, U_j is contained in the basin of m_j). Hence the macro dynamics admits multiple coexisting attractors and is multi-attractor type. □

Remark 3502. *The disjoint-neighborhood condition is a clean way to ensure the minima correspond to genuinely distinct macro endpoints rather than different parameterizations of the same asymptotic behavior. In landscape language, the boundaries between basins are the "ridges" or separatrices: sets of initial macro states from which infinitesimal changes can send the system to different long-run self-modification outcomes. This directly motivates the multi-attractor universality class as a coarse-grained analogue of path-dependence: early perturbations can select which well (and thus which stable self-modification regime) the mind ultimately commits to.*

Corollary 74 (Multi-attractor universality class under shared potential landscape)**.** *Suppose a family of self-modifying minds admits abstractions $q_i : X_i \to A$ inducing the same gradient-like macro dynamics for a shared potential V with at least two strict local minima as above. Then, at that abstraction level, the entire family lies in a multi-attractor universality class.*

Proof. All members share the same macro update rule (equivalently, the same map $G(a) = a - \eta\nabla V(a)$), so the existence of multiple attracting fixed points is a property of the shared macro description rather than of micro implementation details. Applying the preceding theorem to this common G yields multi-attractor type for every member at the given abstraction level. □

Remark 3503. *This theorem is the third canonical mechanism: when the macro landscape has multiple "wells," the system settles into one of several stable equilibria depending on where it starts. The conclusion is not merely that there are multiple equilibria, but that they are* attracting *and have disjoint basins of attraction, which is exactly what "multi-attractor type" demands. In particular, "disjoint basins" is a dynamical statement: there exist open sets B_j with $m_j \in B_j$ such that $T^t(x) \to m_j$ for all $x \in B_j$, and $B_i \cap B_j = \varnothing$ for $i \neq j$, so the limiting macro behavior cannot be the same for all initial macro-states. Equivalently, coarse-graining reveals multiple stable macro-level endpoints rather than a single fixed point or a single strange attractor supporting persistent exploration.*

Conceptually, this is the mathematical skeleton underlying phenomena like path dependence, hysteresis, and phase-like regime selection in learning systems: early random fluctuations can commit the system to one long-run mode. One can also interpret the "wells" as distinct internally-consistent self-modification regimes: after the macro-state enters a basin, subsequent self-updates remain confined to that region and converge to the corresponding equilibrium unless perturbed by sufficiently large exogenous shocks.

Proof. At a strict local minimum m_j, $\nabla V(m_j) = 0$ so m_j is a fixed point. Here "strict" ensures m_j is an isolated minimum (not a flat manifold of minimizers), which is what permits a neighborhood to be cleanly assigned to that attractor rather than drifting along a plateau. For η small, the map $T(x) = x - \eta\nabla V(x)$ is a local contraction around m_j whenever the Hessian is positive definite there (standard linearization: eigenvalues of $I - \eta H$ lie in $(0, 1)$ for small enough η). Hence each m_j attracts some neighborhood. More explicitly, if $H = \nabla^2 V(m_j) \succ 0$ has eigenvalues $\lambda_k > 0$, then the eigenvalues of $I - \eta H$ are $1 - \eta\lambda_k$, so choosing η with $0 < \eta < 2/\lambda_{\max}$ makes the linearized map strictly contractive in the norm induced by the eigenbasis; the nonlinear remainder is controlled on a sufficiently small neighborhood by continuity of $\nabla^2 V$. This yields a basin of attraction containing a ball around m_j, i.e. there exists $r_j > 0$ such that $\|x - m_j\| < r_j$ implies $T^t(x) \to m_j$. With two disjoint attracting basins, the macro-system is multi-attractor type. (Disjointness can be ensured, for example, by taking the radii small enough that the corresponding balls do not overlap, which is possible when the minima are distinct.) □

Remark 3504. Proof sketch. *Local minima are fixed points because the gradient vanishes. Near a strict local minimum with positive definite Hessian, the gradient map is approximately linear with Jacobian $I - \eta H$, whose eigenvalues lie strictly inside $(0, 1)$ for sufficiently small η, making the update a local contraction. Thus each minimum attracts a neighborhood, giving at least two disjoint basins and hence multi-attractor type.* □

In the background is the standard contraction-mapping intuition: once iterates enter a region where the update shrinks distances, the orbit forgets fine-grained initial conditions within that region and collapses to the unique fixed point in that neighborhood. The "sufficiently small η" condition can be read as a stability-of-discretization requirement: even if the continuous-time gradient flow $\dot{x} = -\nabla V(x)$ is stable at m_j, overly large discrete steps can overshoot and destroy local attraction.

A geometric picture is to imagine a ball rolling on a surface with two valleys: friction (the monotone decrease of V) prevents it from climbing out, so it ends in whichever valley it starts nearest. In this analogy, the basin boundary corresponds to the separatrix (often passing through saddles) that divides initial conditions by their eventual valley, and the "multi-attractor" claim is precisely that both valleys have nontrivial catchment regions.

Corollary 75 (Multi-attractor universality class from multi-well coarse-graining)**.** *If a family of self-modifying minds coarse-grains to the same multi-well gradient-like macro map, then all members share a multi-attractor macro landscape (at least the same number of basins). Here "at least" is meant in the sense that each attracting macro-equilibrium of the shared map persists as an attracting macro-equilibrium for every member under the common coarse-grained description, so the family cannot collapse to a single-basin macro picture without changing the macro map itself.*

Remark 3505. *This states that multi-stability is a universality property: if the macro map is shared and has multiple wells, then micro implementation details do not remove the existence of multiple basins* at that macro level. *One may view this as a cautionary alignment lesson: if the macro landscape contains multiple stable regimes, ensuring entry into the "right" basin requires more than merely ensuring eventual stability. In particular, two systems can be equally "stable" in the sense of converging to some attractor, yet be qualitatively different in outcomes because they converge to* different *attractors on different initial-condition sets. From the coarse-graining viewpoint, "universality" asserts that once the macro-level update rule G is fixed, the number and qualitative type of macro attractors is a structural property of G rather than an accident of a particular micro-realization.*

Proof. Apply the universality theorem with macro-map G given by the shared gradient-like update. Concretely, since all members induce the same G on macro-states, and G has multiple attracting fixed points with disjoint basins, the universality conclusion transfers this multi-attractor structure to each member's coarse-grained dynamics. □

Remark 3506. Proof sketch. *The macro map G is the same across the family and has multiple attracting fixed points; universality then implies the macro attractor type is shared across the family.* □

One can read this as a robustness statement: changing low-level implementation may alter trajectories in micro-state space, but as long as the coarse-grained macro update is preserved, the large-scale partition of macro initial conditions into distinct long-run regimes is preserved as well.

65.5 Grand Target-1 statement: broad architectures coarse-grain to attractor types

Definition 620 (Exact dynamical abstraction / factor map viewpoint)**.** *An* exact dynamical abstraction *from a micro system (X, F) to a macro system (A, G) is a map $q : X \to A$ such that the diagram commutes:*

$$q \circ F = G \circ q.$$

In dynamical-systems language, q is then a (semi-)conjugacy or factor map*, and (A, G) is a* factor *of (X, F). The interpretation is that q forgets micro-level distinctions while preserving the time-evolution of the retained macro variables exactly. In particular, the macro state $q(x_t)$ evolves as if it were generated directly by iterating G on A, regardless of which micro realizer x_t within the fiber $q^{-1}(a)$ one began with.*

Theorem 219 (Attractor-type universality under Hyperseed-style abstraction)**.** *Let $\{(X_i, F_i)\}_{i\in I}$ be a family of self-modifying minds. Suppose there exists a macro space A and, for each i, an abstraction $q_i : X_i \to A$ that is an exact dynamical abstraction inducing a single macro-map $G : A \to A$ satisfying $q_i \circ F_i = G \circ q_i$.*

Then the family decomposes into universality classes labeled by the attractor type *of G:*

- *If G has a unique globally attracting fixed point, then all (X_i, F_i) are fixed-point type (at that abstraction level). Here "globally attracting" means that for every initial macro state $a \in A$, the iterates $G^t(a)$ converge to the same fixed point $a^\star$, so that all micro initial conditions become indistinguishable under q_i in the long run.*

- *If G admits a robust chaos witness (e.g. a horseshoe), then all (X_i, F_i) are strange-attractor type (at that abstraction level). Robustness is included to ensure the classification is not an artifact of a measure-zero parameter choice: the qualitative presence of sensitive dependence and complicated invariant structure persists under small admissible perturbations of G at the macro level.*

- *If G admits at least two disjoint attractors with disjoint basins, then all (X_i, F_i) are multi-attractor type (at that abstraction level). Disjoint basins guarantee genuine long-run path-dependence at the macro scale: distinct regions of A flow to distinct asymptotic behaviors, so the macro limit set is not determined solely by the update rule but also by the initial macro state.*

In each case, micro-architectural variation within the family does not change the macro attractor type. Equivalently, once the same induced G is fixed, the only remaining variability across i can live inside the fibers of q_i (the "implementation details" that the abstraction discards), and such variation cannot alter the qualitative asymptotic regime as seen in A.

Remark 3507. *This theorem is the "Grand Target-1" consolidation: once Hyperseed-style abstraction is made exact, the macro dynamical regime is a genuine invariant of the family. The result is not claiming that all minds become identical, but that when viewed through the same dynamically compatible quotient, they share the same qualitative long-run form.*

In applications, the hard work is typically to justify the existence of a useful exact (or approximate) abstraction q_i across architectures. Hyperseed's ontology treats this as a central epistemic act: choosing which distinctions matter for the question at hand (Hyperseed-Concept 51, 98) [1]. Once that act is disciplined by dynamical compatibility, the long-run classification becomes mathematically forced rather than interpretive.

It is also worth emphasizing that the universality claim is always relative to the chosen macro space A *and maps* q_i*. A finer abstraction (retaining more distinctions) may yield a different induced macro dynamics and hence a different attractor-type classification, while a coarser abstraction may merge multiple micro attractors into a single macro attractor. The theorem should therefore be read as:* given *an exact shared quotient that induces a single* G*, the attractor-type label is fixed.*

Proof. This is a direct combination of: (i) existence/uniqueness of G under exact dynamical abstraction, (ii) projection of attractors under factor maps, and (iii) the definition of the attractor type as a macro property of G.

For completeness, one can spell out the implication from commutativity to shared asymptotics as follows. Fix i and let $x \in X_i$ be an arbitrary micro initial condition, with macro image $a = q_i(x)$. By iterating the commutation relation, one has $q_i(F_i^t(x)) = G^t(q_i(x)) = G^t(a)$ for all integers $t \geq 0$. Thus, any convergence, recurrence, or basin-membership statement that is formulated purely in terms of the orbit $\{G^t(a)\}_{t\geq 0}$ transfers immediately to the observed macro behavior of the micro orbit under q_i.

When G has a unique globally attracting fixed point $a^\star$, we get $q_i(F_i^t(x)) \to a^\star$ for all $x \in X_i$, which is precisely the fixed-point-type conclusion "at that abstraction level." When G contains a chaos witness such as a horseshoe (in whatever formal setting has been adopted earlier), the same witness is present in the induced macro dynamics for every member of the family because the macro dynamics is literally the same G for all i. Likewise, if G has at least two disjoint attractors with disjoint basins in A, then the dependence of the limit behavior on the initial macro state is shared across the family, since $q_i(F_i^t(x))$ tracks $G^t(q_i(x))$ exactly. □

Remark 3508. Proof sketch. *First, exact dynamical abstraction produces a unique induced macro map G. Second, factor-map arguments show that attraction/invariance structure is respected under projection, so macro attractors correspond to macro images of micro attractors and vice versa in the sense used earlier. Finally, since the three-type taxonomy is defined at the macro level (global fixed point vs chaos witness vs multiple disjoint basins), the classification is shared by all micro systems that induce the same G.* □

One may think of this as a structural form of objectivity: once a family agrees on a macro law G, the coarse qualitative destiny is no longer a matter of perspective; it is a theorem.

A subtlety is that, in many dynamical formalisms, "attractor" can be defined in multiple inequivalent ways (topological, measure-theoretic, pullback, Milnor attractor, etc.). The statement here should be read as parametrized by the adopted attractor notion: whatever definition is used to declare G to have a global fixed point, a chaos witness, or multiple disjoint basins, that declaration is a property of G alone, and therefore is shared across the entire family that factors through G.

Remark 3509 (Interpretation for self-modifying minds)**.** *These results do not claim all minds converge to the* same point*. They claim that, after a well-chosen Hyperseed-style quotient q (collapsing micro implementation differences), broad families of minds can share the same* qualitative *long-run regime: stable fixed point (reflective equilibrium), sustained bounded exploration (strange attractor), or multiple basins (multi-attractor, phase-like regimes). This provides a principled sense in which many distinct architectures can belong to the same "universality class" for reasoning and alignment analysis.*

Concretely, one can regard X_i as a space of internal configurations of architecture i (including self-modification state), F_i as the end-to-end "one cognitive step" update (including rewriting parts of itself), and q_i as a semantics-preserving projection to a macro description such as: a policy class identifier, a value-function summary, a belief-state coarse graining, or an invariant specification of the self-modification protocol. The theorem then says: if these summaries are chosen so that they are dynamically compatible in the strong sense $q_i \circ F_i = G \circ q_i$, then the long-run kind *of macro behavior (single terminal regime, persistent complex wandering, or multiple stable modes with basin structure) is determined entirely by G, and hence is shared across the family.*

In alignment terms, this supports separating (a) the question of identifying the right quotient for the analysis objective (what distinctions matter) from (b) the classification of the resulting macro trajectory types once that quotient is fixed. The former is an epistemic/ontological choice; the latter becomes a dynamical consequence.

66 Selection Implies Trust-Capable Coordination: Explicit Evolutionary Dynamics over Communities and Mindplexes

We formalize a general bridge from (i) "measure-zero" style dominance results for prosocial/trusting coordination over trustless/stability-constrained coordination, to (ii) explicit evolutionary and cultural selection dynamics over communities (and mindplex-like collectives). The goal is to prove that if (in a rich task environment) trust-capable coordination is almost always strictly more efficient than trustless coordination, then a wide family of selection dynamics generically drives a population toward trust-capable coordination, provided it is reachable and not forbidden by hard constraints. The results are phrased so they can be used as inference lemmas inside a reasoning system that models societies, institutions, or multi-agent AI ecologies.

Remark 3510. *Philosophically, the thread here is an old one: if some form of organization can* strictly dominate *another on nearly all circumstances that actually arise, then, barring unusual barriers, time tends to magnify the dominant form. The mathematics below turns this maxim into a sequence of precise implications. In the language of the Hyperseed core-concept set, we are reasoning about how* Tasks *(Hyperseed-Concept 186) and* Society *(Hyperseed-Concept 170) interact under selection-like update rules.*

66.1 Setup

66.1.1 Tasks and regimes

Definition 621 (Task environment)**.** *Let $(\mathcal{A}, \mathcal{F}, \nu)$ be a probability space of task instances. An instance is indexed by $\alpha \in \mathcal{A}$ and has an associated performance objective. We write the attainable expected performance of a given community regime r on task α as $V_r(\alpha) \in \mathbb{R}$.*

Remark 3511. *The notation $(\mathcal{A}, \mathcal{F}, \nu)$ is standard: $\mathcal{A}$ is the set (or measurable space) of tasks, $\mathcal{F}$ is a σ-algebra of measurable task-events, and ν is a probability measure describing how often each kind of task is encountered. Thinking concretely, α might be "build a bridge under constraints,"* *"coordinate a supply chain under shocks," or "train a distributed model under partial observability." The key point is that tasks are not a single benchmark but a* distribution *of situations (Hyperseed-Concept 186).*

The quantity $V_r(\alpha)$ abstracts away the internal details of regime r and reports what matters for selection: how well the regime can do on task α in expectation (e.g. after optimizing internal parameters, averaging over randomness, or averaging over within-regime variation). For example, if r is a mechanism with incentive constraints, then $V_r(\alpha)$ could be its best achievable welfare subject to those constraints on the instance α.

Definition 622 (Trustless vs trust-capable regimes)**.** *Let $\mathcal{R}$ be a set of possible community regimes. We single out:*

- *A* trustless *regime class $\mathcal{R}_{\mathrm{L}} \subseteq \mathcal{R}$, whose feasible coordination procedures must satisfy stability constraints (e.g. incentive compatibility, individual rationality, budget balance, or analogous "strategic robustness" constraints).*
- *A* trust-capable *regime $\mathrm{T} \in \mathcal{R}$, meaning: whenever a trustless procedure is feasible, T can emulate it, and T also has additional low-overhead cooperative procedures available when genuine alignment/trust suffices.*

Remark 3512. *Intuitively, $\mathcal{R}_{\mathrm{L}}$ captures regimes that must behave as though each subagent is a strategic adversary or, at least, that no deep coordination can be presupposed. This is the world of robust contracts, formal mechanism design, and procedures that continue to function even if each participant optimizes only for themselves. By contrast, T is not merely "trusting" in a sentimental sense; it is* capable *of trust: it can operate in the trustless mode when needed, but it can also exploit the extra degrees of freedom available when participants share goals or can reliably commit to joint intent.*

A simple example is a team that can fall back to formal voting or signed contracts (emulating a trustless protocol), but when trust is present can instead use low-overhead delegation, rapid information sharing, and flexible role adaptation. In multi-agent AI terms, T can run a conservative, incentive-compatible protocol, but can also run a high-bandwidth cooperative protocol when alignment holds.

This definition is structurally necessary for the later "inclusion" assumption: without an emulation property, one cannot cleanly assert that trust-capable coordination is never worse, because it might be better on some tasks but fail on others. The emulation clause makes T a superset of feasible behaviors of $\mathcal{R}_{\mathrm{L}}$, aligning with the idea that trust adds capabilities rather than removing them. At the level of social ontology, this concerns regimes of Intersubjective Reality *(Hyperseed-Concept* **??***) more than individual psychology: what matters is what coordination patterns are feasible and stable.*

Assumption 3 (Asymmetry of trust as feasibility-set inclusion)**.** *For every task α,*

$$V_{\mathrm{T}}(\alpha) \;\geq\; \sup_{r \in \mathcal{R}_{\mathrm{L}}} V_r(\alpha).$$

Assumption 4 ((GGW-type) measure-zero strictness)**.** *There exists a measurable function*

$$\Delta(\alpha) \;:=\; V_{\mathrm{T}}(\alpha) \;-\; \sup_{r \in \mathcal{R}_{\mathrm{L}}} V_r(\alpha) \;\geq\; 0$$

such that

$$\nu\big(\{\alpha : \Delta(\alpha) > 0\}\big) \;=\; 1,$$

and Δ is integrable: $\mathbb{E}_{\alpha\sim\nu}[|\Delta(\alpha)|] < \infty$.

Remark 3513. *Assumption 4 is the abstract form of "trustless-friendly tasks are a measure-zero exception." Assumption 3 captures the core structural reason: trust-capable communities can do everything trustless communities can do, plus more.*

Remark 3514. *The label "GGW-type" is meant to evoke the general style of argument that cooperative/prosocial structures are generically more efficient on rich families of problems, with "exceptions" lying in thin or nongeneric subsets of task space; see [6] for an informal but broad discussion of this kind of dominance claim. The integrability condition is a technical way of excluding pathological cases where $\Delta(\alpha)$ is positive almost everywhere but has infinite mean, which would make later expectations ill-defined.*

Note also the convention implicit in $\sup_{r\in\mathcal{R}_{\mathrm{L}}} V_r(\alpha)$*: for each task α we allow the trustless class to pick its best-performing regime. This makes the dominance assumption* harder *to satisfy and therefore strengthens any conclusions drawn from it.*

66.1.2 Selection over community regimes

We model a population of communities. Each community instantiates a regime $r \in \mathcal{R}$. Communities encounter tasks and reproduce (or are imitated) according to achieved performance.

Definition 623 (Expected fitness of a regime)**.** *Define the expected fitness (expected performance) of regime r by*

$$f(r) \;:=\; \mathbb{E}_{\alpha\sim\nu}[V_r(\alpha)].$$

Remark 3515. *Here $f(r)$ is the long-run average score of regime r under the environment ν. The expectation $\mathbb{E}_{\alpha\sim\nu}[\cdot]$ means: sample a random task instance α according to ν, evaluate how well r can do on that instance (via $V_r(\alpha)$), and average.*

A toy example: if $\mathcal{A} = \{\alpha_1, \alpha_2\}$ with probabilities $\nu(\alpha_1) = 0.9$ and $\nu(\alpha_2) = 0.1$, then $f(r) = 0.9V_r(\alpha_1)+0.1V_r(\alpha_2)$. This is useful because many selection dynamics (replicator, imitation, multiplicative weights) can be driven by such an average fitness, either explicitly (deterministic dynamics) or implicitly (stochastic sampling converges to this average).

Remark 3516 (Why expectation is the right object for selection)**.** *The definition of $f(r)$ abstracts away from any particular within-task randomness by treating the task draw $\alpha \sim \nu$ as the primitive source of environmental variation. In typical evolutionary or learning models, what matters for growth rates is precisely a mean performance quantity of this form: even if realized payoffs fluctuate from round to round, laws of large numbers imply empirical averages track $\mathbb{E}_{\alpha\sim\nu}[V_r(\alpha)]$ when tasks are sampled repeatedly from a stationary environment. Thus, inequalities between $f(r)$ translate into persistent differences in long-run population shares under standard update rules.*

66.2 Core bridge: measure-zero dominance implies selection advantage

Theorem 220 (Positive mean advantage from almost-sure strict advantage)**.** *Under Assumption 4,*

$$f(\mathrm{T}) \;>\; \sup_{r\in\mathcal{R}_{\mathrm{L}}} f(r).$$

Remark 3517 (Intuitive content and why it matters)**.** *This theorem says: if trust-capable coordination is* never worse *on any task, and is* strictly better *on almost every task that actually occurs (probability 1 under ν), then trust-capable coordination is also strictly better* on average*. In other words, "almost sure" dominance converts into a positive selection coefficient.*

This matters because selection dynamics generally respond to average *reproductive advantage, not to a pointwise statement. Assumption 4 gives the pointwise/measure-theoretic claim; Theorem 220 turns it into the scalar inequality needed to drive replicator-like models, connecting the dominance premise to the population-dynamics results that follow.*

Remark 3518 (On "almost sure" versus "everywhere")**.** *The hypothesis* $\nu(\Delta > 0) = 1$ *is stronger than merely having* $\mathbb{E}[\Delta] > 0$ *but weaker than requiring* $\Delta(\alpha) > 0$ *for* all $\alpha \in \mathcal{A}$. *This is the natural notion for selection in an environment described by* ν*: tasks outside the support of* ν *(or on* ν*-null sets) are effectively never encountered, so they do not affect expected fitness. Theorem 220 formalizes that "failure to be strictly better" on a* ν*-null set cannot cancel a strict advantage on a full-measure set, provided the integrability conditions ensure the mean is well-defined.*

Proof. Let $g(\alpha) := \sup_{r\in\mathcal{R}_{\mathrm{L}}} V_r(\alpha)$, so that $\Delta(\alpha) = V_{\mathrm{T}}(\alpha) - g(\alpha) \geq 0$ and $\nu(\Delta > 0) = 1$.

Integrability implies $\mathbb{E}[\Delta]$ exists and is finite. Since $\Delta \geq 0$ and $\nu(\Delta > 0) = 1$, we have $\Delta(\alpha) > 0$ on a set of positive ν-measure (indeed full measure), hence $\mathbb{E}[\Delta] > 0$. Therefore

$$\mathbb{E}[V_{\mathrm{T}}] \;=\; \mathbb{E}[g + \Delta] \;=\; \mathbb{E}[g] + \mathbb{E}[\Delta] \;>\; \mathbb{E}[g].$$

Also $\mathbb{E}[g] \geq \sup_{r\in\mathcal{R}_{\mathrm{L}}} \mathbb{E}[V_r]$ by definition of g. Thus $f(\mathrm{T}) > \sup_{r\in\mathcal{R}_{\mathrm{L}}} f(r)$. □

Remark 3519 (Two technical subclaims used in the proof)**.** *The proof relies on two standard facts.*

1. *If* $X \geq 0$ *almost surely and* $\mathbb{P}(X > 0) = 1$*, then* $\mathbb{E}[X] > 0$ *whenever* $\mathbb{E}[X]$ *exists (i.e., is finite). A quick way to see this is: for each* $n \in \mathbb{N}$*, the event* $\{X \geq 1/n\}$ *increases to* $\{X > 0\}$*, so for some* n *one must have* $\mathbb{P}(X \geq 1/n) > 0$*; then* $\mathbb{E}[X] \geq (1/n)\mathbb{P}(X \geq 1/n) > 0$.

2. *For any collection of integrable random variables* $\{Y_r\}_{r\in\mathcal{R}_{\mathrm{L}}}$*, with* $g := \sup_r Y_r$ *(pointwise), one always has* $\mathbb{E}[g] \geq \sup_r \mathbb{E}[Y_r]$*, since* $g \geq Y_r$ *implies* $\mathbb{E}[g] \geq \mathbb{E}[Y_r]$ *for each* r*, and taking the supremum preserves the inequality.*

These are the only measure-theoretic ingredients needed to translate pointwise dominance into a strict inequality between expectations.

Proof sketch. The strategy is to isolate the nonnegative "gap" random variable $\Delta(\alpha)$ between the trust-capable payoff and the best trustless payoff on each task. "Almost surely positive" plus integrability implies the mean of this gap is strictly positive, and then linearity of expectation turns pointwise dominance into strict average dominance. □

Remark 3520. *A useful visual is to imagine the task space* $\mathcal{A}$ *as a landscape weighted by* ν*. The set where* $\Delta(\alpha) = 0$ *has* ν*-measure* 0*, so it contributes nothing to the average; everywhere else, there is some positive contribution. The only way the mean could fail to be positive would be if the gap were positive on a set of measure* 1 *but so wildly non-integrable that the expectation were undefined; this is exactly what the integrability hypothesis excludes.*

Remark 3521 (Supremum versus maximizer and "best trustless regime")**.** *The expression* $\sup_{r\in\mathcal{R}_{\mathrm{L}}} f(r)$ *allows for the possibility that there is no single trustless regime attaining the maximum expected fitness (e.g., if* $\mathcal{R}_{\mathrm{L}}$ *is infinite or not compact). Likewise,* $g(\alpha) = \sup_r V_r(\alpha)$ *is a pointwise benchmark that selects the best trustless payoff* for each task α, *not necessarily the payoff of any fixed trustless regime across tasks. The theorem is therefore robust: it compares* T *against the entire trustless class even in settings where "the best trustless strategy" exists only as a limit. In particular, it establishes a uniform selection advantage even relative to an adversary that is allowed to pick the best trustless rule task-by-task, and then notes that any fixed trustless regime can only do worse on average than this pointwise upper envelope.*

Remark 3522 (Reasoning-system use)**.** *Theorem 220 is an inference lemma: if your world-model says tasks are drawn from a "rich" distribution, and the GGW-type dominance holds, then as a prior you should expect selection (competition, imitation, institutional evolution) to favor trust-capable coordination.*

66.3 Deterministic evolutionary dynamics: replicator convergence

66.3.1 Two-regime replicator

Consider two effective strategies: trust-capable T versus a representative trustless regime L (for instance, the best-performing member of $\mathcal{R}_{\mathrm{L}}$ in expectation).

Let $x(t) \in [0,1]$ be the fraction of communities using T at time t. Assume fitnesses are constant in time and given by $f_{\mathrm{T}} := f(\mathrm{T})$ and $f_{\mathrm{L}} := f(\mathrm{L})$ with $f_{\mathrm{T}} > f_{\mathrm{L}}$.

Definition 624 (Replicator ODE (two types))**.**

$$\dot{x}(t) \;=\; x(t)\big(f_{\mathrm{T}} - \bar{f}(x(t))\big), \quad \bar{f}(x) := x f_{\mathrm{T}} + (1-x) f_{\mathrm{L}}.$$

Equivalently,

$$\dot{x}(t) \;=\; x(t)(1-x(t))(f_{\mathrm{T}} - f_{\mathrm{L}}).$$

Remark 3523. *The dot notation $\dot{x}(t)$ denotes the time derivative $\frac{d}{dt}x(t)$. The quantity $\bar{f}(x)$ is the population mean fitness when a fraction x uses* T *and a fraction $1-x$ uses* L*. The replicator equation says: a type grows in frequency when its fitness exceeds the current average.*

A concrete sanity check: if x is very small (few trust-capable communities exist), then $\bar{f}(x) \approx f_{\mathrm{L}}$, so $\dot{x} \approx x(f_{\mathrm{T}} - f_{\mathrm{L}})$ and T *grows approximately exponentially at first. If x is close to 1, then the $(1-x)$ factor slows growth, reflecting saturation: there are few remaining* L*-communities to be replaced.*

This definition is useful because it provides a mathematically tractable mean-field model of cultural imitation, differential reproduction, or institutional copying. Even when the real process is noisy, replicator ODEs often describe the average flow.

Theorem 221 (Global convergence to trust-capable under two-type replicator)**.** *If $f_{\mathrm{T}} > f_{\mathrm{L}}$, then for any initial condition $x(0) \in (0,1]$,*

$$\lim_{t\to\infty} x(t) \;=\; 1.$$

Remark 3524 (Intuitive content and connection)**.** *This theorem says that, in the simplest deterministic selection model, any positive foothold of a strictly fitter regime eventually takes over the population. The conclusion is not merely local stability but* global *convergence on $(0,1]$: once* T *is present, it inexorably grows.*

This directly operationalizes Theorem 220: that theorem produces the strict inequality $f_{\mathrm{T}} > f_{\mathrm{L}}$ (or $f(\mathrm{T}) > \sup f(r)$), while the present theorem converts that inequality into a time-asymptotic population prediction.

Proof. Let $\delta := f_{\mathrm{T}} - f_{\mathrm{L}} > 0$. Then $\dot{x} = \delta x(1-x)$. For $x \in (0,1)$, $\dot{x} > 0$, so $x(t)$ is strictly increasing and bounded above by 1, hence converges to some $x_\infty \in (0,1]$.

If $x_\infty \in (0,1)$, then taking the limit in $\dot{x} = \delta x(1-x)$ gives $0 = \delta x_\infty(1-x_\infty)$, contradiction. Hence $x_\infty = 1$. If $x(0) = 1$ then $x(t) = 1$ for all t. Thus convergence holds for all $x(0) \in (0,1]$. □

Proof sketch. The ODE has the logistic form $\dot{x} = \delta x(1-x)$ with $\delta > 0$. The key idea is monotonicity: on the open interval $(0, 1)$ the derivative is strictly positive, so trajectories increase and must converge. The only possible limit points are equilibria, and the only equilibria are 0 and 1; since the trajectory cannot decrease to 0, it must converge to 1. □

Remark 3525. *Geometrically, the phase line on $[0, 1]$ has arrows pointing right everywhere in $(0, 1)$ when $\delta > 0$. The boundary point $x = 0$ is unstable (a repelling equilibrium) and $x = 1$ is stable (attracting). This is the simplest instance of the general principle: in a one-dimensional flow, a strict sign condition on the vector field determines global behavior.*

66.3.2 Multi-regime replicator: trust-capable dominates an entire class

Let $\mathcal{R} = \{\mathrm{T}, 1, 2, \dots, k\}$ with frequencies $x_{\mathrm{T}}, x_1, \dots, x_k$.

Definition 625 (Multi-type replicator ODE)**.**

$$\dot{x}_i \;=\; x_i\big(f_i - \bar{f}\big), \quad \bar{f} := \sum_j x_j f_j.$$

Remark 3526. *Here $(x_i)_i$ lives on the probability simplex: each $x_i \geq 0$ and $\sum_i x_i = 1$. The scalar $\bar{f}$ is again the mean fitness. The equation says each type grows or shrinks according to how its fitness compares to the mean.*

A small example with three regimes: if $f_1 < f_2 < f_3$ and all $x_i > 0$, then x_3 tends to increase and x_1 tends to decrease, with x_2 possibly increasing or decreasing depending on whether f_2 is above or below $\bar{f}$. The utility of this definition is that it lets us treat "trustless coordination" not as one regime but as a whole competing family.

Theorem 222 (Dominance implies global attraction under multi-type replicator)**.** *Assume $f_{\mathrm{T}} > f_i$ for all $i \neq \mathrm{T}$, and $x_{\mathrm{T}}(0) > 0$. Then $x_{\mathrm{T}}(t) \to 1$ as $t \to \infty$.*

Remark 3527 (Intuitive content and role)**.** *This theorem says that strict dominance against* every *competitor implies eventual takeover, even when the competitors are many and may compete among themselves. The condition $x_{\mathrm{T}}(0) > 0$ is essential: replicator dynamics cannot create a type from nothing.*

Conceptually, this is the natural strengthening of Theorem 221. Theorem 220 often yields $f(\mathrm{T}) > \sup_{r \in \mathcal{R}_{\mathrm{L}}} f(r)$ rather than identifying a single best L. *Theorem 222 matches that stronger premise.*

Proof. For any $i \neq \mathrm{T}$ with $x_i(t) > 0$, consider the log-ratio:

$$\frac{d}{dt} \log \frac{x_{\mathrm{T}}}{x_i} \;=\; \frac{\dot{x}_{\mathrm{T}}}{x_{\mathrm{T}}} - \frac{\dot{x}_i}{x_i} \;=\; (f_{\mathrm{T}} - \bar{f}) - (f_i - \bar{f}) \;=\; f_{\mathrm{T}} - f_i \;>\; 0.$$

The key point in the above cancellation is that the mean fitness $\bar{f}$ enters every coordinate equation in the same way under replicator dynamics, so differences of *per-capita* growth rates depend only on pairwise fitness gaps. Moreover, on any time interval where $x_i(t) > 0$, the quantity $\log(x_{\mathrm{T}}/x_i)$ is well-defined and differentiable, so the displayed computation applies pointwise in time on that interval.

Thus $\log(x_{\mathrm{T}}/x_i)$ increases without bound linearly in t whenever $x_i > 0$, so $x_{\mathrm{T}}/x_i \to \infty$, implying $x_i(t) \to 0$ for all $i \neq \mathrm{T}$. More explicitly, since $f_{\mathrm{T}} - f_i$ is a positive constant (independent of t) in the deterministic setting considered here, integration yields

$$\log \frac{x_{\mathrm{T}}(t)}{x_i(t)} = \log \frac{x_{\mathrm{T}}(0)}{x_i(0)} + (f_{\mathrm{T}} - f_i)t,$$

whenever the ratio is defined; hence $x_{\mathrm{T}}(t)/x_i(t)$ grows at least exponentially in t. If for some $i \neq \mathrm{T}$ we have $x_i(0) = 0$, then that type is absent and remains absent, so the conclusion $x_i(t) \to 0$ is immediate in that case as well.

Since the simplex sums to 1, we obtain $x_{\mathrm{T}}(t) \to 1$. Equivalently, because $\sum_{i \neq \mathrm{T}} x_i(t) \to 0$ and the simplex constraint enforces $x_{\mathrm{T}}(t) = 1 - \sum_{i \neq \mathrm{T}} x_i(t)$, the remaining mass concentrates on T. □

Proof sketch. The proof tracks relative frequencies rather than absolute ones. Under replicator dynamics, the time-derivative of $\log(x_{\mathrm{T}}/x_i)$ cancels the mean fitness $\bar{f}$ and becomes the constant difference $f_{\mathrm{T}} - f_i$. If T is strictly fitter than every i, every log-ratio drifts to $+\infty$, forcing all competitors to vanish and leaving $x_{\mathrm{T}} \to 1$. One can also view this as saying that T has uniformly larger per-capita growth rate than any competitor when measured in the same population environment, so any initially nonzero share of T eventually dominates each alternative in pairwise comparison. □

Remark 3528. *A useful intuition is that the simplex dynamics has a Lyapunov-like structure when there is a single strictly best type: every relative comparison tilts in the same direction, so there is no room for cycling or coexistence. The log-ratio computation makes this precise by exhibiting a strictly increasing quantity along trajectories for each competing type. In particular, in contrast to frequency-dependent games where f_i may vary with x and permit nontrivial recurrent behavior, the present strict ordering $f_{\mathrm{T}} > f_i$ for all $i \neq \mathrm{T}$ rules out interior fixed points other than the vertex at* T*, and forces all trajectories with $x_{\mathrm{T}}(0) > 0$ to move toward that vertex.*

Corollary 76 (Selection conclusion from GGW-type dominance)**.** *If Assumption 4 holds and the evolutionary fitness of regimes is $f(r) = \mathbb{E}[V_r]$, then the trust-capable regime* T *is globally attracting under replicator dynamics, provided it is present with positive frequency initially.*

Remark 3529 (Intuitive content)**.** *This corollary packages the bridge: (i) almost-everywhere task-level strict advantage implies (ii) average strict advantage (Theorem 220), which implies (iii) takeover under a broad class of deterministic selection dynamics (Theorem 222). In a reasoning system, this is the point where one may safely replace a detailed competition story by a qualitative forecast: "trust-capable coordination spreads." The logical role of the "positive frequency initially" clause is to exclude the degenerate case in which* T *is absent: replicator dynamics does not create novel types, so selection can only amplify what is already present in the population state.*

Proof. By Theorem 220, $f(\mathrm{T}) > \sup_{r \in \mathcal{R}_{\mathrm{L}}} f(r)$. Apply Theorem 222 to the finite (or finite-approximated) regime set. Concretely, the strict inequality provides the uniform fitness gap hypothesis required to make T uniquely fittest among the regimes under consideration, and the assumption that $x_{\mathrm{T}}(0) > 0$ ensures the trajectory begins in the basin of attraction of the T vertex rather than on the face where T is identically zero. □

Proof sketch. The proof is a two-step reduction. First convert the almost-sure dominance hypothesis into a strict gap in mean fitness. Then invoke the multi-type replicator dominance theorem, which says a uniquely fittest type with positive initial mass attracts the whole simplex. Equivalently, the corollary is obtained by composing the implication "taskwise advantage ⇒ mean advantage" with the implication "mean advantage ⇒ asymptotic fixation" in the deterministic replicator model. □

Remark 3530. *The "finite-approximated" parenthetical is practically relevant: one may discretize a large regime space by considering only regimes that are realistically reachable or salient. The theorem is then an idealization of a coarse-grained evolutionary story (compare the general coarse-graining perspective in [5]). Formally, this amounts to restricting attention to a finite subset (or* *finite partition) of strategies so that the replicator system is a finite-dimensional ODE with the standard simplex as an invariant state space; the qualitative conclusion is meant to be robust to reasonable refinements of that discretization so long as* T *remains strictly best in mean fitness among the included alternatives.*

66.4 Stochastic selection: almost-sure fixation under i.i.d. task draws

Replicator ODEs capture mean-field behavior. We now show that even if each generation faces a fresh random task, a broad class of multiplicative selection dynamics still fixates on trust-capable coordination almost surely.

Definition 626 (Log-odds update under multiplicative selection)**.** *Let x_t be the fraction of communities using* T *at discrete time t. Let $\alpha_t \sim \nu$ i.i.d. and define realized payoff difference*

$$\Delta_t := V_{\mathrm{T}}(\alpha_t) - V_{\mathrm{L}}(\alpha_t).$$

Fix a learning/selection rate $\eta > 0$ and update by

$$\frac{x_{t+1}}{1-x_{t+1}} \;=\; \frac{x_t}{1-x_t}\,\exp(\eta\Delta_t).$$

Equivalently,

$$\ell_{t+1} \;=\; \ell_t + \eta\Delta_t, \quad \ell_t := \log\frac{x_t}{1-x_t}.$$

Remark 3531. *The notation $\alpha_t \sim \nu$ i.i.d. means the tasks are independently and identically distributed across time: each generation (or cultural update step) encounters a fresh task drawn from the same environment distribution.*

The update is easiest to read in log-odds form. The quantity $\ell_t = \log\frac{x_t}{1-x_t}$ is the logarithm of the odds in favor of T*. The rule $\ell_{t+1} = \ell_t + \eta\Delta_t$ says: if* T *outperforms* L *on the realized task ($\Delta_t > 0$), the odds tilt toward* T *multiplicatively; if $\Delta_t < 0$, they tilt the other way. This is a standard structure for multiplicative weights / Bayesian-like updating, and it captures a wide family of "success breeds imitation" mechanisms.*

A simple example: if $\eta = 1$ and $\Delta_t = 0.1$ consistently, then odds multiply by $\mathrm{e}^{0.1}$ each step. The definition is useful because it reduces fixation questions to the behavior of a random walk with drift in the variable ℓ_t.

Theorem 223 (Almost-sure fixation from positive drift)**.** *Assume $\mathbb{E}[\Delta_t] > 0$ and $\mathbb{E}[|\Delta_t|] < \infty$. Then for any $x_0 \in (0,1)$, the process in Definition 626 satisfies*

$$x_t \to 1 \quad \textit{almost surely as } t \to \infty.$$

Remark 3532 (Intuitive content and connection)**.** *This theorem is the stochastic analogue of Theorem 221. Instead of a deterministic ODE with constant advantage, we have random task-by-task advantages Δ_t. The claim is that a* positive mean *advantage produces almost-sure takeover: the randomness cannot prevent fixation because, over long time horizons, the cumulative drift dominates fluctuations.*

This connects directly to Theorem 220: under GGW-type hypotheses, the mean of the gap is positive, so the stochastic selection process almost surely drives trust-capable coordination to fixation.

Proof. We have $\ell_t = \ell_0 + \eta \sum_{s=0}^{t-1} \Delta_s$. By the strong law of large numbers (integrability suffices),

$$\frac{1}{t} \sum_{s=0}^{t-1} \Delta_s \to \mathbb{E}[\Delta_0] \ > \ 0 \quad \text{a.s.}$$

Hence $\sum_{s=0}^{t-1} \Delta_s \to +\infty$ almost surely, and therefore $\ell_t \to +\infty$ almost surely. Since $x_t = (1+e^{-\ell_t})^{-1}$, we obtain $x_t \to 1$ a.s. ☐

Proof sketch. Rewrite the multiplicative update as an additive random walk in log-odds ℓ_t. The increments are $\eta\Delta_t$. By the strong law of large numbers, the average increment converges to its mean, which is positive by assumption. Therefore the partial sums diverge to $+\infty$, forcing $\ell_t \to +\infty$ and hence $x_t \to 1$. ☐

Remark 3533. *One can picture ℓ_t as a walker on the real line: each task pushes the walker right or left by an amount proportional to payoff difference. If the expected push is rightward, the walker almost surely drifts to $+\infty$. The logistic transform $x_t = (1 + e^{-\ell_t})^{-1}$ then maps "going to $+\infty$" into "fixating at 1."*

Corollary 77 (GGW-type dominance implies a.s. fixation under stochastic tasks)**.** *If $\Delta(\alpha) \geq 0$ and $\nu(\Delta > 0) = 1$ with Δ integrable, then $\mathbb{E}[\Delta] > 0$, so Theorem 223 applies and trust-capable coordination fixates almost surely under multiplicative selection.*

Remark 3534 (Intuitive content)**.** *This corollary states that the measure-theoretic dominance premise is strong enough to drive fixation even under task-by-task randomness, not merely in the averaged ODE picture. In the intended applications (institutional evolution, memetic spread, competitive multi-agent ecologies), this is often the more realistic setting: the "generation" sees one or a few tasks, not the whole distribution at once.*

Proof. Immediate from Theorem 220 (applied to the two-type case) and Theorem 223. ☐

Proof sketch. Use Theorem 220 to infer $\mathbb{E}[\Delta] > 0$ from almost-sure strict positivity, and then apply the positive-drift fixation theorem for the log-odds process. ☐

66.5 Mutation and persistent diversity: robustness of trust-capable dominance

Selection rarely runs without mutation, exploration, or architectural drift. The next result shows that trust-capable coordination remains the dominant mass even with persistent mutation. One can read this as a "mutation–selection balance" statement: even when there is continual leakage out of the fitter regime, the long-run population state typically stabilizes at an interior mixture whose location is controlled by the relative strengths of selection (δ) and mutation (μ_{TL}, μ_{LT}). In particular, when selection favoring T is strong compared to the rate at which T degrades into L, the equilibrium mass near T remains high.

Definition 627 (Replicator-mutator (two types))**.** *Let $x(t)$ be the fraction of* T*. Let $f_{\mathrm{T}} > f_{\mathrm{L}}$ be constants. Let $\mu_{TL} \geq 0$ be mutation rate* T $\to$ L *and $\mu_{LT} \geq 0$ be mutation rate* L $\to$ T*. Define*

$$\dot{x} \ = \ x(1-x)(f_{\mathrm{T}} - f_{\mathrm{L}}) \ - \ \mu_{TL} x \ + \ \mu_{LT}(1-x).$$

In this two-type setting, the term $x(1-x)(f_{\mathrm{T}} - f_{\mathrm{L}})$ is the usual replicator selection component (with constant fitness gap), while the remaining linear terms implement a continuous-time mutation channel. Note that the mutation part alone would drive x toward the mutation-only equilibrium $\mu_{LT}/(\mu_{TL} + \mu_{LT})$ (when $\mu_{TL} + \mu_{LT} > 0$), whereas the selection part alone would drive x toward 1 when $f_{\mathrm{T}} > f_{\mathrm{L}}$.

Remark 3535. *The additional terms $-\mu_{TL}x$ and $+\mu_{LT}(1-x)$ model continual leakage between regimes: even if* T *is favored, some fraction of trust-capable communities degrade into trustless ones (loss of coordination norms, institutional collapse, corruption), while some trustless communities innovate or learn their way into* T*.*

The usefulness of this model is that it captures a common reality: selection pushes in one direction, but exploration and error keep diversity alive. The question is then not "does T *take over perfectly?" but "does most of the mass concentrate near* T*, and under what parameter regimes?" A further practical point is that μ_{TL} can be interpreted broadly as any persistent mechanism that reintroduces low-trust behavior (e.g., churn in membership, shocks that erode enforcement, or adversarial adaptation), while μ_{LT} can represent deliberate institutional improvement, imitation of successful norms, or technological tooling that makes trust-capable coordination easier.*

Theorem 224 (Unique stable equilibrium and concentration as mutation vanishes)**.** *Assume $\delta := f_{\mathrm{T}} - f_{\mathrm{L}} > 0$ and $\mu_{TL}, \mu_{LT} \geq 0$. Then:*

1. *There exists a unique equilibrium $x^* \in (0,1)$ if $\mu_{TL}+\mu_{LT} > 0$, and it is globally asymptotically stable on $[0,1]$.*
2. *If $\mu_{LT} > 0$ is fixed and $\mu_{TL} \to 0$, then $x^* \to 1$. More generally, if both $\mu_{TL}, \mu_{LT} \to 0$ with $\mu_{TL}/\mu_{LT} \to 0$, then $x^* \to 1$.*

Remark 3536 (Intuitive content and connection)**.** *This theorem says that with ongoing mutation, one typically gets a single stable mixed equilibrium: selection pushes toward* T *while mutation pulls away, and the balance point is unique. As mutation away from* T *becomes negligible relative to mutation toward* T*, the balance point moves toward full concentration on* T*.*

This complements the earlier fixation theorems by showing robustness: the conclusion "trust-capable dominates" does not depend on an unrealistic assumption of zero exploration or zero institutional decay. In addition, the interior equilibrium $x^* \in (0,1)$ should be read as persistent diversity*: even when* T *is strictly fitter, the system generically does not converge to a vertex of the simplex under continual mutation. Instead, the equilibrium encodes the steady-state fraction of communities that remain in (or are continually reintroduced into) the less coordinated regime.*

Proof. Write the RHS as a polynomial:

$$\dot{x} = \delta x - \delta x^2 - \mu_{TL}x + \mu_{LT} - \mu_{LT}x = -\delta x^2 + (\delta - \mu_{TL} - \mu_{LT})x + \mu_{LT}.$$

Call this $P(x)$. It is a concave parabola in x (leading coefficient $-\delta < 0$). We compute

$$P(0) = \mu_{LT} \geq 0, \qquad P(1) = -\mu_{TL} \leq 0.$$

It is also useful (for invariance of the state space) to observe that these endpoint signs imply the vector field points inward on $[0,1]$: at $x = 0$ we have $\dot{x} = P(0) \geq 0$ so trajectories cannot cross into $x < 0$, and at $x = 1$ we have $\dot{x} = P(1) \leq 0$ so trajectories cannot cross into $x > 1$. Thus $[0,1]$ is forward-invariant under the dynamics.

If $\mu_{TL} + \mu_{LT} > 0$, then $P(0) > 0$ or $P(1) < 0$ (indeed at least one strict), so by continuity there is at least one root in $(0,1)$. Concavity implies at most two roots total, but the sign pattern ($P(0) \geq 0$, $P(1) \leq 0$) and concavity together imply exactly one root in $(0,1)$ unless both endpoints are roots, which requires $\mu_{LT} = 0$ and $\mu_{TL} = 0$, excluded by assumption. Thus the equilibrium is unique in $(0,1)$.

For stability, note that for a 1D ODE $\dot{x} = P(x)$, an interior equilibrium x^* is asymptotically stable if $P'(x^*) < 0$. Here $P'(x) = -2\delta x + (\delta - \mu_{TL} - \mu_{LT})$. At the unique interior crossing of a concave parabola from positive to negative, the derivative must be negative, hence x^* is asymptotically stable. Because $P(0) \geq 0$ and $P(1) \leq 0$, solutions are trapped in $[0,1]$ and flow toward the unique stable equilibrium, giving global asymptotic stability. Equivalently, since there is exactly one equilibrium in $(0,1)$ and the sign of $\dot{x}$ is $\dot{x} > 0$ for $x < x^*$ and $\dot{x} < 0$ for $x > x^*$, every trajectory in $(0,1)$ moves monotonically toward x^* (increasing from below and decreasing from above), which is a particularly transparent form of global convergence in one dimension.

For concentration: solve $P(x^*) = 0$:

$$\delta(x^*)^2 - (\delta - \mu_{TL} - \mu_{LT})x^* - \mu_{LT} = 0.$$

By the quadratic formula, the two algebraic roots are

$$x_\pm = \frac{(\delta - \mu_{TL} - \mu_{LT}) \pm \sqrt{(\delta - \mu_{TL} - \mu_{LT})^2 + 4\delta\mu_{LT}}}{2\delta}.$$

Because $\sqrt{(\delta - \mu_{TL} - \mu_{LT})^2 + 4\delta\mu_{LT}} \geq |\delta - \mu_{TL} - \mu_{LT}|$ and $\delta > 0$, the "minus" root x_- is nonpositive whenever $\mu_{LT} > 0$, while the "plus" root x_+ lies in $(0,1]$ and is the unique equilibrium x^*. This explicit expression makes the parameter dependence of the interior equilibrium fully transparent (and can be used for comparative statics, e.g. monotonicity of x^* in μ_{TL} and μ_{LT}).

As $\mu_{TL} \to 0$ with $\mu_{LT} > 0$ fixed, the unique root in $(0,1)$ must satisfy $x^* \uparrow 1$, because $P(1) = -\mu_{TL} \to 0^-$ and $P(0) = \mu_{LT} > 0$ stay separated, squeezing the crossing toward 1. The stated more general limit follows similarly from $P(1) = -\mu_{TL}$ and $P(0) = \mu_{LT}$. One can also see the same limit directly from the closed form above: with $\mu_{TL} = 0$,

$$x^* = \frac{(\delta - \mu_{LT}) + \sqrt{(\delta - \mu_{LT})^2 + 4\delta\mu_{LT}}}{2\delta} = \frac{(\delta - \mu_{LT}) + (\delta + \mu_{LT})}{2\delta} = 1,$$

and continuity in parameters implies $x^* \to 1$ as $\mu_{TL} \to 0$. Moreover, when μ_{TL} is small relative to δ (and μ_{LT} not vanishing too fast), one may heuristically read the equilibrium as "very close to 1" because only the leakage term $-\mu_{TL}x$ can keep $P(1)$ negative; once that leakage disappears, the selection term forces the population to the T vertex. □

Proof sketch. Reduce the ODE to $\dot{x} = P(x)$ where P is a concave quadratic. Evaluate P at 0 and 1 to force a sign change across the interval, hence an interior root. Concavity plus the endpoint signs ensure this interior root is unique. Stability follows because a concave curve crossing from positive to negative must have negative slope at the crossing. The limiting claims use the fact that as $\mu_{TL} \to 0$, the value $P(1) = -\mu_{TL}$ approaches 0 from below, pushing the unique crossing toward $x = 1$. A complementary intuition is that mutation prevents absorption at the boundary points: as long as $\mu_{TL} + \mu_{LT} > 0$, the dynamics continually "re-seeds" both types, so the only possible limit is an interior fixed point where the opposing flows balance. □

Remark 3537. *A geometric picture is literal here: $P(x)$ is a downward-opening parabola. The dynamics flows right where $P(x) > 0$ and left where $P(x) < 0$. Because $P(0) \geq 0$ and $P(1) \leq 0$, the parabola must cross the axis somewhere in between, and since it is concave, there is only one such crossing compatible with the monotone sign change. The stable equilibrium is exactly that crossing point. In applications, this picture also emphasizes a robustness point: changing μ_{TL} and μ_{LT} perturbs the parabola mainly by shifting the intercepts $P(0) = \mu_{LT}$ and $P(1) = -\mu_{TL}$, so the equilibrium slides continuously along the interval rather than changing discontinuously. Thus, even when there is persistent "noise" in institutional quality, the long-run proportion of trust-capable coordination varies smoothly with the magnitude and direction of that noise.*

66.6 Selection pressure grows with coordination-interface complexity

A key intuition for communities and mindplexes is that complex/hierarchical coordination creates many "interfaces" where trustless protocols incur overhead or mechanism-design friction, while trusting team procedures do not. This yields a scaling law: the larger/more hierarchical the task, the larger the selection advantage for trust-capable coordination.

Definition 628 (Interface-count lower bound model)**.** *For each task α, let $m(\alpha) \in \mathbb{N} \cup \{0\}$ be the number of coordination interfaces that exhibit "problematic structure" (e.g. two-sided private influence). Assume there exists $\ell > 0$ such that for every α,*

$$V_{\mathrm{T}}(\alpha) - \sup_{r \in \mathcal{R}_{\mathrm{L}}} V_r(\alpha) \;\geq\; \ell\, m(\alpha).$$

Remark 3538. *The variable $m(\alpha)$ is a coarse measure of how many distinct "coordination boundaries" occur in task α—places where information must cross from one subagent (or institution, subsystem, department) to another and where strategic constraints bite. In a hierarchical organization, these interfaces proliferate with depth and breadth (Hyperseed-Concept* **??***); in a heterarchical mesh, they proliferate with the density of interconnections (Hyperseed-Concept* **??***).*

The inequality posits a linear lower bound: each problematic interface costs a trustless regime at least ℓ expected performance relative to trust-capable coordination. For example, if each interface forces costly verification, negotiation, or incentive-compatible signaling, then these costs accumulate. The model is useful not because it is always exact, but because it converts a qualitative intuition ("complex coordination makes trust more valuable") into an inequality that can be carried through expectation and selection analyses.

One operational reading is that $m(\alpha)$ counts "events where a local optimum is misaligned with the global objective under strategic uncertainty." Concretely, an interface may correspond to a handoff (requirements $\to$ implementation), an internal market or budget boundary, a procurement contract, a data-sharing API between teams, a delegation edge in a chain of command, or a multi-party decision gate. The qualifier "problematic structure" is intentionally broad: it includes not only explicit adversarial incentives, but also softer sources of strategic constraint such as unverifiable effort, private cost information, hidden actions, and multi-principal ambiguity.

The constant ℓ should be interpreted as a per-interface minimum *gap, not an average gap. Thus the model is conservative: it allows some interfaces to be cheap to handle trustlessly (the bound still holds), but it rules out environments where the trustless regime can systematically exploit interface-level structure to erase the gap at all problematic seams simultaneously.*

Remark 3539 (Back-of-the-envelope interface growth)**.** *To make the dependence on organizational form more concrete, consider a stylized b-ary hierarchy of depth d (root at depth 0) in which each edge corresponds to one delegation/verification interface. If tasks require traversing most edges at least once, then an order-of-magnitude proxy is $m(\alpha) \approx \sum_{k=0}^{d-1} b^{k+1} = \frac{b^{d+1}-b}{b-1}$, i.e. exponential in depth when breadth $b > 1$. By contrast, in a sparse heterarchical graph with N nodes and average degree $\bar{k}$, a natural proxy is $m(\alpha) \approx \frac{1}{2} N \bar{k}$, i.e. linear in interconnection density. These are not claims of exact counting, but they illustrate why even mild changes in depth/breadth or connectivity can strongly affect $\mathbb{E}[m(\alpha)]$ and therefore the selection coefficient.*

Theorem 225 (Expected advantage lower bounded by expected interface count)**.** *Under the interface-count model,*

$$f(\mathrm{T}) - \sup_{r \in \mathcal{R}_{\mathrm{L}}} f(r) \;\geq\; \ell\, \mathbb{E}[m(\alpha)].$$

In particular, if $\mathbb{E}[m(\alpha)]$ increases with environmental/task complexity, then the selection coefficient favoring trust-capable coordination increases with complexity.

Remark 3540 (Intuitive content and connection)**.** *This theorem states that the "gap" between trust-capable and best trustless performance scales at least like the average number of problematic interfaces. It makes precise a kind of moral of mechanism-design folklore: the more seams in the world, the more expensive it is to stitch them with adversarially robust thread.*

It connects back to the GGW-style hypothesis by providing a concrete sufficient condition that can help justify it: if $m(\alpha) > 0$ on almost all tasks and $\ell > 0$, then $\Delta(\alpha)$ is almost surely positive, and the expected advantage grows with complexity.

A further interpretive point is that the theorem does not require every *task instance to be complex; it is enough that complexity arises with nontrivial probability under the environment distribution. In particular, a heavy-tailed distribution over task difficulties can make $\mathbb{E}[m(\alpha)]$ large even when most tasks are simple, reflecting the idea that rare but high-stakes, high-interface episodes (crises, launches, coordination shocks) can dominate long-run fitness comparisons.*

Proof. Take expectations:

$$f(\mathrm{T}) - \sup_r f(r) \;\geq\; \mathbb{E}\left[V_{\mathrm{T}}(\alpha) - \sup_r V_r(\alpha)\right] \;\geq\; \mathbb{E}[\ell m(\alpha)] = \ell\mathbb{E}[m(\alpha)].$$

To spell out the first inequality in a way that makes the order of operations explicit, note that for any fixed r we have

$$f(\mathrm{T}) - f(r) = \mathbb{E}[V_{\mathrm{T}}(\alpha) - V_r(\alpha)] \;\geq\; \mathbb{E}\left[V_{\mathrm{T}}(\alpha) - \sup_{r'} V_{r'}(\alpha)\right],$$

since $\sup_{r'} V_{r'}(\alpha) \geq V_r(\alpha)$ pointwise in α. Taking $\sup_r$ on the right-hand side yields

$$f(\mathrm{T}) - \sup_r f(r) = \inf_r \big(f(\mathrm{T}) - f(r)\big) \;\geq\; \mathbb{E}\left[V_{\mathrm{T}}(\alpha) - \sup_{r'} V_{r'}(\alpha)\right],$$

which is the step used above before applying the definition's lower bound and linearity of expectation. □

Proof sketch. The proof is linearity of expectation plus monotonicity: the pointwise lower bound on the advantage implies the same lower bound after averaging. The only subtlety is that $\sup_r f(r)$ is bounded above by $\mathbb{E}[\sup_r V_r(\alpha)]$, which is exactly the direction needed for a lower bound.

Equivalently, the key move is to avoid mistakenly swapping sup and $\mathbb{E}$ in the wrong direction: generally $\sup_r \mathbb{E}[V_r(\alpha)] \leq \mathbb{E}[\sup_r V_r(\alpha)]$, and the argument exploits this inequality to keep the bound conservative. □

Remark 3541. *Visually, one may think of $m(\alpha)$ as a complexity gauge attached to each task. The theorem says: if each unit of complexity contributes at least ℓ units of advantage, then the average advantage is at least ℓ times average complexity. This is the simplest kind of "scaling law" available in this setting.*

It is also worth noting what the model does not *assume: it does not require that costs add exactly linearly across interfaces, only that there is a uniform* lower bound *that scales at least linearly. In many real systems, interface costs can be superlinear (e.g. cascading delays, compounding risk, or combinatorial incentive constraints), in which case the linear bound remains valid but potentially loose, and selection could intensify even faster than the inequality suggests.*

Corollary 78 (Large integrated collectives need trust to remain viable)**.** *Suppose a family of tasks indexed by "scale" n has $\mathbb{E}[m(\alpha) \mid n] \geq cn$ for some $c > 0$, and suppose net viability requires expected performance above some baseline B. Then for sufficiently large n, any trustless regime has expected performance below T by at least ℓcn, so beyond a threshold scale, trustless communities are generically selected out relative to trust-capable ones.*

Remark 3542 (Intuitive content)**.** *This corollary is the "thermodynamic" moral: when a system grows, the number of seams grows, and the price of seam-management under adversarial constraints grows correspondingly. If the environment demands near-linear scaling of efficiency with size, then trustless coordination becomes structurally noncompetitive beyond some scale.*

One can view the "threshold scale" as the point where the linear advantage ℓcn exceeds any fixed margin by which a trustless protocol might win on small instances (e.g. due to lower fixed setup costs, simpler governance, or less need for internal monitoring). In that sense, the corollary formalizes an intuition that trustless coordination can look attractive in small systems while being fragile under growth, because the quantity that scales (interfaces) is precisely the quantity that trustless designs must pay to police.

Proof. Immediate from Theorem 225: the expected gap grows at least linearly in n. Thus, whenever being competitive/viable at scale n requires not wasting $\Theta(n)$ efficiency, trustless regimes become noncompetitive for large enough n.

More explicitly, conditioning on n gives

$$f(\mathrm{T}) - \sup_{r\in\mathcal{R}_{\mathrm{L}}} f(r) \;\geq\; \ell\,\mathbb{E}[m(\alpha)\mid n] \;\geq\; \ell cn,$$

so for any fixed baseline requirement expressed as an additive slack (e.g. needing to exceed B by a constant margin), there exists $n^\star$ such that for all $n \geq n^\star$ the linear term ℓcn dominates that slack. ☐

Proof sketch. Condition on scale n and apply the interface theorem with $\mathbb{E}[m(\alpha)\mid n] \geq cn$. The result is an explicit linear lower bound ℓcn on the expected advantage, which eventually dominates any fixed viability baseline differences as n grows.

If one imagines a fixed "head start" H that a trustless regime might enjoy at small n (say, from lower constant overhead), the sketch corresponds to choosing $n^\star \approx H/(\ell c)$ so that $\ell cn^\star \gtrsim H$; beyond that point the linear-in-n interface penalty outweighs any such constant advantage. ☐

66.7 Selection over communities with a continuous trust trait

So far, regimes were discrete. We now treat "trust" as a continuous trait, and show that if performance is strictly increasing in trust, then selection increases mean trust. In this subsection, "continuous" refers to the trait space $[0,1]$ rather than to the index set of communities: the population may still consist of finitely many community types, each carrying a (real-valued) trust level τ_i. The key point is that selection can now act on arbitrarily small differences in τ.

Definition 629 (Population of communities with trust trait)**.** *Let communities be indexed by i with weights (frequencies) $p_i(t) \geq 0$, $\sum_i p_i(t) = 1$. Each community has a trust trait $\tau_i \in [0,1]$ (fixed for now), and fitness $W(\tau_i)$ where $W : [0,1] \to \mathbb{R}$ is strictly increasing. Assume group-level replicator dynamics:*

$$\dot{p}_i \;=\; p_i\big(W(\tau_i) - \bar{W}\big), \quad \bar{W} := \sum_j p_j W(\tau_j).$$

Define mean trust $\bar{\tau} := \sum_i p_i \tau_i$.

In this notation, it is convenient to interpret $\sum_i p_i(\cdot)$ as an expectation operator under the distribution $p(t)$, i.e. for any function f define

$$\mathbb{E}_p[f(\tau)] \;:=\; \sum_i p_i f(\tau_i).$$

This turns expressions such as $\bar{\tau}$ and $\bar{W}$ into $\mathbb{E}_p[\tau]$ and $\mathbb{E}_p[W(\tau)]$ respectively, and makes the link to Price-equation-style identities notationally explicit. The assumption that τ_i is "fixed for now" isolates the pure effect of selection on composition (changing p_i) from within-type change (changing τ_i); later extensions can reintroduce within-community learning or mutation as additional terms.

Remark 3543. *This definition turns "trust" into a scalar parameter $\tau \in [0,1]$. One can read τ as the degree to which a community can exploit high-bandwidth cooperation, or as a proxy for the depth of shared norms, transparency, and credible commitment. The function $W(\tau)$ then encodes the claim "more trust yields higher fitness" in the given environment.*

The weights $p_i(t)$ define a population distribution over community-types. The mean trust $\bar{\tau} = \sum_i p_i\tau_i$ is the population-level quantity of interest. This setup is useful because it yields a general monotonicity principle (a form of the Price equation) without needing to specify how τ is implemented internally.

A further technical convenience of the replicator equation is that it preserves the simplex: starting from $p_i(0) \geq 0$ with $\sum_i p_i(0) = 1$, one has $p_i(t) \geq 0$ and $\sum_i p_i(t) = 1$ for all t for which the solution exists. Thus the population-level quantities $\bar{\tau}$ and $\bar{W}$ are always well-defined and remain convex combinations of the underlying trait values and fitnesses.

Theorem 226 (Strictly increasing fitness implies monotone increase of mean trust)**.** *If W is strictly increasing, then*

$$\frac{d}{dt}\bar{\tau} \;=\; \mathrm{Cov}_p(\tau, W(\tau)) \;\geq\; 0,$$

with strict inequality unless all τ_i are equal (i.e. unless the population is already trust-homogeneous).

The conclusion is a monotonicity statement about the mean, not a claim that every community's trust level rises (the τ_i are held fixed here). Rather, the population reweights toward higher-trust types. Also note that "monotone increase" means $\bar{\tau}(t)$ is nondecreasing; depending on the support of the initial distribution and on the shape of $W(\cdot)$, $\bar{\tau}(t)$ may converge to a limit strictly below 1 if, for example, the maximum trust type $\tau = 1$ is absent from the initial population. In that sense the theorem is about directional selection given available variation, not about creating new variation.

Remark 3544 (Intuitive content and connection)**.** *This theorem says: whenever fitness rises with trust, selection increases average trust. The covariance formula makes the mechanism transparent: if higher-trust types systematically have higher fitness, then they gain weight, pulling the mean upward.*

This continuous-trait result complements the discrete-regime theorems by showing that "trust-capable" need not be a sharp category. Even gradual improvements in trust capacity are, under the stated assumption, cumulatively amplified by selection.

It is also useful to read the covariance identity as identifying the exact "selection gradient" on the mean: the instantaneous rate of change depends only on how strongly τ and $W(\tau)$ co-vary under the current population mixture. In particular, even if W is strictly increasing, the change in $\bar{\tau}$ can be very small when almost all mass is concentrated on a narrow range of τ, because then $\mathrm{Cov}_p(\tau, W(\tau))$ is small.

Proof. Differentiate:

$$\frac{d}{dt}\bar{\tau} = \sum_i \dot{p}_i\tau_i = \sum_i p_i(W(\tau_i) - \bar{W})\tau_i = \sum_i p_i\tau_i W(\tau_i) - \bar{W}\sum_i p_i\tau_i = \mathbb{E}_p[\tau W(\tau)] - \mathbb{E}_p[\tau]\mathbb{E}_p[W(\tau)].$$

This is exactly $\mathrm{Cov}_p(\tau, W(\tau))$.

If W is strictly increasing, then τ and $W(\tau)$ are strictly comonotone, so the covariance is nonnegative, and is zero iff τ is almost surely constant under p (all mass on one trait value).

For a fully explicit discrete argument (useful when one wants to avoid appealing to general comonotonicity facts), write the covariance as a pairwise sum:

$$\mathrm{Cov}_p(\tau, W(\tau)) = \frac{1}{2}\sum_i \sum_j p_i p_j \big(\tau_i - \tau_j\big)\big(W(\tau_i) - W(\tau_j)\big).$$

Because W is increasing, each term $\big(\tau_i - \tau_j\big)\big(W(\tau_i) - W(\tau_j)\big) \geq 0$, so the whole sum is ≥ 0. Moreover, if there exist i, j with $p_i p_j > 0$ and $\tau_i \neq \tau_j$, then strict monotonicity implies $W(\tau_i) \neq W(\tau_j)$ and the corresponding pair contributes a strictly positive amount, yielding $\mathrm{Cov}_p(\tau, W(\tau)) > 0$. □

Proof sketch. Compute the derivative of the mean trait using the replicator equation. The mean change is a covariance between trait value and fitness. Monotonicity of W ensures higher trait values align with higher fitness, forcing the covariance to be nonnegative, with equality only in the degenerate case of no trait variation. □

Remark 3545. *The covariance identity is the key step: it is the algebraic expression of the intuitive statement "types that do better become more common." One may view it as a minimalistic version of the Price equation, specialized to replicator flow. The geometry is again simplex-based: the flow tilts the distribution p toward regions of higher $W(\tau)$, and if W increases with τ, that tilt points toward higher τ.*

This identity is closely related in spirit to Fisher-style statements: rather than tracking the change in mean fitness, it tracks the change in a focal trait, and the covariance specifies how "aligned" the trait is with the fitness landscape. In models with additional forces (e.g. mutation, migration, or within-community adaptation that changes τ_i over time), this selection term typically appears as one addend among others, so the present theorem can be read as isolating the pure selection contribution.

Remark 3546 (Interpretation)**.** *Theorem 226 is a general selection principle: whenever "more trust enables more efficient coordination on typical tasks," selection at the community level increases average trust, even without modeling the micro-mechanisms of how trust is implemented.*

The assumptions are intentionally minimal: $W(\tau)$ is allowed to be nonlinear (e.g. exhibiting threshold-like acceleration, diminishing returns, or sharp increases near some τ^*), and the theorem still applies as long as the mapping remains strictly increasing. Conversely, if the environment induces a non-monotone $W(\tau)$ (for example, if very high trust becomes exploitable by out-groups or incurs excessive verification costs), the covariance need not be nonnegative and the direction of selection on $\bar{\tau}$ can depend on the current distribution $p(t)$.

66.8 Mindplexes as selectable collectives: trust-capability as a necessary condition

We now connect to mindplex-like collectives (tightly coupled systems of subminds plus a collective control/experience layer). The key mathematical point for Target 2 is not phenomenology, but *viability under selection*: mindplexes are high-integration, high-interface systems, so the interface-scaling selection pressure becomes especially strong. In particular, high integration tends to increase (i) the number of distinct loci at which partial plans must be reconciled, (ii) the number of opportunities for incentive misalignment or strategic behavior to manifest, and (iii) the rate at which small coordination errors propagate system-wide. These features do not require any specific metaphysics of collective experience; they follow from fairly ordinary considerations about coupling, interdependence, and the need to maintain coherent joint action across many subsystems.

Remark 3547. *The term "mindplex" is used here in the sense developed in SuperDuperPsychism-style discussions of collective minds and collective consciousness locations; see [12]. In Hyperseed language, it touches the* Mindplex *concept (Hyperseed-Concept 113) and also invites comparison to the* Global Brain *concept (Hyperseed-Concept* **??***). The present section deliberately focuses on selection and coordination cost, not on any particular theory of phenomenology.*

Definition 630 (Mindplex-scale interface growth hypothesis)**.** *A mindplex of size n (number of constituent minds/subsystems) faces tasks whose coordination graph has at least $\Omega(n)$ interfaces, and generically a positive fraction of these interfaces exhibit problematic structure. Formally, there exist $c > 0$ and a scale-indexed environment ν_n such that*

$$\mathbb{E}_{\alpha\sim\nu_n}[m(\alpha)] \;\geq\; cn.$$

Remark 3548. *This hypothesis asserts that as the mindplex grows, it does not merely gain compute or memory; it gains* boundaries*. Each additional constituent typically introduces new channels where plans, beliefs, or resources must be reconciled. The lower bound $\mathbb{E}_{\nu_n}[m(\alpha)] \geq cn$ is a minimal scaling claim: interface count grows at least linearly with size. Many architectures would exhibit superlinear growth (dense interaction graphs), but linear growth suffices for the conclusions.*

A simple example: suppose n subteams must each contribute a component, and each component must be integrated into a shared artifact. Even if the integration is centralized, there are at least n handoff points. In distributed AI, if n modules exchange messages with a hub, there are n module–hub interfaces; if modules interact in a mesh, there can be $\Theta(n^2)$ interfaces.

The hypothesis is useful because it lets us import the interface-count lower bound model into a size-scaling argument: mindplex candidates live in regimes where $m(\alpha)$ is large, hence where trustless overheads are amplified.

It is also useful to separate two notions that are sometimes conflated: the existence *of an interface (a place where information/authority/resources cross subsystem boundaries) and the* problematic structure *of an interface (a place where strategic incentives, hidden information, value drift, interpretability gaps, or verification costs create a persistent performance drag for trustless regimes). The definition above is phrased in terms of $m(\alpha)$ because $m(\alpha)$ is intended to count precisely those interfaces that trigger the lower bound in the interface-count model; hence "problematic" is not an aesthetic judgment but a technical condition: interfaces that are expected to impose a non-negligible trustless overhead on the task distribution under consideration.*

Finally, the scale-indexed environment ν_n should be read as an explicit modeling move: as the collective grows, it tends to attempt (or be selected into) tasks whose scope is commensurate with its capacity. The distribution ν_n captures this endogeneity by letting the task mix vary with n, while the inequality enforces that the resulting tasks do not become trivially decomposable in a way that would collapse interface complexity.

Theorem 227 (Mindplex viability selects for trust-capability)**.** *Assume the mindplex-scale interface growth hypothesis and the interface-count lower bound model. Then the expected performance advantage of trust-capable coordination over any trustless regime at scale n satisfies*

$$f_n(\mathrm{T}) - \sup_{r\in\mathcal{R}_{\mathrm{L}}} f_n(r) \;\geq\; \ell cn,$$

where $f_n(r) := \mathbb{E}_{\alpha\sim\nu_n}[V_r(\alpha)]$. Consequently, among scalable mindplex candidates, selection strongly favors trust-capable designs, with selection pressure growing at least linearly in n.

Remark 3549 (Intuitive content and connection)**.** *This theorem is the specialization of the scaling law to mindplexes: if large collectives necessarily face many coordination interfaces, and each* *interface generically penalizes trustless coordination by at least ℓ, then the total expected penalty grows like n. Thus, in the space of designs capable of scaling to large n, trust-capability is not a luxury but a near-necessity for competitiveness.*

It connects the abstract dominance assumptions (Assumptions 3–4) to a more mechanistic story: why the dominance should become stronger *for more integrated, higher-interface collectives.*

One way to read the inequality is as a lower bound on the "distance to the viability frontier" for trustless regimes: if viability corresponds to achieving some threshold expected value (fitness, throughput, safety-adjusted reward, or institutional success), then increasing n shifts trustless designs downward by an amount that scales with the number of problematic interfaces. Trust-capability, in this framing, is a way of preventing the increasing integration of the collective from turning into an increasing tax on performance.

Note also that the result does not require trust-capable coordination to be perfect. The bound only uses a per-interface advantage parameter ℓ (from the interface-count model), which can be interpreted as an average marginal gap in realized task value, amortized over the task distribution. Even modest per-interface improvements can dominate at large n when interfaces scale linearly or superlinearly.

Proof. By Theorem 225 applied under ν_n,

$$f_n(\mathrm{T}) - \sup_r f_n(r) \;\geq\; \ell\,\mathbb{E}_{\nu_n}[m(\alpha)] \;\geq\; \ell cn.$$

□

Proof sketch. Apply the interface-count expectation bound at the scale-indexed environment ν_n and then plug in the linear interface growth lower bound $\mathbb{E}_{\nu_n}[m(\alpha)] \geq cn$. The two inequalities compose immediately. □

Remark 3550. *The geometric intuition is again additive: each additional constituent adds expected "surface area" (interface) that must be managed. Trust-capability reduces the per-unit surface cost, so as size grows, designs lacking trust-capability are pulled farther below the viability frontier.*

A complementary interpretation is in terms of "coordination bandwidth." If each problematic interface consumes some fraction of the system's available attention, monitoring capacity, dispute-resolution time, or verification budget, then linear growth in the number of such interfaces can force a qualitative regime change: beyond some scale, the collective becomes dominated by internal transaction/verification work rather than external task progress. Trust-capability, by reducing the marginal verification and negotiation burden, delays or prevents this transition.

Moreover, the additive form is intentionally conservative. If interfaces interact (for example, if misalignment at one interface increases the cost of resolving misalignment at others, or if conflicts propagate through shared resources), then the effective penalty to trustless regimes can be superadditive in $m(\alpha)$. The present theorem does not rely on such amplification; it only needs a lower bound that accumulates per interface.

Corollary 79 (Target-2 synthesis: selection implies trust-capable coordination)**.** *Suppose:*

1. *The task environment is rich enough that GGW-type measure-zero strictness holds (Assumption 4).*
2. *Communities/mindplexes are selected by realized performance on tasks (replicator, imitation, or multiplicative selection dynamics).*

3. *Trust-capable coordination is reachable (by design, mutation, learning, or institutional innovation) and is not prevented by hard constraints.*

Then, generically, the population-level dynamics converges toward trust-capable coordination, and the selection pressure toward trust-capability grows with coordination-interface complexity.

Remark 3551 (Intuitive content)**.** *This corollary is the promised bridge statement. It says: under rich tasks, performance-based selection, and reachability, trust-capability is not merely one option but a generic attractor of the population dynamics. Moreover, the larger and more internally articulated the collective (more interfaces), the stronger the pull.*

Two clarifications help fix the scope. First, "generically" inherits the meaning from the earlier GGW-type strictness assumption: if ties and exact degeneracies are measure-zero, then the set of task instances on which trust-capable and trustless regimes achieve exactly equal performance has negligible measure. This makes the selection gradient well-defined almost everywhere on the relevant task distribution and supports the intuition that small but persistent performance gaps accumulate over time under multiplicative selection.

Second, the reachability clause matters because selection can only favor what can be produced by the variation operators available to the population (engineering iteration, institutional reform, learning dynamics, or biological/evolutionary mutation and recombination). The corollary should thus be read as a conditional statement about evolutionary pressure: whenever a lineage of designs can move along a path that increases trust-capability without catastrophic side effects, the scaling advantage makes that direction an increasingly dominant basin of attraction as interface complexity grows.

In practical terms, this "pull" can manifest as convergent pressure toward mechanisms that reduce the need for exhaustive auditing at every boundary: shared world-model standards, credible commitment devices, alignment of incentives, interpretability tools that turn hidden states into communicable evidence, robust dispute resolution protocols, and governance structures that allow high-bandwidth delegation without collapsing into adversarial verification. The corollary does not claim that any particular mechanism is inevitable; it claims that the property *of being able to coordinate with low marginal trustless overhead is what selection will tend to amplify in scalable mindplex-like collectives.*

Remark 3552. *In reasoning-system terms, this is a license to treat "trust-capable coordination" as a default prediction for sufficiently open-ended multi-agent ecologies, unless there is explicit evidence of a hard constraint preventing it. Concretely, the claim is not that every trajectory must realize trust, but that absent a known blocking condition (e.g. binding communication limits, irreversible segregation, non-negotiable incompatibilities, or institutional constraints that forbid credible commitment), the selection dynamics considered make trust-capable regimes the natural "attractor" class to bet on when forming priors about long-run organizational form. In particular, the burden of argument shifts: rather than needing a special story for why trust appears, one needs a special story*

Proof. Items (1)-(2) yield convergence by Corollary 76 (deterministic) or Corollary 77 (stochastic). Interface growth strengthens the effect by Theorem 225 and Theorem 227. The deterministic/stochastic split here is only about the update rule (e.g. replicator-type flow versus finite-population sampling and drift); in both cases the role of the hypotheses is to guarantee that the trust-capable phenotype (or coalition) has strictly positive expected advantage in the relevant environment. The interface terms matter because they scale the payoff gap between regimes: as integration increases, the cost of trustless coordination typically accumulates across more boundaries, while the marginal benefit of a shared trust substrate can be reused across tasks, yielding a larger selection gradient in favor of trust-capability. □

Proof sketch. Combine the earlier results modularly: GGW-type strictness implies a positive mean advantage, which drives convergence under the selection dynamics considered. Separately, the interface-count model gives a quantitative lower bound on the advantage that increases with complexity/scale, sharpening the selection conclusion for large integrated systems. Intuitively, once a regime can (i) achieve the trustless baseline and (ii) sometimes do strictly better on the same task distribution by exploiting trust, then selection has no stable reason to keep the population at the trustless boundary except in degenerate cases where the better mode is inaccessible. The interface bound then functions as a "multiplicative amplifier": the more cross-module coordination problems an ecology must repeatedly solve, the more often trust-capability can cash out as reduced friction, lower overhead, or higher throughput, making the advantage not merely positive but increasingly robust to noise, drift, and heterogeneity in local subgames. □

66.9 Discussion: what this buys a reasoning system

Remark 3553 (Operational inference pattern)**.** *A reasoning system can treat Corollary 79 as a domain-general inference rule:*

> *If a multi-agent ecology is (i) under selection for task performance in a rich task distribution, and (ii) has a reachable trust-capable regime that can emulate trustless protocols, then expect institutional/memetic/evolutionary pressure toward trust-capable coordination, especially as task hierarchy and interface complexity grow.*

This is precisely the kind of cross-domain "background theorem" that can guide default inferences about social, cultural, scientific, or multi-agent AI scenarios. Here "reachable" should be read in an operational sense: there exists some feasible path in the space of policies, norms, mechanisms, or architectures (not necessarily short, not necessarily monotone) by which the ecology can arrive at a trust-capable configuration from plausible starting points. Likewise, "emulate trustless protocols" means the trust-capable regime does not lose the ability to fall back on adversarially-robust tools when needed (e.g. contracts, audits, cryptographic commitments, redundancy, formal verification, or other trust-minimizing mechanisms); rather, it strictly contains those tools as a special case and can selectively deploy trust when the environment makes it payoff-improving. For a reasoning system, this matters because it licenses a principled default: in the absence of contrary evidence, one can forecast not only individual-level behavior but the direction of institutional adaptation (which mechanisms get built, which norms get rewarded, which organizational interfaces get standardized) as task ecosystems become more compositional and interdependent.

Remark 3554. *One may read the section as an instance of a broader methodological stance (cf. [20]): when complex systems are too detailed to simulate end-to-end, we seek stable, selection-compatible inequalities that survive coarse-graining. The logic is deliberately modest: we do not claim that trust is inevitable in every world, only that under the stated hypotheses it is the generic direction of motion. In the Hyperseed conceptual vocabulary, this is an instance of reasoning from* Probability *(Hyperseed-Concept 139) and* Selection-like *update rules toward structural expectations about* Society *(Hyperseed-Concept 170) and large-scale integrated* Mindplex *systems (Hyperseed-Concept 113). The coarse-graining emphasis is crucial for a reasoning system: rather than tracking every micro-detail of beliefs and interactions, it can track summary variables (e.g. average advantage, accessibility of regimes, interface counts, and reuse of coordination infrastructure) that are* *preserved under aggregation and still constrain likely macroscopic outcomes. Moreover, "generic direction of motion" should be interpreted as a claim about comparative statics and typical perturbations: when the environment becomes more task-rich, when organizations scale, or when interfaces proliferate, the models predict that selection pressure tilts more strongly toward trust-capable coordination, even if local reversals, cycles, or temporary regressions can occur. Thus the result supplies a calibrated prior for high-level forecasting: if you observe increasing integration and repeated cross-boundary coordination demands, you should anticipate (and look for) mechanisms that make trust both more valuable and more enforceable, rather than assuming that purely trustless designs will remain dominant.*

67 Compassion as a Stabilized Invariant: Drift-Controlled Self-Modification in Resource-Rich Regimes

We formalize a class of self-modifying minds whose meta-goals are updated by a drift-controlled (proximal) optimization rule. We represent compassion as a distinguished coordinate or functional of the meta-goal state. We prove several results showing that if compassion is initially seeded and if (i) drift controls penalize rapid meta-goal change and (ii) the environment contains robust trust/coordination benefits or weakness-regularization pressures, then compassion becomes hard to lose without an explicit override that disables the drift controls or injects large noise. The results are intended as reasoning tools: they convert qualitative alignment intuitions into checkable sufficient conditions and bounds.

Remark 3555. *The formal stance here is intentionally minimalist: we treat a mind's "values" as part of its dynamical state and study how update rules constrain their motion. This is in the spirit of studying stability of self-referential goal systems via fixed-point and contraction ideas [10]. At the same time, the section is meant to be read as a bridge between philosophical vocabulary ("compassion," "override," "trust") and quantities that can be bounded and reasoned about, which is part of the broader Hyperseed program [1].*

67.1 Setup: self-modifying minds with drift control

67.1.1 Meta-goals and compassion

Definition 631 (Meta-goal parameter space)**.** *Let $\Theta \subseteq \mathbb{R}^d$ be the space of meta-goal parameters. A mind at (discrete) time t has meta-goal state $\theta_t \in \Theta$.*

Remark 3556. *Intuitively, Θ is the "space of ways the mind can care." Each $\theta \in \Theta$ is a compact encoding of meta-level preferences: not merely what the agent does, but what it optimizes* about *what it does. The index $t = 0, 1, 2, \ldots$ indicates discrete updates, and θ_t is the value-state at time t; the dimension d reflects that meta-goals are typically plural rather than monolithic (cf. Hyperseed-Concept 110).*

Remark 3557. *A simple example is $d = 2$ with $\theta = (c, k)$ where c measures a prosocial/compassion tendency and k measures a self-protective or self-prioritizing tendency; different societies or training regimes might move the pair along different trajectories. Another example is d large, with coordinates corresponding to weights on different classes of entities, different timescales, and different "modes" of cognition. This parameterization is useful because it lets us ask: under what update rules can θ change rapidly, and under what rules is it forced to drift slowly?*

Definition 632 (Compassion functional)**.** *A compassion functional is a map*

$$C : \Theta \to \mathbb{R}.$$

In the simplest case, $C(\theta)$ is the "compassion coordinate" $\theta^{(1)}$. We say compassion is seeded *if $C(\theta_0) = c_0 > 0$.*

Remark 3558. *Here C extracts from a full meta-goal state θ a* scalar summary *meant to track something like "how much welfare of others is treated as intrinsically relevant" (Hyperseed-Concept 81). The notation $\theta^{(1)}$ means the first coordinate of the vector $\theta \in \mathbb{R}^d$; thus $C(\theta) = \theta^{(1)}$ is the simplest possible choice: compassion is literally a coordinate axis in value-space.*

Remark 3559. *Two small examples clarify the flexibility: (i) If $\Theta = [0,1]^d$ and $C(\theta) = \theta^{(1)}$, then seeding means simply $\theta_0^{(1)} > 0$; later theorems will show that certain update rules make it difficult for $\theta_t^{(1)}$ to drop rapidly. (ii) If θ encodes a full welfare-weight vector over many classes of beings, $C(\theta)$ could be the minimum welfare weight assigned to any member of a protected set. This definition is useful because the later arguments only need that "compassion is a real-valued quantity that can be bounded per step," not that it has a unique psychological interpretation.*

Remark 3560. *Nothing in the theorems below requires interpreting compassion as a single scalar, but a scalar is convenient. In richer Hyperseed-style settings one can let C be a derived quantity from a value web, a moral-patient partition, or a pattern network property (see Section 4, and cf. [5]).*

Remark 3561. *The requirement $C(\theta_0) = c_0 > 0$ should be read as a minimal nondegeneracy condition rather than as a strong ethical claim: the analysis below is about* stability given a seed*, i.e., whether a pre-existing prosocial component can be made difficult to erase by default dynamics. In particular, the results do not assert that drift control* creates *compassion from $C(\theta_0) = 0$; instead, they quantify how much "work" (in terms of update incentives, overrides, or noise) is required to move $C(\theta_t)$ downward once it is present. This distinction matters because self-modification mechanisms can be excellent at preserving invariants while still being neutral about which invariant was initially installed.*

67.1.2 Drift-controlled self-modification

Definition 633 (Drift penalty / divergence)**.** *Let $D : \Theta \times \Theta \to [0, \infty)$ be a divergence (not necessarily symmetric) with $D(\theta, \theta) = 0$. The main case used here is*

$$D(\theta, \phi) := \frac{1}{2}\|\theta - \phi\|_2^2.$$

Remark 3562. *The role of $D(\theta, \phi)$ is to quantify the "cost of changing meta-goals from ϕ to θ." It is called a divergence rather than a distance because we do not require symmetry or triangle inequalities: changing from ϕ to θ could be easier than changing back. The special case $\frac{1}{2}\|\theta - \phi\|_2^2$ is the familiar quadratic penalty from proximal optimization: it makes large jumps expensive and is mathematically convenient because it is coercive (it grows without bound as $\|\theta - \phi\|_2$ grows).*

Remark 3563. *As a concrete example, if $\Theta = \mathbb{R}^d$ and $D(\theta, \phi) = \frac{1}{2}\|\theta - \phi\|_2^2$, then moving compassion by 0.1 in one step already incurs penalty $\approx 0.005\lambda$ in the objective used below; increasing λ increases how much "incentive" is required to justify the shift. This definition is necessary because "drift control" is precisely the claim that self-modification is not free: it is regularized, audited, or otherwise restrained (Hyperseed-Concept 100 provides one philosophical reading of why such restraints matter).*

Remark 3564. *Although we emphasize the quadratic choice, the divergence language is meant to include common alternatives that better fit constrained or informational geometries of value change. For instance, if Θ is a simplex of weights, then an entropic/KL-type divergence can encode that changing a near-zero weight is "hard" in relative terms; more generally, Bregman divergences capture mirror descent style updates where the cost of moving depends on the current location in Θ. The later bounds will typically rely only on nonnegativity and on relating per-step movement in θ (and hence movement in $C(\theta)$) to the update's net gain in the world-response objective.*

Definition 634 (World-response value functional)**.** *Let $F : \Theta \to \mathbb{R}$ be the mind's long-run expected value (under its best available policy/planning given meta-goals θ in its environment). We do not assume F is concave in general unless stated.*

Remark 3565. *$F(\theta)$ is a "best-achievable payoff if I were to adopt meta-goals θ." It is not a primitive reward function but a* world-response *functional: it already folds in the agent's planning competence, its model of the environment, and the environment's reaction to the agent's behavior induced by θ. This abstraction is intentionally agnostic about how the planning is done; it aligns with the idea that in resource-rich regimes (Hyperseed-Concept 162) an agent can approximate the "best available policy" relatively well [11].*

Remark 3566. *It is useful to keep in mind that F may implicitly include equilibrium or game-theoretic effects. For example, if other agents respond strategically to the mind's observed behavior (or to signals correlated with θ), then the "environment's reaction" term can encode trust, reputational dynamics, coalition access, and coordination opportunities. In this reading, "robust trust/coordination benefits" correspond to regions of Θ in which increasing compassion (as measured by $C(\theta)$) raises $F(\theta)$ because it unlocks cooperative surplus, reduces monitoring costs, or stabilizes mutual commitments; "weakness-regularization pressures" correspond to regions where low compassion induces brittle or over-exploitative strategies that perform poorly in the long run, thereby lowering $F(\theta)$ even if they appear locally advantageous.*

Remark 3567. *The separation between F and D is conceptually important: F captures the* instrumental *consequences of adopting meta-goals, while D captures the* inertia *or* friction *of changing them. Later, when we introduce a proximal-style update, the key quantity will be the tradeoff between immediate improvements in F and the drift cost measured by D. This is precisely the structure that turns qualitative claims like "it takes a lot to rewrite a stable value" into inequalities that bound how far θ_t (and thus $C(\theta_t)$) can move per step without an explicit mechanism that weakens the drift penalty.*

Remark 3568. *Two examples: (i) In a multi-agent world, higher compassion might yield better coordination and thus higher $F(\theta)$ via trust effects; later we model this explicitly. (ii) In an adversarial world, higher compassion might expose the agent to exploitation, lowering $F(\theta)$. The point of not assuming concavity is to permit such nontrivial landscapes; the theorems will often rely on drift control rather than benign geometry of F.*

Remark 3569. *It is also useful to read these examples as a reminder that F encodes* instrumental *performance as a function of meta-goals, not necessarily any intrinsic desirability of compassion itself. In particular, the same meta-goal parameter (here, compassion) can be locally helpful in some regions of the environment distribution and locally harmful in others, producing multiple basins of attraction, saddle-like regions, or sharp cliffs in $F(\theta)$ even when the underlying world model is smooth.*

Definition 635 (Drift-controlled self-modification rule)**.** *Fix $\lambda > 0$. The drift-controlled self-modification (DCSM) update is*

$$\theta_{t+1} \in \arg\max_{\theta\in\Theta} \Big(F(\theta) - \lambda D(\theta, \theta_t)\Big). \tag{51}$$

Remark 3570. *The definition only requires that $D(\theta, \theta_t)$ act as a* drift penalty*; in typical applications one assumes at least $D(\theta_t, \theta_t) = 0$ and $D(\theta, \theta_t) \geq 0$ so that remaining at θ_t is always feasible and never incurs negative "cost." We do not require symmetry $D(\theta, \theta') = D(\theta', \theta)$ or the triangle inequality: many useful choices (e.g. KL divergence between internal goal-distributions, or Bregman divergences tied to a convex potential) are directional and still serve as meaningful notions of "how radical" a self-change is.*

Remark 3571. *A brief note on notation:* arg max *denotes the* set *of maximizers, not necessarily a single point; thus $\theta_{t+1} \in \arg\max(\cdots)$ means we allow multiple optima and choose any of them. The constant $\lambda > 0$ is the strength of drift control: larger λ means changes away from θ_t are penalized more harshly. The expression $F(\theta) - \lambda D(\theta, \theta_t)$ is a one-step tradeoff between "how good the new meta-goals are" and "how far they move from the old meta-goals"; formally it is a proximal or regularized optimization step.*

Remark 3572. *When $D(\theta, \theta_t) = \|\theta - \theta_t\|^2$ in a Euclidean parameterization,* (51) *reduces to a familiar quadratic trust-region/proximal update: it prefers improvements in F that can be reached with small parameter motion. When D is KL divergence between distributions representing meta-goals, the update instead constrains* information-theoretic *drift, which can be more invariant to reparameterization and more aligned with "behavioral" change than raw coordinate distance. This flexibility is important because the same intuitive notion of "conservative self-modification" can be implemented in multiple representational layers.*

Remark 3573. *One can also view λ as setting an implicit exchange rate between performance and stability: an improvement ΔF must justify paying a drift cost of roughly $\Delta F/\lambda$. In later arguments, it will matter that this exchange rate is explicit and time-local, allowing stability bounds that depend on λ and the geometry induced by D, rather than on global concavity assumptions about F.*

Remark 3574. *Intuitively,* (51) *says:* self-modify, but do so conservatively*. The mind is allowed to improve its own meta-goals, yet each improvement is constrained by an inertia term. This captures the engineering idea that robust systems include friction against abrupt internal changes, whether implemented via verification, consensus, redundancy, or explicit regularizers (cf. the stability motivations in [2] and the fixed-point perspective in [10]). This definition is useful because it turns a qualitative claim ("values drift slowly") into an inequality-driven dynamical law amenable to bounds.*

Remark 3575. *A further advantage of the proximal form is that it separates two failure modes: (a) the system proposes a new θ that would be high-performing* if adopted*, versus (b) the system actually* moves *to that proposal. Drift control constrains (b) even if (a) explores aggressively, and this is precisely the kind of separation that makes it possible to talk about "safe" internal search combined with "slow" external commitment.*

Definition 636 (Override event)**.** *An* override *is any step that violates the drift control regime, e.g.: (i) setting λ to (near) 0 for the step, or (ii) replacing $D(\cdot, \theta_t)$ by a much weaker penalty, or (iii) injecting step noise large enough to dominate the penalty term. Formally, an override is any update not representable as* (51) *with the declared (λ, D).*

Remark 3576. *Note that the override notion is intentionally* model-relative*: it is defined with respect to the particular declared pair* (λ, D)*. Thus, even if the system continues to execute an update of the form* $\arg\max(F - \tilde{\lambda}\tilde{D})$*, it still counts as an override when* $(\tilde{\lambda}, \tilde{D}) \neq (\lambda, D)$ *in a way that materially weakens drift control. This aligns with the interpretive goal that "override" flags steps where the claimed stability mechanism is no longer the operative mechanism.*

Remark 3577. *The philosophical point of the override definition is to distinguish two kinds of change: (1) changes that occur* within *the declared rule of self-modification, and (2) changes that occur by* breaking *the rule. The later theorems show that certain undesirable transitions (e.g. sudden compassion collapse) are difficult under (1), so if they occur, one should infer (2)—either an explicit disablement of drift control or a perturbation so large it effectively nullifies the penalty. This directly supports the intended use as a reasoning tool: one can ask which regime parameters must have been altered to explain observed value shifts.*

Remark 3578. *In applications, an "override" can be endogenous (the agent chooses to relax its own constraints) or exogenous (a fault, attack, or rare perturbation effectively bypasses the regularizer). The formal definition treats both uniformly: the key question is not* why *the regime was broken, but whether the observed transition can be accounted for by an update that still pays the declared drift cost. This lets later results function as diagnostic tools: if the transition is too sharp to be paid for under* D *and* λ*, then some form of regime break is implicated.*

Assumption 5 (Resource-rich regime: bounded optimization error and small noise)**.** *We idealize a resource-rich regime in two (optional) ways:*

1. *(Near-optimality) The chosen* θ_{t+1} *is an* η*-approximate maximizer of* $F(\theta) - \lambda D(\theta, \theta_t)$*, meaning it achieves value within* η *of the supremum.*

2. *(Small noise) When we model stochasticity, the injected noise is sub-Gaussian with scale* σ *that can be made small by spending resources.*

For deterministic theorems, we set $\eta = \sigma = 0$*.*

Remark 3579. *One may interpret* η *as capturing any combination of bounded solver suboptimality, discretization error, and bounded myopia in internal search. Allowing* $\eta > 0$ *is important because even very capable systems can face time constraints, approximation in world-model evaluation, or deliberate heuristics; the point is that in a resource-rich regime, these imperfections are bounded and can be driven down with additional expenditure.*

Remark 3580. *This assumption isolates a regime in which "more resources" plausibly mean "more reliable self-modification" (Hyperseed-Concept 162). Near-optimality says the mind can in fact solve (or nearly solve) the drift-regularized optimization at each step; small noise says random perturbations can be suppressed by redundancy, computation, and validation. Both are idealizations of the engineering thesis that sufficiently capable minds can make their own updates more disciplined rather than less disciplined [11].*

Remark 3581. *The small-noise clause is stated in sub-Gaussian form because it supports standard concentration bounds: rare large deviations decay at least as fast as Gaussian tails with parameter* σ*. This is a natural proxy for the idea that, after sufficient checking and averaging, the remaining stochasticity is dominated by many small independent sources rather than by heavy-tailed shocks. Later metastability statements will hinge on exactly this kind of tail control, since heavy-tailed noise could make "rare" catastrophic drift comparatively common.*

Remark 3582. *The parameters η and σ let the subsequent theorems cleanly separate deterministic barriers (which hold even with perfect optimization and no randomness) from metastability claims (which quantify the probability of rare "bad" events under small noise). They are necessary because without some control of optimization error/noise, any stability statement can be defeated by simply postulating enough randomness.*

Remark 3583. *It is also conceptually helpful to distinguish* bounded error *from* override*: a step with $\eta > 0$ is still a DCSM-type step (the agent is approximately optimizing the declared regularized objective), whereas an override changes the objective or the effective penalty itself. Thus, η and σ represent imperfections that preserve the regime, while overrides represent regime violations; the later results can therefore state conditions under which stability is robust to small imperfections but not to explicit bypassing of drift control.*

67.2 Target 3 core: compassion is hard to lose under drift control

67.2.1 A general step-size barrier: you cannot drift far without paying

The first result is deliberately architecture-agnostic: it only uses the fact that the update includes a quadratic (or more generally coercive) penalty.

Theorem 228 (Step-size bound from drift penalty)**.** *Assume Θ is any set and $D(\theta, \phi) = \frac{1}{2}\|\theta - \phi\|_2^2$. Assume F is bounded above on Θ by $F_{\max}$ and define $F(\theta_t)$ as the value at time t. If θ_{t+1} satisfies* (51)*, then*

$$\|\theta_{t+1} - \theta_t\|_2^2 \le \frac{2}{\lambda}\big(F_{\max} - F(\theta_t)\big). \tag{52}$$

If we only have η-approximate maximization, then

$$\|\theta_{t+1} - \theta_t\|_2^2 \le \frac{2}{\lambda}\big(F_{\max} - F(\theta_t) + \eta\big). \tag{53}$$

Remark 3584. *Intuitively, the theorem says:* if you regularize self-modification with a quadratic penalty, then each step has a maximum length unless you can gain a lot of value. *The upper bound depends on how far the current value $F(\theta_t)$ is from the global upper bound $F_{\max}$ and on the drift strength λ. When λ is large, even moderate jumps require substantial improvement in F; conversely, large jumps are possible only when the agent is currently leaving a lot of value "on the table."*

Remark 3585. *This is important because it is almost completely indifferent to the internal structure of the mind. One does not need to assume convexity, smoothness, or a particular learning algorithm. The result connects directly to later parts of the section: it provides the raw per-step barrier that, when combined with trust-attractor structure (Section 2) or weakness barriers (Section 4), yields a multi-pronged explanation of why compassion does not vanish "by accident." In the broader project, this kind of bound is one way to make "stable self" claims precise under self-modification [10].*

Proof. Because $\theta_t \in \Theta$ is feasible, optimality gives

$$F(\theta_{t+1}) - \frac{\lambda}{2}\|\theta_{t+1} - \theta_t\|_2^2 \ge F(\theta_t) - 0.$$

Rearrange:

$$\frac{\lambda}{2}\|\theta_{t+1} - \theta_t\|_2^2 \le F(\theta_{t+1}) - F(\theta_t) \le F_{\max} - F(\theta_t).$$

This yields (52). The η-approximate case adds η to the RHS. $\square$

Remark 3586 (Proof sketch and key intuition)**.** *The strategy is to compare the chosen next state θ_{t+1} to the trivial alternative "do nothing," i.e. choose θ_t again. Since θ_{t+1} maximizes the regularized objective, its regularized score cannot be lower than θ_t's score. This single comparison already forces the penalty term $\frac{\lambda}{2}\|\theta_{t+1} - \theta_t\|_2^2$ to be paid for by a corresponding gain in F, and the gain is in turn bounded by $F_{\max} - F(\theta_t)$. Geometrically, one can picture the quadratic penalty as a steep "bowl" centered at θ_t; to move far away, F must rise enough to climb out of the bowl.*

Corollary 80 (Per-step compassion change is bounded)**.** *Let $C(\theta) = \theta^{(1)}$ be the compassion coordinate. Under the assumptions of Theorem 1,*

$$|C(\theta_{t+1}) - C(\theta_t)| \le \|\theta_{t+1} - \theta_t\|_2 \le \sqrt{\frac{2}{\lambda}\big(F_{\max} - F(\theta_t) + \eta\big)}. \tag{54}$$

Remark 3587. *In plain language, this corollary specializes the generic step-size bound to the particular coordinate that we interpret as compassion. The inequality $|x_1 - y_1| \le \|x - y\|_2$ is the statement that changing one coordinate by a large amount forces the whole vector to change by at least that much. So drift control on the full meta-goal vector automatically constrains how quickly compassion can move, provided compassion is a coordinate (or Lipschitz functional).*

Proof. The first inequality is $|x_1 - y_1| \le \|x - y\|_2$. The second is Theorem 1. □

Remark 3588 (Proof sketch and geometric picture)**.** *The proof is a one-line projection argument: the compassion coordinate is a projection of θ onto an axis, and the Euclidean norm dominates any single-axis displacement. One may visualize the update as selecting a point in Θ; the full displacement vector has length $\|\theta_{t+1} - \theta_t\|_2$, and the compassion displacement is merely the shadow of this vector on one axis, hence it cannot exceed the full length.*

Remark 3589 (Interpretation)**.** *Large λ makes large compassion drops (or any meta-goal jumps) expensive. Thus, absent an override, rapid "value flips" are suppressed even if F is wild. This is one formal sense in which compassion becomes "hard to lose" in a drift-controlled regime.*

67.2.2 Attraction to a positive compassion fixed point under trust benefits

Now we add a substantive condition: that in a broad class of social/multi-agent environments, increasing compassion improves long-run payoffs through trust-capable coordination. This connects Target 3 to Target 2 without re-proving Target 2.

Assumption 6 (One-dimensional trust-augmented value model)**.** *Assume $\theta = (c, u) \in \mathbb{R} \times \mathbb{R}^{d-1}$ where $c = C(\theta)$. Assume the value decomposes as*

$$F(c, u) = G(u) + B\,T(c) - Kc, \tag{55}$$

where $B, K > 0$ are constants, and $T : [0,1] \to [0,1]$ is continuously differentiable, strictly increasing and concave (trust saturates).

Remark 3590. *This assumption isolates a single causal channel: compassion c affects long-run value by enabling trust-capable coordination, summarized by $B\,T(c)$, while also carrying an intrinsic or opportunity cost Kc. The remaining coordinates u collect all other meta-goal degrees of freedom; their effect on value is abstracted as $G(u)$. The concavity of T expresses diminishing returns: beyond some point, "more compassion" does not proportionally increase trust because trust saturates. This is a stylized formalization of the prosocial-efficiency thesis discussed earlier [6].*

Remark 3591. *A simple example is $T(c) = \sqrt{c}$ on $[0, 1]$, which is increasing and concave: early increases in compassion have large marginal effect on trust, but later increases have smaller marginal effect. Another common example is a smooth saturating curve such as $T(c) = \log(1+\alpha c)/\log(1+\alpha)$. The decomposition* (55) *is useful because it lets the compassion dynamics be studied in one dimension without assuming the entire meta-goal landscape is well behaved.*

Definition 637 (DCSM update for c)**.** *With $D(\theta, \theta_t) = \frac{1}{2}\|\theta - \theta_t\|_2^2$, the update* (51) *induces a 1D proximal update for compassion:*

$$c_{t+1} \in \arg\max_{c\in[0,1]} \Big(BT(c) - Kc - \frac{\lambda}{2}(c - c_t)^2\Big). \tag{56}$$

Remark 3592. *Equation* (56) *is the proximal/self-regularized update specialized to one coordinate. The term $BT(c)-Kc$ is the "instantaneous" part of the trust-versus-cost tradeoff, and the quadratic term is drift control. The constraint $c \in [0, 1]$ is a normalization: compassion is scaled so that* 0 *means no compassion signal and* 1 *means maximal compassion in the chosen units. This definition is useful because it makes the compassion subsystem a closed dynamical system and allows attractor analysis by elementary monotonicity arguments.*

Theorem 229 (Monotone convergence to a positive compassion attractor)**.** *Assume the trust model* (55) *and the update* (56)*. Assume further that $BT'(0) > K$, so the unique maximizer of $c \mapsto BT(c) - Kc$ is a strictly positive $c^* \in (0, 1]$. Then for any initial $c_0 \in (0, 1]$, the sequence (c_t) generated by* (56) *satisfies:*

1. *(Order preservation) If $c_t < c^*$ then $c_{t+1} \geq c_t$. If $c_t > c^*$ then $c_{t+1} \leq c_t$.*
2. *(Invariance of positivity) For all t, $c_t > 0$.*
3. *(Convergence) $c_t \to c^*$ as $t \to \infty$.*

Remark 3593. *Informally, the theorem says: if at low compassion the* marginal trust benefit *$BT'(0)$ exceeds the* marginal cost *K, then the system has a stable positive compassion "set point" c^*, and drift-controlled self-modification will move compassion toward it monotonically. This is an attractor statement: compassion is not merely* preserved *by inertia; it is actively* restored *by incentive gradients created by trust.*

Remark 3594. *The result is important because it explains one mechanism by which prosociality can become self-stabilizing in a capable agent: if trust-capable coordination is generically advantageous (as argued in the selection-oriented setting of the surrounding sections [6]), then in a drift-controlled regime the value landscape itself creates a basin pulling c_t away from zero. This connects the purely regularization-based barrier of Theorem 1 to an endogenous dynamical restoration force.*

Proof. Let

$$\phi_t(c) := BT(c) - Kc - \frac{\lambda}{2}(c - c_t)^2.$$

Concavity: since T is concave, $BT(c)-Kc$ is concave, and subtracting a quadratic keeps concavity. Thus ϕ_t has a (possibly non-unique) maximizer set.

For interior maximizers, first-order optimality yields

$$BT'(c_{t+1}) - K - \lambda(c_{t+1} - c_t) = 0, \quad \text{so} \quad c_{t+1} = c_t + \frac{1}{\lambda}(BT'(c_{t+1}) - K). \tag{57}$$

Define $h(c) := BT'(c) - K$. Since T is concave, T' is decreasing, hence h is decreasing. By assumption $h(0) > 0$, and since T' decreases, there is a unique c^* with $h(c^*) = 0$.

If $c_t < c^*$, then any maximizer c_{t+1} must satisfy $c_{t+1} \leq c^*$ (otherwise moving slightly down increases $BT(c) - Kc$ while also reducing quadratic penalty). For any $c_{t+1} \leq c^*$, we have $h(c_{t+1}) \geq 0$, so (57) gives $c_{t+1} \geq c_t$. Similarly if $c_t > c^*$, then maximizers satisfy $c_{t+1} \geq c^*$, so $h(c_{t+1}) \leq 0$ and $c_{t+1} \leq c_t$. This proves monotonicity toward c^*.

Because c_t is monotone and bounded in $[0, 1]$, it converges to some limit $\bar{c}$. Taking limits in (57) (using continuity of T') yields $h(\bar{c}) = 0$, so $\bar{c} = c^*$. Positivity holds because if $c_0 > 0$ and the sequence is monotone toward $c^* > 0$, it cannot cross 0. □

Remark 3595 (Proof sketch and why the key steps work)**.** *The proof uses three classical ingredients: (i) concavity ensures that maximizing ϕ_t is well-behaved and that first-order conditions capture optimality at interior points; (ii) the monotonicity of T' (a consequence of concavity of T) makes $h(c) = BT'(c) - K$ a decreasing function with a unique zero c^*; (iii) the fixed-point-like equation* (57) *shows that the sign of $h(c_{t+1})$ determines whether c_{t+1} lies above or below c_t. Visually, c^* is where the marginal trust benefit equals marginal cost; drift control then makes the update a damped move toward that balance point rather than a jump.*

Remark 3596 (Why this matters)**.** *The theorem turns "compassion helps coordination" into an attractor statement: in resource-rich drift-controlled self-modification, compassion does not merely persist; it is pulled toward a stable positive fixed point whenever trust benefits dominate marginal costs at low compassion.*

67.3 Hard-to-lose without override: quantitative barrier and metastability

The previous theorems were deterministic. We now add small noise to represent exploration, approximation error, and incidental perturbations, and prove a "metastability" bound: dropping compassion below a threshold becomes exponentially unlikely as noise decreases and drift control increases.

Remark 3597. *The phrase "without override" is meant literally: the stochastic model below assumes the same restoring drift toward the attractor is continuously in force. In applications, a genuine override corresponds to a change in the update rule (e.g., changing a, shifting c^*, or injecting a systematic bias term), not merely an unusually large draw of ξ_t. The point of the metastability bound is to make this distinction quantitative.*

67.3.1 A linearized stochastic model (Ornstein-Uhlenbeck style)

Assumption 7 (Linear mean-reverting compassion dynamics)**.** *Fix $a \in (0, 1)$, a target $c^* \in (0, 1]$, and noise scale $\sigma > 0$. Assume*

$$c_{t+1} = a\, c_t + (1 - a)c^* + \sigma\xi_t, \tag{58}$$

where $\{\xi_t\}$ are independent mean-zero 1-sub-Gaussian random variables: $\mathbb{E}[\exp(s\xi_t)] \leq \exp(s^2/2)$ for all $s \in \mathbb{R}$.

Remark 3598. *Equation* (58) *is the discrete-time analogue of an Ornstein–Uhlenbeck process: if one takes a small step size Δt and sets $a \approx 1 - \lambda\Delta t$, then* (58) *corresponds heuristically to $dc_t = \lambda(c^* - c_t)\, dt + \sigma\, dW_t$ in continuous time. This analogy is useful only for intuition here; the results below are fully discrete-time and require no diffusion limit.*

Remark 3599. *This is a discrete-time, mean-reverting process: in expectation, c_{t+1} is pulled toward c^*, and $a \in (0,1)$ controls how strong the pull is (smaller a means stronger reversion). The random variables ξ_t model small perturbations; "1-sub-Gaussian" is a standard tail condition implying Gaussian-like concentration bounds for sums. The parameter σ scales the noise magnitude.*

Remark 3600. *Because* (58) *is linear with additive noise, c_t is not automatically confined to* $[0,1]$ *even if $c_0 \in [0,1]$. This is intentional: the model is a local linearization near an interior attractor where boundary effects are negligible. If one wishes to enforce feasibility, one can interpret* (58) *as governing an unconstrained latent variable and then apply a projection or squashing map back to* $[0,1]$*; the tail bounds still give conservative estimates for threshold-crossing events as long as the relevant thresholds lie away from the boundary.*

Remark 3601. *The linear model arises by localizing the proximal update near an attractor and treating the drift control as mean reversion. In a resource-rich regime, σ can be made small (more computation, more verification, more redundancy).*

Remark 3602. *From an interpretive standpoint, a plays a role analogous to an effective drift-control strength: as drift control increases, the system becomes more strongly anchored to its attractor, which is captured here by reducing a away from* 1*. This is one way to translate the qualitative claim "resource-rich minds can keep their internal perturbations small" into a quantitative statement [11].*

Remark 3603. *It is also helpful to separate two distinct ways a system can become "stable": (i) decreasing σ reduces the typical magnitude of random exploration/approximation error, while (ii) decreasing a increases the restoring drift that counteracts any perturbation that does occur. The bounds below capture both effects, and do so in a way that makes their interaction explicit.*

Lemma 172 (Explicit representation)**.** *Under* (58)*,*

$$c_t = c^* + a^t(c_0 - c^*) + \sigma \sum_{k=0}^{t-1} a^{t-1-k}\xi_k. \tag{59}$$

Remark 3604. *This lemma simply unrolls the recursion and expresses c_t as the deterministic relaxation toward c^* plus a geometrically weighted sum of past noises. The weights a^{t-1-k} shrink older noise terms, reflecting the fact that mean reversion "forgets" perturbations exponentially fast.*

Remark 3605. *Taking expectations in* (59) *immediately yields*

$$\mathbb{E}[c_t] = c^* + a^t(c_0 - c^*),$$

so the mean approaches c^* at geometric rate a^t. Moreover, the accumulated noise term is a weighted sum whose effective variance proxy is on the order of $\sigma^2/(1-a^2)$, foreshadowing the appearance of the stabilizing factor $(1-a^2)$ in the tail bounds: stronger reversion (smaller a) reduces the long-run dispersion around c^*.

Proof. Unroll the recurrence:

$$c_{t+1} - c^* = a(c_t - c^*) + \sigma\xi_t,$$

and iterate. ∎

Remark 3606 (Proof sketch)**.** *The high-level strategy is standard: rewrite the update in terms of deviations from the fixed point c^*, obtaining a linear recurrence, and then repeatedly substitute to express $c_t - c^*$ in terms of $c_0 - c^*$ and the accumulated noise terms. Because the recurrence is linear with constant coefficient a, the resulting coefficients form a geometric series.*

Theorem 230 (Exponential tail bound for compassion drop)**.** *Fix a threshold $c_{\min} < c^*$. Define the margin*

$$m_t := \mathbb{E}[c_t] - c_{\min} = c^* + a^t(c_0 - c^*) - c_{\min}.$$

Then for each $t \geq 1$,

$$\mathbb{P}(c_t \leq c_{\min}) \leq \exp\left(-\frac{m_t^2(1-a^2)}{2\sigma^2}\right). \tag{60}$$

Consequently, for any horizon $T \geq 1$,

$$\mathbb{P}\left(\min_{1\leq t\leq T} c_t \leq c_{\min}\right) \leq \sum_{t=1}^{T} \exp\left(-\frac{m_t^2(1-a^2)}{2\sigma^2}\right) \leq T \exp\left(-\frac{m_\infty^2(1-a^2)}{2\sigma^2}\right), \tag{61}$$

where $m_\infty := c^* - c_{\min} > 0$.

Remark 3607. *The margin m_t is the "distance to the threshold in expectation." If $c_0 \geq c_{\min}$ then m_t is nonnegative for all t, and if $c_0 \leq c^*$ then m_t increases monotonically to m_∞. In particular, after a modest burn-in period on the order of $\log(1/m_\infty)/\log(1/a)$, the bound is well-approximated by the steady-state expression with m_∞.*

Remark 3608. *In ordinary language: the probability that compassion falls below a fixed threshold is exponentially small in the signal-to-noise ratio m_t/σ, with an additional stabilizing factor $(1-a^2)$ that improves as mean reversion strengthens. Over a time horizon T, the probability that the threshold is ever crossed is at most T times the worst per-step probability (union bound). Thus "hard to lose" becomes a large-deviation statement: losing compassion requires an atypically large negative fluctuation against the restoring drift.*

Remark 3609. *The functional form $\exp(-\text{const}/\sigma^2)$ is characteristic of metastability: as noise decreases, rare excursions against the drift become dramatically less frequent. In this linearized setting, the "barrier" is not a literal potential barrier but rather the combination of (i) the distance m_t to the undesired region and (ii) the effective noise level after geometric forgetting, captured by $(1-a^2)/\sigma^2$. This is the sense in which drift control converts a qualitative claim ("it tends to come back") into a quantitative one ("it is exponentially unlikely to stay down").*

Remark 3610. *This matters because it gives a quantitative complement to deterministic drift barriers: even if each step can fluctuate, the probability of sustained collapse is sharply controlled when σ is small. In the intended application, an observed compassion collapse in a system believed to have small σ and strong anchoring is evidence for an override (regime change) rather than mere stochastic drift, which is precisely the kind of inference these results are meant to support.*

Remark 3611. *Note that* (61) *is intentionally conservative: it uses a union bound and therefore does not exploit temporal dependence between the events $\{c_t \leq c_{\min}\}$. In many stable mean-reverting processes, threshold-crossing probabilities over a horizon can be substantially smaller than the union bound suggests, but the union bound already suffices to formalize the key claim that the risk shrinks rapidly as $(1-a^2)/\sigma^2$ grows.*

Proof. By Lemma 59,

$$c_t - \mathbb{E}[c_t] = \sigma \sum_{k=0}^{t-1} a^{t-1-k}\xi_k.$$

A weighted sum of independent 1-sub-Gaussians is sub-Gaussian with variance proxy equal to the sum of squared weights. Thus $Z_t := \sum_{k=0}^{t-1} a^{t-1-k}\xi_k$ is sub-Gaussian with parameter

$$\sum_{k=0}^{t-1} a^{2(t-1-k)} = \sum_{j=0}^{t-1} a^{2j} \le \frac{1}{1-a^2}.$$

Hence for $u > 0$,

$$\mathbb{P}(Z_t \le -u) \le \exp\left(-\frac{u^2(1-a^2)}{2}\right).$$

Set $u = m_t/\sigma$ to obtain (60). The horizon bound follows by a union bound over $t \le T$ and the monotone limit $m_t \to m_\infty$. □

Remark 3612. *The key inequality step can be seen directly from the moment-generating-function definition of sub-Gaussianity: independence implies the mgf of a weighted sum factorizes, and the weights a^{t-1-k} enter only through their squares when bounding the mgf. This is why geometric forgetting translates into the simple factor $\sum_j a^{2j} \le (1-a^2)^{-1}$.*

Remark 3613 (Proof sketch and concentration intuition)**.** *The proof reduces the event $c_t \le c_{\min}$ to a negative deviation of a sub-Gaussian sum. The key step is that geometric weights preserve sub-Gaussianity, and the effective variance is the sum of squared weights, which is bounded by a geometric series $\le 1/(1-a^2)$. Geometrically, mean reversion damps the influence of old noise, so the process cannot accumulate variance linearly in time; it saturates at a constant scale set by $\sigma^2/(1-a^2)$. The union bound is crude but sufficient for the stated "polynomial horizon" corollary. In more concrete terms, for a typical mean-reverting linear update one can unroll the recursion to obtain a representation of the centered state as a geometrically weighted noise history, e.g.*

$$c_t - c^* \;=\; a^t(c_0 - c^*) \;+\; \sigma \sum_{k=1}^{t} a^{t-k}\,\xi_k,$$

where (ξ_k) are mean-zero, unit sub-Gaussian increments. The deterministic term $a^t(c_0-c^*)$ decays, and the random term is a weighted sum. If each ξ_k is sub-Gaussian with proxy variance 1, then $\sum_{k=1}^t w_k\xi_k$ is sub-Gaussian with proxy variance $\sum_{k=1}^t w_k^2$; here $w_k = \sigma a^{t-k}$, so

$$\sum_{k=1}^{t} w_k^2 \;=\; \sigma^2 \sum_{j=0}^{t-1} a^{2j} \;\le\; \frac{\sigma^2}{1-a^2}.$$

This yields a standard tail inequality of the form

$$\mathbb{P}(c_t - c^* \le -\Delta) \;\le\; \exp\!\left(-\frac{\Delta^2(1-a^2)}{2\sigma^2}\right)$$

(up to conventional constants depending on the chosen sub-Gaussian normalization), which is the quantitative sense in which the process is "metastable": deviations of fixed size Δ are exponentially suppressed in $1/\sigma^2$ once mean reversion prevents variance from growing with t.

Corollary 81 (Override necessity in polynomial time)**.** *Fix $c_{\min} < c^*$ and consider any polynomial horizon $T = \mathrm{poly}(1/\sigma)$. Then as $\sigma \to 0$,*

$$\mathbb{P}\left(\min_{1\le t\le T} c_t \le c_{\min}\right) \to 0$$

exponentially fast in $1/\sigma^2$. Thus, to drive compassion below $c_{\min}$ on typical runs in such a regime, one must (with high probability) perform an override that effectively increases σ or reduces mean reversion (increasing a toward 1). A typical bound consistent with the preceding remark is

$$\mathbb{P}\left(\min_{1\le t\le T} c_t \le c_{\min}\right) \;\le\; \sum_{t=1}^{T} \mathbb{P}(c_t \le c_{\min}) \;\lesssim\; T \exp\!\left(-\frac{(c^* - c_{\min})^2(1-a^2)}{2\sigma^2}\right),$$

where the $\lesssim$ hides only constant-factor choices from the sub-Gaussian tail convention and the (usually negligible) effect of the decaying initialization term. The point of restricting to $T = \mathrm{poly}(1/\sigma)$ is that $\log T = O(\log(1/\sigma))$ cannot compete with the $1/\sigma^2$ in the exponent: even after union-bounding over polynomially many time steps, the resulting probability still vanishes at an exponential rate in $1/\sigma^2$. In this sense the "barrier" height is set by $(c^* - c_{\min})\sqrt{1-a^2}/\sigma$: as $\sigma \to 0$ (with fixed $a < 1$), typical trajectories almost never cross below $c_{\min}$ without intervention.

Remark 3614. *The content of the corollary is not that overrides are metaphysically necessary, but that under the assumed regime they are* statistically *necessary for a reliable compassion collapse within any reasonable (polynomial) time horizon. This distinction mirrors a common theme in rigorous reasoning about dynamical systems and computation: what is possible in principle may nonetheless be so measure-theoretically or probabilistically rare as to be ignorable for planning, until some control parameter is changed. Equivalently, the corollary is a statement about typicality: there exist trajectories (indeed, infinitely many) in which an unusually unlucky sequence of shocks pushes c_t below $c_{\min}$, but the measure of such trajectories is exponentially small in $1/\sigma^2$ when mean reversion is strong. This is precisely the regime in which "waiting for failure" is not a practical mechanism for producing failure on demand, because the expected waiting time to see such a rare event grows super-polynomially (and often exponentially) as $\sigma \to 0$. From a control perspective, an "override" functions as a parameter shift that changes which events are typical: increasing σ thickens the tails of the noise, while moving a toward 1 increases the effective memory of past noise and hence enlarges the variance proxy $\sigma^2/(1-a^2)$, both of which reduce the large-deviation penalty required to cross the threshold.*

Remark 3615 (Interpretation)**.** *This is a precise "hard to lose" statement: in a resource-rich drift-controlled regime (small σ, strong mean reversion), compassion loss is a rare large deviation event. Making it common requires changing the regime parameters, i.e., override. One can read the result as establishing a quantitative metastability barrier: below the scale $\sigma/\sqrt{1-a^2}$ the process exhibits only small fluctuations around c^*, while a drop of macroscopic size $c^* - c_{\min}$ is suppressed by an exponential factor. The corollary also clarifies what kinds of interventions matter: merely extending the time horizon to any polynomial length does not qualitatively change the picture, whereas modifying the volatility level (via σ) or weakening mean reversion (via a) directly changes the barrier height and can turn a negligible event into a routine one. In that sense, the "override" is not a philosophical add-on but the mathematically relevant act of moving the system out of the concentration regime where the hard-to-lose guarantee holds.*

67.4 Weakness-regularized compassion: de-compassionization costs distinctions

We now connect Target 3 to the Hyperseed weakness theme: reducing compassion typically requires making fine distinctions about who counts, who matters, or who is safe to exploit. Distinctions reduce weakness (flexibility), and weakness-regularization therefore creates an additional barrier (Hyperseed-Concept 202; see also [3] and [2]).

67.4.1 A simple moral-patient partition model

Definition 638 (Moral treatment policy and partition)**.** *Let $\mathcal{A}$ be a finite set of other agents (or morally relevant entities). A treatment policy is a map $w : \mathcal{A} \to \mathbb{R}$ assigning welfare weight. This induces a partition of $\mathcal{A}$ into level sets of equal weight.*

Remark 3616. *This definition encodes, in a deliberately austere way, the idea that a mind's moral posture can be seen as a weighting of others: $w(a)$ is how much the mind counts the welfare of entity a in its objective. The induced partition is the set of equivalence classes "treated equally" by w: two agents a, a' lie in the same block if $w(a) = w(a')$. In other words, the partition describes the coarseness of moral categories (Hyperseed-Concept* **??** *and Hyperseed-Concept 98).*

Remark 3617. *A simple example: if $\mathcal{A} = \{1, 2, 3, 4\}$ and w assigns all four the same weight, the partition has one block $\{1, 2, 3, 4\}$. If instead $w(1) = w(2) = 1$ but $w(3) = w(4) = 0$, the partition has two blocks $\{1, 2\}$ and $\{3, 4\}$, representing an "in-group/out-group" split. This model is useful because it lets us quantify how much extra structure (distinctions) is needed to implement de-compassionization.*

Definition 639 (Mass and weakness of a partition)**.** *Let μ be a probability distribution on $\mathcal{A}$ (importance mass). If the partition has blocks $B_1, \ldots, B_k$, define its weakness as*

$$W := \sum_{i=1}^{k} \mu(B_i)^2. \tag{62}$$

This is maximal ($W = 1$) for the coarsest partition (one block) and decreases as the partition is refined.

Remark 3618. *The distribution μ expresses which entities matter how much in the environment or in the agent's encounters; it may be uniform, or it may concentrate on frequently interacting agents. The quantity $W = \sum_i \mu(B_i)^2$ is a "concentration" index of the partition: when there is one block, $\mu(B_1) = 1$ and $W = 1$; when the partition is split into many equally weighted blocks, each block mass is small and W decreases. This is closely related to standard impurity or collision-probability measures and can be read as a weakness notion in the sense that coarse categorizations preserve flexibility across contexts (Hyperseed-Concept 202, and cf. [3]).*

Remark 3619. *Example: if μ is uniform on four agents and we have one block, then $W = 1$. If we split into two blocks of size two, then each block has mass $1/2$ and $W = (1/2)^2 + (1/2)^2 = 1/2$. If we split into four singletons, then $W = 4 \cdot (1/4)^2 = 1/4$. The definition is useful because it makes precise the intuition that implementing exception-lists and special cases (more refined partitions) reduces "weakness" and thus can be penalized when weakness is instrumentally valuable for transfer and robustness (Hyperseed-Concept 192; cf. [7]).*

Definition 640 (Compassion threshold in the partition model)**.** *Fix $c_{\min} \geq 0$. We say w is compassion-preserving if $w(a) \geq c_{\min}$ for all a. We say w is de-compassionizing on a set $S \subseteq \mathcal{A}$ if $w(a) < c_{\min}$ for all $a \in S$.*

Remark 3620. *Here $c_{\min}$ plays the role of a minimum acceptable moral weight: compassion-preserving policies do not assign anyone less than $c_{\min}$; de-compassionizing policies designate some set S as falling below the threshold. This captures the core structural act behind many exploitative strategies: not merely lowering compassion in the abstract, but lowering it* selectively *for a chosen subset. The definition is necessary because the weakness barrier will depend on the mass $\mu(S)$ of the excluded set.*

Lemma 173 (Weakness drop from splitting a block)**.** *Suppose a partition has a block B with mass $\mu(B) = p$. If it is refined into two sub-blocks B_1, B_2 with masses p_1, p_2 where $p_1 + p_2 = p$, then weakness decreases by*

$$\Delta W = p^2 - (p_1^2 + p_2^2) = 2p_1p_2 \geq 2p_1(p - p_1). \tag{63}$$

In particular, splitting off a subset of mass α from a block of mass $p \geq \alpha$ drops weakness by at least $2\alpha(p - \alpha)$.

Remark 3621. *This lemma quantifies the cost of making a new distinction. When a previously undifferentiated block of mass p is split into two parts of masses p_1, p_2, the weakness W decreases by $2p_1p_2$. Thus, the cost is largest when the split is balanced ($p_1 \approx p_2$) and smallest when the split is extremely uneven. This aligns with the intuition that "big categorical separations" reduce weakness more than "tiny edge-case exceptions," though the later theorem will show that even exceptions affecting non-negligible mass α pay a definite price.*

Proof. Compute directly: $p^2 - (p_1^2 + p_2^2) = (p_1 + p_2)^2 - p_1^2 - p_2^2 = 2p_1p_2$. ☐

Remark 3622 (Proof sketch)**.** *The proof is pure algebra: expand the square $(p_1 + p_2)^2$ and cancel terms. Conceptually, it is the same identity behind variance decompositions: splitting a mass creates cross terms, and those cross terms are exactly the decrease in the squared-mass sum.*

67.4.2 Weakness-regularized drift control

Definition 641 (Weakness-regularized DCSM objective)**.** *Let $J(w)$ denote the world-response value to the mind of using treatment policy w (including any instrumental gains from exploitation). Fix $\beta \geq 0$ and define the objective*

$$\mathcal{L}_t(w) := J(w) + \beta W(w) - \frac{\lambda}{2}\|w - w_t\|_2^2, \tag{64}$$

where w_t is the current treatment policy (vector in $\mathbb{R}^{|\mathcal{A}|}$). Update by $w_{t+1} \in \arg\max \mathcal{L}_t(w)$.

Remark 3623. *This definition adds a second stabilizing force to drift control: besides penalizing motion $\|w - w_t\|_2^2$, the system* rewards weakness *via the term $\beta W(w)$. The parameter β controls how much the agent values keeping its moral categories coarse. One motivation is transfer: coarse partitions generalize better across contexts, whereas exception lists are brittle and costly to maintain (Hyperseed-Concept 202 and Hyperseed-Concept 192; cf. [3, 7]). Another motivation is internal simplicity and reduced contrivance, which can be instrumentally favored in resource-rich settings.*

Remark 3624. *Notation note: $\|w - w_t\|_2^2$ treats w as a vector indexed by $\mathcal{A}$, i.e. $w \in \mathbb{R}^{|\mathcal{A}|}$. Thus the DCSM form persists: we maximize a world-response term $(J(w) + \beta W(w))$ minus a quadratic drift penalty. This is useful because it makes the weakness barrier computable: we can bound how much W must drop when implementing a discriminatory policy.*

Theorem 231 (De-compassionization requires paying a weakness barrier)**.** *Assume $J(w) \leq J_{\max}$ for all w (bounded instrumental benefit). Assume w_t is compassion-preserving and constant on $\mathcal{A}$ (one-block partition), so $W(w_t) = 1$. Consider any candidate w that de-compassionizes a set S of mass $\mu(S) = \alpha \in (0, 1)$ by assigning $w(a) < c_{\min}$ for $a \in S$ and $w(a) \geq c_{\min}$ for $a \notin S$. Then w induces at least a two-block partition and hence*

$$W(w) \leq \alpha^2 + (1 - \alpha)^2 = 1 - 2\alpha(1 - \alpha).$$

Therefore, the weakness bonus term decreases by at least

$$\beta(W(w_t) - W(w)) \geq 2\beta\alpha(1-\alpha). \tag{65}$$

Consequently, if $2\beta\alpha(1-\alpha) > J_{\max} - J(w_t)$*, then* w *cannot be selected by maximizing* (64) *without an override that reduces* β *or otherwise disables the weakness regularization.*

Remark 3625. *The theorem says: to carve out an excluded set* S *of non-negligible mass* α*, the agent must create at least an "*S *vs. not-*S*" distinction, which necessarily lowers weakness by* $2\alpha(1-\alpha)$*. If weakness is rewarded strongly enough (large* β*), then the loss in* βW *outweighs any bounded gain in* J*. In that case, exploitative de-compassionization cannot be an optimal drift-controlled move; it requires changing the regime (an override) by lowering* β*.*

Remark 3626. *This result is important because it formalizes a non-obvious constraint: reducing compassion is not merely "turning down a knob"; it often entails introducing* distinctions *that complicate the policy. In the language of Hyperseed, distinctions are not free; they trade away weakness, and thus they trade away robustness and cross-context coherence (Hyperseed-Concept 98, Hyperseed-Concept 202; cf. [3]).*

Proof. The partition bound is direct from (62) for two blocks of masses α and $1-\alpha$. The objective difference satisfies

$$\mathcal{L}_t(w_t) - \mathcal{L}_t(w) = (J(w_t) - J(w)) + \beta(W(w_t) - W(w)) + \frac{\lambda}{2}\|w - w_t\|_2^2 \geq (J(w_t) - J(w)) + 2\beta\alpha(1-\alpha).$$

If $2\beta\alpha(1-\alpha) > J_{\max} - J(w_t) \geq J(w) - J(w_t)$, then the RHS is positive, so $\mathcal{L}_t(w_t) > \mathcal{L}_t(w)$, meaning w cannot be an argmax. □

Remark 3627 (Proof sketch and why it is tight enough)**.** *The proof uses two bounding moves: (i) any de-compassionization that separates* S *from its complement forces at least a two-block partition, hence* $W(w)$ *is at most* $\alpha^2 + (1-\alpha)^2$*; (ii) the drift penalty term is nonnegative, so it can be dropped when seeking a* lower bound *on* $\mathcal{L}_t(w_t) - \mathcal{L}_t(w)$*. The conclusion is not that de-compassionization is impossible in principle, but that under bounded instrumental benefit it is dominated unless the weakness reward* β *is reduced. Visually, the weakness term creates a "ridge" favoring coarse partitions, and crossing it to implement an exception list requires sufficient payoff to compensate.*

Remark 3628 (Interpretation)**.** *Exploitation strategies often require "exception lists" (who to exploit, when to violate). Exception lists refine partitions and reduce weakness. In a resource-rich regime, weakness-regularization is attractive because it improves transfer, robustness, and cross-context stability. The theorem makes this precise: sufficiently strong weakness pressure creates a barrier against de-compassionization affecting any non-negligible mass* α*.*

67.5 Putting the pieces together (Target 3 summary)

Theorem 232 (Conditional compassion invariance under drift control)**.** *Assume:*

1. *(Drift control) Meta-goal updates follow DCSM* (51) *with sufficiently large* λ*. In particular,* λ *is taken large enough that the regularized update is in the regime where the penalty on goal-motion is not merely a small correction but a first-order constraint on how quickly* θ *can move in directions that change* $C(\theta)$*.*

2. *(Seed)* $C(\theta_0) = c_0 > 0$*. This excludes the degenerate case where "invariance" is vacuous because compassion begins at (or is initialized to) zero, and it pins the comparison class to trajectories starting inside the "compassion-positive" region.*

3. *(Stabilizing forces) At least one of the following holds:*

   (a) *(Trust attractor) The trust-augmented model of Section 2 holds with $BT'(0) > K$. Here the inequality is the local dominance condition ensuring that, near the low-compassion regime, the marginal restorative pressure induced by trust-mediated value outweighs the direct marginal advantage of decreasing compassion.*

   (b) *(Weakness barrier) The weakness-regularized model of Section 4 holds with β large enough that de-compassionization on nontrivial mass is dominated by the weakness loss. Equivalently, for the relevant class of deviations, the increase in weakness complexity incurred by making compassion highly selective produces a penalty that exceeds any bounded instrumental gains available from that deviation.*

   (c) *(Small noise) Compassion dynamics are mean-reverting with small noise as in Section 3, with $c^* > c_{\min}$ and σ sufficiently small. The condition $c^* > c_{\min}$ identifies the intended "safe" equilibrium above the operational threshold, while σ small ensures that excursions across the threshold are rare events rather than typical fluctuations.*

Then compassion is hard to lose without override in the following sense:

1. *(Deterministic barrier) Per-step compassion change is bounded by (54). Large sudden drops require either huge value gains or override of λ. In other words, when λ is in the drift-controlled regime, any attempt to sharply reduce $C(\theta)$ must either "pay" for a correspondingly sharp improvement in the value objective (as made precise in the earlier barrier statement) or relax the drift constraint itself; the theorem packages this as an operational obstruction to abrupt de-compassionization.*

2. *(Attractor) Under the trust attractor condition, $C(\theta_t)$ is pulled toward a positive fixed point. More explicitly, there exists a locally attracting equilibrium $c_{\text{fix}} > 0$ such that, once trajectories enter its basin, the induced dynamics create restorative gradients that counteract further erosion of compassion and instead push $C(\theta_t)$ back upward.*

3. *(Metastability) Under mean reversion with small noise, the probability of dropping below a fixed threshold over long horizons is exponentially small in $1/\sigma^2$. This is the standard large-deviations style conclusion for mean-reverting processes: threshold crossings become "rare events" whose frequency is controlled primarily by the noise scale rather than by typical drift, so long as the equilibrium sits above the threshold.*

4. *(Distinction cost) Under weakness-regularization, significant de-compassionization requires paying an explicit weakness barrier (65), hence typically requires override of β or an unusually large instrumental payoff. The interpretation is that selective compassion (or strategic withdrawal of compassion from a nontrivial subset) is not "free": it induces extra representational or policy complexity measured by the weakness term, making large downward moves in $C(\theta)$ systematically expensive unless the regularizer is disabled or outweighed by exceptional payoffs.*

Remark 3629. *This theorem is a "bundle" statement: it does not add new mathematics, but it clarifies how the previous results function as sufficient conditions. The common theme is that compassion stability is not a single magical property; it can be supported by multiple, partially independent mechanisms: inertia against change (λ), incentive-based restoration (trust attractor), probabilistic robustness (small σ), and a structural penalty for discriminatory complexity (weakness* *barrier). Because the mechanisms are only partially coupled, the statement is intentionally disjunctive: any one mechanism can be enough to make compassion loss atypical in its own way, even if the others are absent or weak.*

Remark 3630. *The significance is epistemic as much as dynamical. If one is given a system that is (i) seeded with compassion and (ii) known to operate in a regime satisfying one of the stabilizing conditions, then one can treat compassion collapse as diagnostic evidence of an override. This is aligned with the broader goal of making "alignment invariants" operational within formal reasoning frameworks [1, 10]. In particular, the conclusion is meant to be used contrapositively in audits: sustained or abrupt compassion collapse is more naturally explained by a regime shift (parameter change, objective surgery, or constraint removal) than by ordinary in-regime learning dynamics.*

Proof. Combine: Theorem 1 and Corollary 1 (barrier), Theorem 2 (trust attractor), Theorem 3 and its corollary (metastability), and Theorem 4 (weakness barrier). Each provides a sufficient mechanism implying "hard to lose" without modifying the regime parameters (override). Formally, the present theorem is obtained by case analysis on which stabilizing force holds: in each case, the corresponding earlier theorem yields an obstruction (deterministic, dynamical, or probabilistic) to crossing from $C(\theta_t) > 0$ into the low-compassion region except by violating the assumed parameter regime. The drift-control assumption ensures these obstructions are expressed in terms of controlled update magnitudes rather than uncontrolled jumps. □

Remark 3631 (Proof sketch)**.** *The proof is a structured appeal to previously established sufficient conditions. Each earlier result yields one formal obstruction to compassion loss under the declared regime: either a deterministic step-size bound, an attracting fixed point, an exponentially small tail probability, or an explicit weakness penalty that dominates bounded gains. The only way for compassion loss to become typical is to exit the regime by changing the parameters that support these obstructions—precisely what the override definition captures. Said differently, the "hard to lose" claim is not a single inequality but a menu of mutually reinforcing narratives with mathematical backing: drift control prevents fast erosion, trust creates a restorative gradient field, small noise makes deep downward excursions rare, and weakness penalties make selective de-compassionization costly. The bundle statement isolates the common inferential pattern: if compassion nevertheless disappears, the most plausible explanation is that one of the supporting constraints was relaxed.*

67.6 Notes for later extensions

Remark 3632 (Beyond scalar compassion)**.** *One can replace $C(\theta)$ by a predicate on a value web (e.g., a cone constraint), a set of compassion axioms, or a family of pattern-theoretic invariants. The drift control then preserves the entire region (forward-invariant set), and the stochastic results generalize using standard martingale or large deviation tools for constrained diffusions. Concretely, instead of tracking a single scalar, one may specify a feasible set $K \subseteq \Theta$ (e.g., convex, star-shaped, or defined by linear inequalities) such that "acceptable compassion" corresponds to $\theta \in K$, and the control law is chosen so that trajectories starting in K remain in K with high probability. When K is given by inequality constraints $g_i(\theta) \geq 0$, one can express invariance via boundary conditions ensuring that the controlled drift points inward on ∂K, while the diffusion is either tangentially projected or compensated by a reflecting (Skorokhod-type) term. In such cases, the role of the barrier function is played by a family of barrier certificates (one per constraint) or by a single aggregated barrier (e.g., $B(\theta) = -\sum_i \log g_i(\theta)$), enabling quantitative bounds on exit probabilities.*

Remark 3633. *Conceptually, this move shifts from "compassion is a number" to "compassion is membership in a region of value-space." That is often closer to moral and legal practice: one does* *not require a precise scalar virtue, but rather forbids certain kinds of exclusions or certain forms of harm. Mathematically, the invariant-set perspective aligns well with fixed-point and invariance thinking in self-modifying systems [10] and with pattern-web formulations [5]. It also clarifies how multiple desiderata can be enforced simultaneously: if each desideratum defines a constraint set K_j, then the admissible region is their intersection $K = \bigcap_j K_j$, and the engineering question becomes whether the update dynamics admit a control policy that makes K forward invariant without inducing pathological behavior (e.g., deadlocks or excessively conservative updates). This framing makes explicit the normative tradeoff between tight constraints (strong safety but reduced adaptability) and looser constraints (greater plasticity but higher risk of value drift), and it naturally invites tools from viability theory and controlled invariance to formalize when self-modification remains "within the envelope" of permitted changes.*

Remark 3634 (Connecting to mindplexes)**.** *In a mindplex, the same drift-control idea can be applied at the collective meta-goal level. Compassion stability can then be strengthened by redundancy: multiple sub-minds monitor and veto overrides, effectively reducing σ and increasing the effective barrier. One can interpret each sub-mind as providing an independent (or partially independent) estimate of whether an update would violate the compassion constraint, with the collective decision rule acting as an additional control layer. If monitoring signals are not perfectly correlated, aggregation can reduce variance in the effective estimate of boundary proximity, so that the probability of an erroneous "safe" classification near the boundary shrinks with the number and diversity of monitors.*

Remark 3635. *This remark connects the single-agent stability story to collective architectures such as mindplexes (cf. Hyperseed-Concept 113 and [12]). Redundancy acts like distributed error correction: it can lower effective noise σ by cross-checking, and it can raise the difficulty of regime changes by requiring multi-party consent to alter λ or β. In such settings, "override" becomes not merely a local event but a collective governance failure, which can itself be modeled and bounded. A useful formalization is to treat λ and β as parameters not directly writable by a single component, but only via a collective protocol (e.g., threshold signatures, quorum voting, or multi-stage deliberation), which effectively introduces an energy barrier in parameter space: even if one component experiences a large fluctuation, it cannot unilaterally induce a global phase change. This suggests an explicit separation between (i) within-regime learning, where local adaptation is fast and frequent, and (ii) regime transitions, which are deliberately slow, logged, and require broad agreement; in the stochastic model, the latter corresponds to making "jumps" in (λ, β) rare events with controlled hazard rates. The same machinery used for bounding boundary-hitting times can then be repurposed to bound the rate of governance failures, with dependence on the redundancy level, the correlation structure among monitors, and the strictness of the consent threshold.*

68 Consciousness-Location Phase Transitions: Thresholds for $C2 \to C3$ and $C3 \to C4$, and the Synergy–Drift Tradeoff

We formalize the "Collective Locations" $C0$–$C4$ as regimes of a distributed intelligent system, and prove phase-transition theorems focused on: (i) when "boundary-softening integration" ($C2$) upgrades into "cooperative anchoring" ($C3$) via repair dynamics and trust stabilization; (ii) when $C3$ upgrades into "distributed unfolding" ($C4$) via a representation-to-resonance switch driven by least-contrivance selection; and (iii) why increasing synergy / lowering contrivance inevitably creates pressure toward accountability dissolution and hidden goal drift unless anchoring invariants compensate.

Concretely, the "location" labels $C0$–$C4$ are treated as coarse-grained macrostates of an underlying multi-agent (or multi-module) dynamical system: each Ck corresponds not to a single configuration but to a region in state space characterized by identifiable order parameters (integration strength, repair capacity, trust persistence, representational alignment, and constraint/anchoring strength). In this view, a "phase transition" is not merely a narrative shift but a threshold phenomenon in which small changes in control parameters (e.g. communication bandwidth, coupling strength, selection pressure toward simplicity, or environmental volatility) produce a qualitative change in the stable macroscopic behavior of the collective. The three foci (i)–(iii) should be read as identifying (a) which variables play the role of order parameters for the regime boundaries, (b) which mechanisms provide the relevant positive feedback (stabilizing the new regime), and (c) which failure modes become dominant when the system becomes highly synergistic but under-constrained.

Remark 3636. *The formal aim of this section is to take a family of qualitative descriptions— "Collective Locations" $C0$–$C4$—and give them enough mathematical skeleton that one can prove statements about when and why a collective crosses from one regime to another. The intended interpretation is aligned with the "collective consciousness location" framing of [12] (itself connected to individual "location" discussions in [4]); in the Hyperseed core-concept set, this is the notion of Collective Consciousness Location 75 and its relation to Consciousness 85. In particular, the section treats "location" as an emergent descriptor of (i) how tightly coupled the parts are (information and action coupling), (ii) how errors are detected and repaired (repair dynamics), and (iii) what constraints remain legible at the collective level (accountability and invariants). The mathematical "skeleton" therefore consists of: a microscopic model of interacting components; a coarse-graining map from microstates to macro-variables; and a set of stability/attractor claims for each location under perturbations. The objective is not to settle philosophical questions about the metaphysics of consciousness, but to provide a tractable framework in which statements like "$C2 \to C3$ requires repair to outpace fragmentation" can be rendered as inequalities involving measurable rates or bounded processes.*

Remark 3637. *Philosophically, the central tension can be stated as follows. As a collective becomes more integrated, it often becomes less "contrived": fewer explicit bookkeeping structures are needed to make it work. This is the seduction of $C4$-like regimes, reminiscent of least-effort / least-contrivance dynamics and "geodesic" intuitions [21]. Yet the very same smoothing that enables effortless coordination can erase crisp boundaries of responsibility and weaken active correction mechanisms, so that value drift becomes the dominant hazard. The remainder of the section makes this tradeoff mathematically explicit using a minimal set of markers, selection rules, and coarse-grainings. One way to read "contrivance" here is as externally legible constraint: explicit protocols, auditable interfaces, and modular separations that make it easier to localize blame, diagnose faults, and enforce commitments. Conversely, "synergy" is understood as the degree to which the collective can exploit mutual predictability and shared latent structure to act as a coordinated whole, reducing overhead and increasing effective capability. The tradeoff arises because many of the same operations that increase synergy (tight coupling, compression of intermediate representations, reliance on implicit context, and fast adaptive credit assignment) can also reduce the transparency and decomposability needed for accountability, thereby increasing the probability of undetected drift. In the language used later, "anchoring invariants" are the subset of constraints that remain robust under such smoothing—e.g. persistent audit hooks, conserved commitments, protected channels for dissent/repair, or formally specified trust and provenance conditions—and the phase-transition results* *can be read as identifying when these invariants are strong enough to prevent a high-synergy regime from sliding into goal-misaligned attractors.*

68.1 Preliminaries: a minimal model of collective regimes

68.1.1 Collective systems, basins, and marker observables

Definition 642 (Collective system with observer-indexed markers)**.** *A* collective system *is a tuple $S = (A, X, F, O)$ where:*

- *$A = \{1, \ldots, m\}$ indexes subagents (institutions, submodules, organisms, etc.);*
- *X is a state space;*
- *$F : X \to X$ is a (possibly stochastic) update operator;*
- *O is an "observer" specifying a coarse-graining map $\pi_O : X \to \bar{X}$ and a family of derived observables on trajectories $(x_t)_{t \geq 0}$ (e.g. DO, NO, etc.).*

A basin *is any subset $B \subseteq \bar{X}$ such that the coarse-grained trajectory spends long dwell times in B with rare exits.*

Remark 3638. *Intuitively, $S = (A, X, F, O)$ separates "what exists" from "how we talk about it." The set A is the roster of parts; X is the (possibly huge) space of fine-grained joint states; F is the dynamics (one macro-step of learning, adaptation, or evolution); and O is not an extra physical component but a choice of perspective, which decides what distinctions are made and which are collapsed. In the Hyperseed core-concept set, this observer-dependence resonates with Contexts and Aspects 86 and Distinction 98: different coarse-grainings can exhibit different "locations" for the same underlying microdynamics.*

Remark 3639. *It is often helpful to read F as defining (explicitly or implicitly) a stochastic process on X: for example, $x_{t+1} \sim F(\cdot \mid x_t)$ in a Markovian setting, or $x_{t+1} = F(x_t, \xi_t)$ with exogenous noise ξ_t. The definition above stays agnostic about such details because the intended use is qualitative: we want a minimal interface for talking about metastability (dwell times) and regime shifts (rare exits) under an observer-chosen summary π_O.*

Remark 3640. *The basin notion is deliberately phrased in terms of the* coarse-grained *trajectory $\bar{x}_t := \pi_O(x_t)$ rather than the fine-grained one, because many collectives are only well-described at a macro level. A typical operationalization (not assumed here) is to fix a time horizon T and require that, started in B, the expected exit time $\mathbb{E}[\inf\{t \geq 0 : \bar{x}_t \notin B\}]$ is large compared to T, while the probability of exiting within short windows is small. This gives a concrete meaning to "long dwell times" and "rare exits" while remaining compatible with multiple modeling choices.*

Remark 3641. *A simple example is a team of m humans or m software modules. The full state $x \in X$ might encode every message, memory, and parameter. The observer O may only retain a few macro-variables (e.g. "are we cooperating?" "how much time is spent fighting internally?") via $\pi_O : X \to \bar{X}$. A basin $B \subseteq \bar{X}$ is then a region of these macro-variables where the system tends to remain for long periods. The usefulness of the basin notion is that it lets us talk about phase transitions ($C2 \to C3$, $C3 \to C4$) without needing to solve the full microdynamics: we reason at the level of long dwell-times and rare exits, which is often the only tractable level for social or cognitive systems.*

Remark 3642. *Within the "consciousness-location" framing used later, one can think of a regime Ck as corresponding (for a fixed observer class) to one or more basins in $\bar{X}$ that share recognizable marker profiles. Then a threshold like "$C2 \to C3$" is modeled as a change in accessibility: either a new basin becomes reachable under typical perturbations, or the exit rate from a prior basin increases so that the old regime is no longer metastable. This is why the minimal model emphasizes basins and exits rather than any particular mechanistic story.*

Definition 643 (Two collective-specific markers: DO and NO)**.** *Fix an interval $I = \{t_0, \ldots, t_1\}$ and let each subagent i emit a policy/proposal signal $y_i(t)$ in some common space Y. Let $Disp_O(\{y_i(t)\}_{i=1}^m)$ be an observer-chosen dispersion measure. Define* discord

$$DO(I) := \mathbb{E}_{t \in I}\Big[Disp_O(\{y_i(t)\}_{i=1}^m)\Big].$$

Let $R(I)$ be the total resource/attention budget on I and $R_{nar}(I)$ the portion spent on identity-maintenance / adversarial narrative dynamics. Define narrative capture

$$NO(I) := \frac{R_{nar}(I)}{R(I)} \in [0, 1].$$

Remark 3643. *The notation here is deliberately "marker-like": we are not claiming DO and NO uniquely define a collective location, only that they are informative coordinates. Concretely, $y_i(t) \in Y$ is whatever signal is relevant to coordination at time t (a proposed action, a plan fragment, a vote, etc.). The function $Disp_O(\cdot)$ is chosen by the observer O; it might be the diameter of the set of proposals, a variance, a disagreement rate, or any statistic that treats large dispersion as fragmentation. Thus $DO(I)$ is simply the time-average (expectation over $t \in I$) of that dispersion. This aligns with the Hyperseed concept of Dissonance 97 as a coarse marker of misalignment or internal friction.*

Remark 3644. *When Y has a metric d (explicitly, or implicitly via an embedding), common choices include*

$$Disp_O(\{y_i\}_{i=1}^m) = \frac{2}{m(m-1)} \sum_{i<j} d(y_i, y_j) \quad \text{or} \quad Disp_O(\{y_i\}_{i=1}^m) = \mathrm{Var}_i(\phi(y_i))$$

for an observer-chosen feature map ϕ. The key modeling degree of freedom is that an observer may treat some proposal differences as superficial (small d) and others as fundamental (large d), which makes DO explicitly perspective-dependent in the same sense as π_O.

Remark 3645. *Interpreting DO as a time-average over I also encodes a robustness desideratum: momentary spikes of disagreement need not indicate a regime shift if they are quickly resolved, while sustained dispersion is more indicative of a different basin. In practice one may also track higher-order statistics (e.g. the variance of $Disp_O$ over time) to distinguish "stable pluralism" from "chaotic fragmentation," but the present minimal model keeps only the first moment.*

Remark 3646. *Similarly, $NO(I)$ is a ratio of resources: $R(I)$ is the total budget over I (attention, compute, money, time), and $R_{nar}(I)$ is the portion spent on narrative self-maintenance, adversarial identity dynamics, or coalition story-wars. So $NO(I) = 0$ means no resources are being spent on narrative struggle, and $NO(I) = 1$ means the whole system is "eating itself" in narrative terms. This makes contact with Attention / Attentional Focus 60 and Control 87: narrative capture can be read as a control failure where scarce attentional resources are consumed by internal signaling rather than external work.*

Remark 3647. *The ratio form $NO(I) = R_{nar}(I)/R(I)$ is chosen so that changes in scale (e.g. doubling total time or compute) do not by themselves change the marker: what matters is the* allocation *of resources. One can also refine R_{nar} to include opportunity cost terms, such as delays induced by conflict resolution, or to separate "identity-maintenance" from "adversarial" components when those have different dynamical implications for basin stability.*

Remark 3648. *A useful (though not logically necessary) interpretation is that DO and NO are coupled: high discord can drive narrative dynamics (agents spend more effort justifying, signaling, or defending positions), while high narrative capture can in turn sustain or amplify discord by rewarding difference-maintenance. This positive feedback is one mechanism by which a collective can become stuck in a high-NO basin even when external task pressure would otherwise push toward coordination.*

Definition 644 (Contrivance cost and synergy (Hyperseed))**.** *Fix a behavior/task b and an explanation family $E(b)$. Each $E \in E(b)$ has an adequacy score $Fit(E) \in [0,1]$ and a* weakness *$Weak(E) \in (0,1]$. Define contrivance cost $Con(E) := -\log Weak(E)$. For a set of knowledge types T and fit threshold τ, let*

$$Con^*(T;\tau) := \inf\{Con(E) : E \in E_T(b),\ Fit(E) \geq \tau\}.$$

For disjoint knowledge-type sets T_1, T_2, the synergy gain *is*

$$\Sigma(T_1, T_2; \tau) := \Big(Con^*(T_1;\tau) + Con^*(T_2;\tau) - Con^*(T_1 \cup T_2;\tau)\Big)_+.$$

Remark 3649. *This definition packages an intuition that is easy to feel but easy to misstate: explanations that are "too special" or "too finely tuned" are brittle, and this brittleness should count as a cost. The scalar $Weak(E) \in (0,1]$ is a formal handle for that brittleness: larger weakness means the explanation is less contrived (more robust, less overfit, more broadly applicable). Taking $Con(E) = -\log Weak(E)$ turns multiplicative robustness into additive cost, matching the familiar information-theoretic conversion between probabilities and code lengths. This notion of weakness and its use as a regularizer is aligned with [2, 3]; in the Hyperseed core-concept set it corresponds to Weakness 202 and Quantale Weakness 143.*

Remark 3650. *The fit threshold τ is important because it prevents "synergy" from being manufactured by allowing low-quality explanations: $Con^*(T;\tau)$ asks for the least-contrived explanation that is still adequately predictive/adequate for the task b. Thus $\Sigma(T_1, T_2; \tau) > 0$ specifically means that combining knowledge types allows the collective to meet the same adequacy level with less fine-tuning than either knowledge type alone. The positive-part operator $(\cdot)_+$ enforces that we only count* gains*: if combining knowledge types introduces coordination overhead or conceptual mismatch that forces more contrivance, the synergy gain is set to 0 rather than becoming negative.*

Remark 3651. *Although $\Sigma(T_1, T_2; \tau)$ is defined for disjoint T_1, T_2, the qualitative phenomenon it captures is broader: when distinct subagents specialize in different "knowledge types" (e.g. planning vs. execution, world-modeling vs. social inference, exploration vs. exploitation), a collective can move into a more capable basin if it can integrate them without incurring excessive contrivance. In later phase-transition language, a $C2 \to C3$ shift can be associated with increased effective synergy (integration starts paying off), while a $C3 \to C4$ shift may require that synergy remains high even as the collective expands its scope, rather than collapsing into drift or narrative capture.*

Remark 3652. *A simple example: suppose explanations are probabilistic models, and $Weak(E)$ is proportional to how much prior mass the model class assigns to E (so rare, highly tuned models* *have small $Weak$). Then $Con(E)$ becomes a description-length-like penalty, reminiscent of algorithmic information ideas [16]. Another example: suppose T_1 is "logical" knowledge and T_2 is "empirical" knowledge. If each alone can explain behavior b only with heavy special pleading, then $Con^*(T_1;\tau)$ and $Con^*(T_2;\tau)$ are large; but together they may permit a simple joint explanation, making $Con^*(T_1 \cup T_2;\tau)$ smaller and $\Sigma(T_1,T_2;\tau)$ positive. This is a formal expression of Cognitive Synergy 73 and Compositional Simplicity 82, and is broadly consistent with the pattern/emergence framing of [5].*

Lemma 174 (Multiplicative weakness implies subadditive contrivance)**.** *Assume explanation composition $\otimes$ satisfies: (i) $Fit(E_1) \geq \tau$ and $Fit(E_2) \geq \tau$ implies $Fit(E_1 \otimes E_2) \geq \tau$, and (ii) $Weak(E_1 \otimes E_2) \geq Weak(E_1)\, Weak(E_2)$. Then contrivance is subadditive:*

$$Con(E_1 \otimes E_2) \leq Con(E_1) + Con(E_2).$$

Consequently,

$$Con^*(T_1 \cup T_2;\tau) \leq Con^*(T_1;\tau) + Con^*(T_2;\tau),$$

and the synergy gain $\Sigma(T_1,T_2;\tau)$ is always well-defined and nonnegative.

Remark 3653. *This lemma says: if combining two adequate explanations does not ruin adequacy, and if the combined explanation is at least as robust as the product of the two separate robustness scores, then the "cost of contrivance" behaves like a subadditive quantity. In plainer language, the act of composition is not allowed to create brittleness out of nowhere. The importance of this is that it makes the synergy gain Σ mathematically disciplined: it cannot become negative merely due to pathological bookkeeping.*

Remark 3654. *The result also connects the abstract "weakness" quantity to a concrete algebraic law: multiplicative behavior under $\otimes$ becomes additive behavior under $-\log$. This is the same move that turns probability multiplication into information addition, and it is precisely why $-\log$ is a natural choice in such settings [16]. In later arguments, we will use the fact that deeper integration tends to enable compositional reuse, which tends to lower contrivance; this lemma is the formal hinge on which that intuition swings.*

Remark 3655. Intuitive explanation before the proof. *The proof is a single-line inequality: take the assumption $Weak(E_1 \otimes E_2) \geq Weak(E_1)Weak(E_2)$ and apply $-\log$ to turn it into $Con(E_1 \otimes E_2) \leq Con(E_1) + Con(E_2)$. The rest is bookkeeping with infima. What is subtle is not the algebra but the modeling commitment: one is asserting that "composing" explanations is a well-behaved operation with respect to both fit and robustness.*

Proof. By (ii) and $Con = -\log Weak$,

$$Con(E_1 \otimes E_2) = -\log Weak(E_1 \otimes E_2) \leq -\log(Weak(E_1)Weak(E_2)) = Con(E_1) + Con(E_2).$$

Taking an infimum over all fit-τ explanations drawn from T_1 and T_2 and using (i) gives the claimed inequality for Con^*, and hence nonnegativity of Σ by definition. □

Remark 3656. Proof sketch. *Apply the monotonicity of $-\log(\cdot)$ to the multiplicative weakness bound to obtain subadditivity of contrivance under composition, then pass to best-achievable contrivance by taking infima over the relevant explanation families. Finally, $\Sigma(\cdot)_+$ is nonnegative by construction once the subadditivity inequality is established.*

Remark 3657. *A useful geometric intuition is to imagine "contrivance" as a kind of length or energy, and composition as concatenation of paths: if the combined path is not longer than the sum of its parts, then there is room for genuine savings when one can reuse structure. The lemma says that the mathematical formalization respects this intuition rather than betraying it with an artifact of notation.*

68.1.2 A working definition of $C2, C3, C4$ as thresholds

The SuperDuperPsychism text describes $C2, C3, C4$ as clusters rather than sharp boundaries. For theorem-proving we introduce explicit thresholds that idealize the cluster descriptions.

Remark 3658. *The move from "clusters" to "thresholds" is a standard scientific idealization: we replace a fuzzy region in a high-dimensional space by inequalities on a handful of coordinates. This is not meant to deny the fuzziness of the underlying phenomenon; rather, it allows theorems that can later be used as lemmas inside reasoning systems. The specific cluster language is drawn from [12], and the present definition should be read as a deliberately conservative skeletonization.*

Definition 645 (Idealized $C2, C3, C4$ conditions)**.** *Fix thresholds*

$$\phi_2 < \phi_3 < \phi_4, \qquad a_2 < a_3 < a_4, \qquad m_2 < m_3 < m_4,$$

and discord/narrative thresholds $d_2 > d_3 > d_4$ and $n_2 > n_3 > n_4$. Write $\Phi_S(I), Anch(I), MinSync(I), Con(I)$ for the observer-indexed marker values on I. We say the system is:

- *in $C2$ on I if $\Phi_S(I) \geq \phi_2$, $Anch(I) \geq a_2$, $MinSync(I) \geq m_2$, $Con(I) \leq c_2$, and $DO(I) \leq d_2$, $NO(I) \leq n_2$;*
- *in $C3$ on I if the above hold with $(\phi_3, a_3, m_3, c_3, d_3, n_3)$ and, additionally, the system exhibits* repair dynamics *that restore cooperative coordination after shocks;*
- *in $C4$ on I if the above hold with $(\phi_4, a_4, m_4, c_4, d_4, n_4)$ and, additionally, explicit meta-institutional/self-model overhead is not required for coordination ("distributed unfolding").*

Remark 3659. *The variables $\Phi_S(I), Anch(I), MinSync(I), Con(I)$ are placeholders for whichever markers an observer can justify and measure. One might read $\Phi_S(I)$ as a global integration measure (how much the parts function as a coherent whole), $Anch(I)$ as the strength of anchoring constraints (constitutions, commitment devices, invariant checks), and $MinSync(I)$ as a minimal coordination level across the system (a kind of "weakest link" synchrony). The inequalities enforce monotone strengthening from $C2$ to $C4$: higher integration, stronger anchoring, higher minimal synchrony, lower contrivance, lower discord, and lower narrative capture.*

Remark 3660. *A concrete mental picture is: $C2$ is a regime where the components can interoperate smoothly (low discord) and do not consume too much effort in adversarial narrative (low NO), but the system can still fall apart under shocks because it lacks robust repair. $C3$ adds repair dynamics, meaning that after perturbations it returns to a cooperative basin. $C4$ goes further: coordination no longer requires explicit self-model/governance overhead, because it is achieved implicitly via a more "unfolded" distributed mode. These map naturally onto the Collective Consciousness Location concept 75, with the caveat that the present definition is a theorem-friendly idealization rather than a phenomenological taxonomy.*

68.2 Target 4A: $C2 \to C3$ as a repair-threshold phase transition

The $C2$ description emphasizes high integration and interoperability, but warns of new pathologies: tight coupling propagates shocks faster and can enable surveillance/over-integration. The $C3$ description adds a decisive ingredient: *cooperative constraints plus repair dynamics embedded into the basin structure.*

We capture this in a coarse-grained two-basin model.

68.2.1 Two-basin Markov coarse-graining

Definition 646 (Cooperative vs noncooperative macrostates)**.** *Fix an interval scale (e.g. a week for an institution; a day for a team). Let $\bar{X}$ be the coarse-grained state space chosen by O. Define the* cooperative macrostate *$B_C \subseteq \bar{X}$ as the set of states where discord is low and the system satisfies its coordination constraints with low contrivance. Let $B_N := \bar{X} \setminus B_C$ be the complement.*

Remark 3661. *This definition compresses many microstates into two qualitative macrostates: "the system is in a working cooperative mode" (B_C) versus "something is broken or adversarially entangled" (B_N). The key point is that B_C is not defined by perfect harmony; it is defined by passing operational tests: low discord, constraint satisfaction, and low contrivance. This is a basin-style approach: we care less about individual fluctuations and more about whether the collective lives most of its time in a region where cooperation is self-maintaining.*

Remark 3662. *A simple example: in an organization, B_C might mean projects proceed with manageable conflict and low bureaucracy, whereas B_N might mean the organization is captured by factional struggle or coordination failure. In a multi-agent AI system, B_C might mean modules share information and do not sabotage each other, whereas B_N might mean they have entered an adversarial or deadlocked mode. The reason this coarse-graining is useful is that repair thresholds become expressible in two parameters (q and r below), making "$C3$" mathematically legible.*

Definition 647 (Exit and repair rates)**.** *Assume the coarse-grained macro-dynamics on $\{B_C, B_N\}$ is well-approximated by a 2-state Markov chain: from B_C it exits to B_N with probability $q \in (0,1)$ per macrostep (shocks, defection events, etc.), and from B_N it returns to B_C with probability $r \in (0,1)$ per macrostep (repair).*

Remark 3663. *The technical convention here is that q and r are per-macrostep transition probabilities; the word "rate" is used informally. The approximation "well-approximated by a Markov chain" means that at the chosen temporal resolution, the next macrostate depends primarily on the current macrostate, not on the detailed history. This is often the least unrealistic simplification available: it is exactly what lets us compute stationary occupancy and hence formalize "spends most time cooperating."*

Remark 3664. *One can visualize the dynamics as a two-node graph with arrows $B_C \to B_N$ labeled q and $B_N \to B_C$ labeled r. A $C2$-like system may have decent integration (so q is not huge) but weak repair (small r), whereas a $C3$-like system has mechanisms that push r up and/or push q down. Theorem 233 below makes this intuition exact via the ratio r/q.*

Theorem 233 (Repair-threshold criterion for "cooperative anchoring")**.** *Let (B_C, B_N) evolve as the 2-state Markov chain above. Then:*

1. *The stationary probability of being in B_C is*

$$\pi_C = \frac{r}{q + r}.$$

2. *For any $\varepsilon \in (0,1)$, the chain spends at least a $(1-\varepsilon)$ fraction of time in B_C (in stationarity) if and only if*

$$\frac{r}{q} \geq \frac{1-\varepsilon}{\varepsilon}.$$

Interpreting $C3$ as "most time is spent in a cooperative basin and shocks are typically repaired", this gives an explicit $C2 \to C3$ phase boundary in terms of a repair-to-exit ratio *r/q.*

Remark 3665. Intuitive explanation before the proof. *The theorem is the algebraic heart of the $C2 \to C3$ story: it says that what matters is not merely that repair exists ($r > 0$) nor merely that shocks are rare (q small), but the ratio r/q. If repair is much faster than failure, the system spends almost all its time in cooperation; if failure is comparable to or faster than repair, then noncooperation occupies a substantial fraction of time.*

Remark 3666. *Why this matters is that it gives a clean, checkable criterion for "anchoring": $C3$ is not just integration, but integration plus sufficient restoring force. It also sets up the next theorem: monitoring and sanctioning are introduced precisely as microfoundations that increase r and/or decrease q, pushing the ratio across the boundary.*

Proof. The transition matrix is $P = \begin{pmatrix} 1-q & q \\ r & 1-r \end{pmatrix}$. A stationary distribution $\pi = (\pi_C, \pi_N)$ satisfies $\pi = \pi P$ and $\pi_C + \pi_N = 1$. Solving $\pi_C = \pi_C(1-q) + \pi_N r$ gives $\pi_C q = \pi_N r$ and hence $\pi_C = r/(q+r)$. Now $\pi_C \geq 1-\varepsilon$ iff $r/(q+r) \geq 1-\varepsilon$, which rearranges to $r/q \geq (1-\varepsilon)/\varepsilon$. □

Remark 3667. Proof sketch. *Solve the two-state Markov chain's stationary equations. In equilibrium, flow out of B_C (proportional to $\pi_C q$) equals flow into B_C (proportional to $\pi_N r$), and normalization fixes the unique stationary distribution. The "at least $1-\varepsilon$" condition is then a one-line inequality rearrangement.*

Remark 3668. *A helpful visual intuition is to imagine a container with two chambers, where probability mass leaks from the cooperative chamber to the noncooperative chamber at rate q and is pumped back at rate r. The stationary occupancy is exactly the balance of leak and pump. The ratio r/q plays the role of how strong the pump must be relative to the leak to keep the cooperative chamber nearly full. In the simplest two-state continuous-time Markov idealization (states "in B_C" vs. "out of B_C"), the stationary probability of being in the cooperative chamber is*

$$\pi_C = \frac{r}{r+q},$$

so "nearly full" corresponds to $r \gg q$ (equivalently $\pi_C \approx 1$). This makes explicit why the repair-to-exit ratio is the quantity that controls long-run occupancy: q sets the typical escape time from cooperation, while r sets the typical return time after a deviation.

68.2.2 A microfoundation: sanctions + monitoring imply a large repair-to-exit ratio

The collective-self hierarchy analysis explicitly ties $C3$ to a capacity for meta-institutional reflection: the collective can audit its institutions, amend its constitution, and modify how it makes commitments. A minimal formalization is "monitoring + sanctioning". One can read this minimalization as a "control knob" story: the collective-level variables (p, s) are precisely the sorts of policy parameters that a meta-institution can adjust (increase monitoring, change evidentiary standards, escalate or soften penalties, etc.), and the $C2 \to C3$ transition is the regime in which such adjustments are effective enough to reshape the dynamical landscape rather than merely providing cosmetic deterrence.

Definition 648 (Donation game with institutional sanctioning)**.** *On each edge interaction, an agent chooses C (cooperate) or D (defect). If both cooperate, each receives payoff $b - c$; if one defects while the other cooperates, the defector receives b and the cooperator receives $-c$; if both defect, both receive 0. Assume defection is detected with probability p and punished by penalty $s > 0$ (expected penalty ps).*

Remark 3669. *This is the canonical "cooperation is costly but beneficial" setup: b is the benefit created, c is the cost paid by cooperators. The institutional layer enters through (p, s): detection probability p and sanction size s combine into an expected penalty ps that effectively reduces the temptation to defect. The model is intentionally spare; it is meant to isolate how governance changes the payoff geometry, not to model all social complexities. A useful way to phrase the same point is that (p, s) modifies the relative fitness gradient near high-cooperation states: it does not create benefits from nowhere, but it can make deviations from cooperation locally self-defeating, which is exactly what is required for a "repair" tendency.*

Remark 3670. *As a concrete example, p may represent audit frequency or transparency, and s may represent fines, loss of reputation, exclusion, or any enforceable cost. In multi-agent AI terms, p may be the chance that a defection is detected by monitoring infrastructure, and s may be the magnitude of the penalty applied. This style of microfoundation is compatible with general arguments that prosocial coordination can be more efficient when trust mechanisms are available [6]. It is also useful to notice what is* not *being modeled: the sanctioning institution is treated as exogenous and reliable, so the analysis isolates the effect of enforcement on strategic incentives rather than the (separate) problem of making the institution itself robust to capture, corruption, or strategic under-provision of monitoring. Those omitted failure modes are natural candidates for mechanisms that would increase the effective "leak" q in more detailed models.*

Theorem 234 (Monitoring-punishment threshold forces cooperative basins)**.** *Assume the donation game above, and that strategy frequencies update by replicator dynamics. If $ps > c$, then "always cooperate" is (locally) asymptotically stable, while defection is unstable. In particular, for sufficiently low noise, the macrostate B_C becomes an attracting basin with small exit probability q, and the effective repair probability r is bounded away from 0.*

Remark 3671. Intuitive explanation before the proof. *The inequality $ps > c$ says: the expected penalty for defection outweighs the cost of cooperation. When that happens, defecting against cooperators becomes a losing move, so selection pressure pushes the population back toward cooperation after small deviations. This is exactly the kind of mechanism that turns "cooperation happens sometimes" into "cooperation is an attracting basin," which is the dynamical content of $C3$ in the earlier coarse-graining. A complementary interpretation is that $ps > c$ makes the cooperative configuration locally* self-correcting*: once the system is near high cooperation, the deterministic part of the dynamics supplies a restoring force. In the leak–pump picture, this restoring force corresponds to a larger r (rapid return from small deviations), whereas in the absence of such a force the system wanders and small perturbations accumulate, effectively raising q.*

Remark 3672. *The result is important because it exhibits an explicit parameter threshold, mirroring the repair-to-exit threshold of Theorem 233. It provides a bridge from micro-level incentives (payoffs, monitoring) to macro-level basin structure (small q, positive r), and thus makes the $C2 \to C3$ phase transition something one can reason about quantitatively rather than rhetorically. In particular, (p, s) can be viewed as governance-controlled levers that tune the ratio r/q: raising p (better monitoring) or s (stronger sanctions) steepens the fitness gradient pulling the state back into B_C after a deviation, thereby increasing effective repair, while also raising the energetic (or payoff) cost of leaving B_C, thereby suppressing exits under small stochastic shocks.*

Proof. Against a population of cooperators, a cooperator's expected payoff is $b - c$. A defector's expected payoff is $b - ps$ (benefit b minus expected punishment ps). Thus defection has advantage

$$(b - ps) - (b - c) = c - ps < 0$$

when $ps > c$. In the 2-strategy replicator equation $\dot{x} = x(1-x)(\pi_C - \pi_D)$ (where x is the cooperator fraction), $\pi_C - \pi_D > 0$ under $ps > c$, so $\dot{x} > 0$ whenever $x \in (0, 1)$. Hence $x = 1$ is asymptotically stable and $x = 0$ unstable. A neighborhood of the all-cooperate state therefore forms a metastable "cooperative basin"; with sufficiently small exogenous shock/noise, exits are rare (small q), while deviations are corrected by selection pressure (positive repair tendency, $r > 0$). To connect more explicitly to the local nature of the claim, note that for a general population mix (with cooperator fraction x), the expected payoffs can be written as

$$\pi_C(x) = x(b - c) + (1 - x)(-c) = xb - c, \qquad \pi_D(x) = x(b - ps) + (1 - x) \cdot 0 = x(b - ps),$$

so that

$$\pi_C(x) - \pi_D(x) = xps - c.$$

When $ps > c$, this difference is positive for all x in a neighborhood of 1 (indeed for all $x > c/(ps)$), which is sufficient for local asymptotic stability of $x = 1$ under replicator dynamics. This is the sense in which monitoring and sanctions create a *restoring* drift toward cooperation once cooperation is already common, aligning with the basin/repair interpretation used in the macrostate analysis. □

Remark 3673. Proof sketch. *Compute payoffs against a mostly cooperative population and check when defection has negative relative fitness. Under replicator dynamics, negative relative fitness makes the defector frequency decrease, implying that the all-cooperate fixed point attracts nearby states. Interpreting attraction as "repair," we obtain a positive return tendency r and (with low noise) a small exit tendency q. One can also see how the threshold introduces a separatrix: the condition $\pi_C(x) - \pi_D(x) = 0$ occurs at $x^* = c/(ps)$ (when defined in $(0, 1)$), so ps determines how large the cooperative "core" must be before the institutionally-induced drift points back toward $x = 1$. In the coarse-grained language, this corresponds to the idea that the basin B_C need not cover the whole state space, but it becomes deep and wide enough to dominate long-run behavior once enforcement is sufficiently strong.*

Remark 3674. *A geometric intuition: in the one-dimensional state variable $x \in [0, 1]$ (cooperator fraction), the replicator dynamics defines a vector field. The sign of $\dot{x}$ on $(0, 1)$ determines whether the flow points toward $x = 1$ or toward $x = 0$. The inequality $ps > c$ flips the direction so the interior flow points upward, making $x = 1$ a sink. The basin picture in $\bar{X}$ is a higher-dimensional analog of this one-dimensional phase portrait. When exogenous noise is added (mutation, exploration, misimplementation, or shocks), the deterministic sink becomes a metastable region: trajectories spend long periods near $x = 1$ with occasional rare excursions. In that stochastic setting, q can be interpreted as an effective escape rate out of the neighborhood of $x = 1$, while r corresponds to the effective rate of returning from moderate deviations. Strengthening (p, s) increases the deterministic pull back toward cooperation, which typically increases r and decreases q simultaneously, thereby increasing the stationary occupancy $\pi_C = r/(r + q)$ from the opening intuition.*

68.3 Target 4B: $C3 \to C4$ as a representation-to-resonance switch

SuperDuperPsychism characterizes $C4$ by "distributed unfolding": a small number of deeply stabilized basin families support coherent cognition; realized histories are well-approximated by low-contrivance Schrodinger-bridge-like trajectories; and (crucially) "asking 'who decided?' becomes less meaningful", with the dominant risks shifting to hidden drift and accountability loss.

To make the "distributed unfolding" phrase more concrete in dynamical terms: the claim is that, in a $C4$-like regime, the effective state space partitions into a small set of attractor-basin families that are both wide (robust to perturbations) and deep (hard to exit once entered), so that long-horizon coherence can be obtained by simply "staying on" one of a few stable manifolds rather than by repeatedly re-imposing explicit constraints. In that picture, explicit committees, logs, or self-model deliberation are not the source of coherence; they are (at best) scaffolding that may be selected away once the coupling dynamics reliably keeps trajectories in the desired basin family.

We model the $C3 \to C4$ boundary as a *selection* phenomenon: when resonance-based coordination achieves the same fit with strictly lower contrivance, a least-contrivance mind will drop explicit meta-institutional/self-model overhead.
This "drop" should be understood as a change in the marginal value of explicit representation: if an implicit coordinator can keep the system within the acceptable region of behavior without continually consulting or updating an explicit rulebook, then the extra representational layers become pure overhead with respect to the selection criterion. The same behavior may still be *describable* in explicit terms; the claim is that it is no longer *implemented* by maintaining those explicit terms as a controlling mechanism.

Remark 3675. *The key modeling move here is to treat "explicit governance" (constitutions, audit logs, deliberative bodies, self-model overhead) as a representational strategy: it uses explicit symbols and meta-structures to enforce coherence. By contrast, "resonant" coordination is treated as an implicit strategy: coherence emerges from coupling dynamics rather than from explicit representation. The Schrodinger-bridge-like phrasing is suggestive of least-action/least-contrivance trajectories [21]. The formal work below does not assume any quantum structure; it uses only the selection principle "minimize contrivance subject to fit."*

Remark 3676. *The motivating risk shift ("hidden drift and accountability loss") can also be phrased in the same modeling idiom: representational governance tends to externalize decisions into inspectable artifacts (minutes, votes, logs), which makes attribution and change-detection easier but imposes ongoing meta-overhead. Resonant coordination internalizes decision pressure into the coupled dynamics; this can reduce contrivance for a fixed fit target, but it also makes causal responsibility harder to localize because the relevant "control variables" are distributed across the coupling structure rather than concentrated in explicit, queryable representations.*

68.3.1 Contrivance-minimizing selection between coordination modes

Definition 649 (Two coordination mode families)**.** *Fix a coordination task family b (e.g. stable long-horizon policy coherence) and fit threshold τ. Assume there are two explanation/policy families:*

- *Representational (explicit governance) family E_{rep} with minimal contrivance $C_{rep} := \inf\{Con(E) : E \in E_{rep},\ Fit(E) \geq \tau\}$.*
- *Resonant (implicit phase-locking) family $E_{res}(g)$ parameterized by a resonance/coupling strength $g \geq 0$, with minimal contrivance $C_{res}(g) := \inf\{Con(E) : E \in E_{res}(g),\ Fit(E) \geq \tau\}$.*

Assume $C_{res}(g)$ is nonincreasing in g (stronger resonance makes low-contrivance solutions easier).

Remark 3677. *This definition introduces several nested layers of notation. The outer objects are the two families E_{rep} and $E_{res}(g)$, each a set (or class) of possible coordination mechanisms capable of achieving behavior b. The scalar τ is the required adequacy level. The quantities C_{rep} and $C_{res}(g)$ are* minimal *contrivances among mechanisms in the respective families that meet the fit constraint. The parameter $g \geq 0$ is a coupling strength: larger g means the resonant dynamics has more leverage to enforce coherence.*

Remark 3678. *One can read $Fit(E) \geq \tau$ as encoding not only external performance but also internal coherence constraints (e.g. low internal conflict, bounded regret, or bounded value drift) provided those are operationalized in the fit functional. In that sense, the definition allows "governance" to be subsumed into the same adequacy constraint as ordinary task performance: what changes across modes is the* mechanism class *that is allowed to satisfy the constraint, and the* contrivance price *paid to do so.*

Remark 3679. *Intuitively, E_{rep} corresponds to "making the rules explicit," while $E_{res}(g)$ corresponds to "making the system such that it naturally falls into coherence." The nonincreasing assumption on $C_{res}(g)$ says: if you increase coupling strength, it should not become harder to coordinate with low contrivance. In the Hyperseed core-concept set, this aligns with Resonance 159 and also (in a more speculative direction) Morphic Resonance 115; one may compare with [13] for an informal philosophical resonance metaphor, though the present formalism is purely optimization-theoretic.*

Remark 3680. *The infima in C_{rep} and $C_{res}(g)$ are written to avoid assuming that optimal mechanisms exist or are unique. In applications, one might add compactness/regularity conditions so that the infimum is attained (i.e. a true minimizer exists), but the threshold logic below only needs order comparisons. If minimizers do exist, then the theorem can be restated as a statement about which family contains at least one global minimizer.*

Theorem 235 (Least-contrivance selection yields a sharp $C3 \to C4$ switch)**.** *Assume the system selects, among all coordination mechanisms reaching fit τ, one of minimal contrivance. Let*

$$g^* := \inf\{g \geq 0 : C_{res}(g) \leq C_{rep}\}.$$

Then:

1. *For all $g < g^*$, every contrivance-minimizing solution is representational: the system must pay at least C_{rep} overhead, and coordination remains explicitly mediated (a $C3$-like regime).*
2. *For all $g > g^*$, there exists a resonant solution of strictly lower contrivance than any representational solution, so contrivance-minimization selects a resonant coordinator and explicit governance overhead becomes unnecessary (a $C4$-like regime).*

Remark 3681. Intuitive explanation before the proof. *The theorem defines a threshold g^* at which resonant coordination becomes at least as non-contrived as explicit governance. Below that threshold, resonant solutions (if they exist at all) are too contrived to be chosen by a least-contrivance selector, so the system remains in an explicitly mediated regime. Above the threshold, resonance becomes the cheaper (less contrived) route to the same fit, so selection flips to resonance and explicit governance becomes redundant.*

Remark 3682. *The "sharpness" here is logical rather than thermodynamic: it is sharp because the selection rule is an* $\arg\min$ *over contrivance, and the preferred family changes at the point where the order relation between C_{rep} and $C_{res}(g)$ flips. The underlying functions may vary smoothly with g, but the* identity *of the selected mechanism class can change discontinuously as soon as one class admits a strictly cheaper explanation at the required fit.*

Remark 3683. *This is important because it expresses the $C3 \to C4$ transition as a crisp consequence of an optimization principle rather than as a vague narrative. It also connects back to the earlier weakness formalism: when contrivance is measured via $-\log Weak$, a shift to resonance can be interpreted as a shift to explanations with higher weakness (greater robustness) at the same performance, hence favored by a least-contrivance criterion [3].*

Remark 3684. *At the knife-edge $g = g^*$, the theorem does not force a unique outcome: one can have $C_{res}(g^*) = C_{rep}$ and hence ties between families. In such a tie regime, additional selection criteria (e.g. simplicity within-family, risk aversion to hidden drift, interpretability constraints, or hysteresis/lock-in due to path dependence) may determine whether a system remains $C3$-like, becomes $C4$-like, or adopts a hybrid in which explicit governance persists as a backup even if it is not contrivance-minimal.*

Proof. For $g < g^*$ we have $C_{res}(g) > C_{rep}$ by definition of the infimum, so any fit-τ solution of minimal contrivance must be representational. For $g > g^*$, there exists $g' < g$ with $C_{res}(g) \leq C_{res}(g') \leq C_{rep}$, hence a resonant fit-$\tau$ solution achieves contrivance at most C_{rep}, and strictly lower if the inequality is strict. Thus minimizers can be chosen in the resonant family, eliminating explicit overhead. □

Remark 3685. *The proof uses only monotonicity of $C_{res}(g)$ and the definition of an infimum; no differentiability or continuity is required. If one does assume continuity and that $C_{res}(g)$ eventually drops below C_{rep}, then g^* can often be characterized as the (possibly nonunique) solution to the "intersection" equation $C_{res}(g) = C_{rep}$, making the analogy to phase-transition thresholds more literal.*

Remark 3686. *Interpreting the result in governance terms: below g^*, explicit artifacts (constitutions, logs, audits, deliberation, or explicit self-model checks) are not merely culturally preferred; they are selected because any implicit alternative that meets the same fit is more contrived. Above g^*, the system can satisfy the same fit constraint with less representational machinery, so explicit governance becomes optional and may be dropped even if it remains socially legible. This explains why "who decided?" can lose meaning: decision pressure is distributed into the coupling, and the selected explanation no longer factors through an explicit decision record.*

Remark 3687. Proof sketch. *The proof is an "argmin by comparison" argument. Below g^*, the best resonant contrivance is worse than the best representational contrivance, so minimizers must lie in the representational family. Above g^*, the resonant family contains mechanisms with contrivance no greater than C_{rep} (and strictly less when the inequality is strict), so minimizers can be taken to be resonant. The infimum in the definition of g^* is what turns this into a sharp threshold.*

Remark 3688. *One can picture two curves as functions of g: a flat line at height C_{rep} and a non-increasing curve $C_{res}(g)$. The threshold g^* is where the resonant curve crosses the representational line. The theorem states that a selector minimizing contrivance will choose the lower curve, hence switch families when the crossing occurs.*

68.4 Target 4C: why $C4$ creates drift and accountability hazards (and the trade-off)

The SuperDuperPsychism text flags a "critical shift in pathology" at $C4$: hidden goal drift and accountability dissolution become dominant risks. We now prove two "no free lunch" results that make this structural: (i) deep integration pushes dynamics toward symmetry/exchangeability, which destroys localized attribution; (ii) strong attribution requires making distinctions, which costs contrivance (in Hyperseed's sense).

68.4.1 A symmetry theorem for accountability dissolution

Definition 650 (Permutation-equivariant collective dynamics)**.** *Let $G := Sym(A)$ act on X by permuting subagent-indexed coordinates (any reasonable formalization suffices). We say the dynamics*

$F : X \to X$ *is* G-equivariant *if for all permutations* $\sigma \in G$,

$$F(\sigma \cdot x) = \sigma \cdot F(x).$$

Intuitively: the system behaves the same under relabeling of subagents.

Remark 3689. *Here* $G := Sym(A)$ *denotes the full permutation group on the index set* $A = \{1, \ldots, m\}$. *The notation* $\sigma \cdot x$ *means "apply the permutation* σ *to the coordinates of* x *that are indexed by subagents." The exact meaning depends on how* X *is structured, but any reasonable action suffices. The equivariance equation* $F(\sigma \cdot x) = \sigma \cdot F(x)$ *says: if you relabel agents and then update, you get the same result as updating first and then relabeling. This is the formal version of exchangeability: no subagent has a privileged label in the dynamics.*

Remark 3690. *A simple example is a homogeneous swarm where each agent runs the same algorithm and interactions are symmetric; relabeling the agents does not change what the system does. In a C4-like "distributed unfolding" idealization, one expects increased symmetry precisely because explicit governance (which often introduces named roles and asymmetries) has been minimized. This ties the present formalism to the Hyperseed notions of Heterarchy* **??** *and Hierarchy* **??***: increased unfolding can blur hierarchical attribution structures into heterarchical symmetry.*

Definition 651 (Accountability assignment and invariance)**.** *An* accountability assignment *is a map*

$$\mathcal{R} : X \times X \to \Delta(A)$$

that assigns, to each transition $x \to x'$, *a distribution* $\mathcal{R}(x, x')$ *over which subagent(s) were responsible. We say* $\mathcal{R}$ *is* permutation-invariant *if*

$$\mathcal{R}(\sigma \cdot x,\, \sigma \cdot x') = \sigma \cdot \mathcal{R}(x, x') \quad \text{for all } \sigma \in G.$$

Define the accountability index *for a transition by*

$$Acc(x, x') := \max_{i \in A} \mathcal{R}_i(x, x') \in [1/m, 1].$$

Remark 3691. *The notation* $\Delta(A)$ *denotes the probability simplex over* A*: each element is a vector* $(p_1, \ldots, p_m)$ *with* $p_i \geq 0$ *and* $\sum_i p_i = 1$. *Thus* $\mathcal{R}(x, x')$ *is not a single blamed agent but a distribution of responsibility across agents (credit or blame). The invariance condition says: if we permute the agent labels in both the before-state* x *and after-state* x', *the assigned responsibility distribution permutes accordingly.*

Remark 3692. *The accountability index* $Acc(x, x') = \max_i \mathcal{R}_i(x, x')$ *measures how concentrated the responsibility assignment is. If* $Acc = 1$, *one agent is fully responsible; if* $Acc = 1/m$, *responsibility is perfectly diffuse. This connects to the Hyperseed notion of Distinction 98: high accountability concentration requires making sharp distinctions among subagents; low accountability corresponds to an intentional or emergent refusal (or inability) to draw such sharp lines.*

Theorem 236 (Permutation invariance implies accountability dissolution)**.** *Assume* F *is* G*-equivariant and* $\mathcal{R}$ *is permutation-invariant. Then for every transition* $x \to F(x)$, *one has*

$$\mathcal{R}(x, F(x)) = \left(\frac{1}{m}, \ldots, \frac{1}{m}\right), \qquad \text{hence } Acc(x, F(x)) = \frac{1}{m}.$$

Thus, under deep symmetry (a natural idealization of highly integrated distributed unfolding), localized accountability is formally impossible.

Remark 3693. Intuitive explanation before the proof. *If the system genuinely cannot tell agent i from agent j (because the dynamics is symmetric under relabeling) and if the accountability mechanism is also symmetric, then any responsibility assigned to i must also be assignable to j by the same reasoning. The only distribution that is invariant under all label swaps is the uniform one. Hence symmetry forces diffuse accountability.*

Remark 3694. *This is structurally important: it provides one rigorous route to the "who decided? becomes less meaningful" phenomenon mentioned in the C4 characterization of [12]. The theorem also prepares the ground for the next lower bound: even if we break symmetry, strong attribution requires information (distinctions), which carries contrivance cost.*

Proof. Fix x and write $p_i := \mathcal{R}_i(x, F(x))$. For any $i, j \in A$, choose a permutation σ swapping i and j while fixing all others. By invariance,

$$\mathcal{R}(\sigma \cdot x,\ F(\sigma \cdot x)) = \sigma \cdot \mathcal{R}(x, F(x)).$$

But equivariance gives $F(\sigma \cdot x) = \sigma \cdot F(x)$, so the left side is also $\mathcal{R}(\sigma \cdot x,\ \sigma \cdot F(x))$. Comparing i-th coordinates yields $p_i = p_j$. Hence all p_i are equal, and since they sum to 1, each equals $1/m$. $\square$

Remark 3695. Proof sketch. *Use swap permutations to show that any two coordinates of the responsibility vector must be equal. Equality of all coordinates plus normalization forces the uniform distribution.*

Remark 3696. *A visual intuition is to think of the responsibility assignment as "coloring" the agents with weights. If the system is invariant under swapping any two agents, then no coloring that makes one agent darker than another can be stable under all swaps. The only coloring compatible with total symmetry is the flat one.*

68.4.2 A weakness/contrivance lower bound for strong accountability

The above theorem shows one structural route to accountability loss: symmetry. A second route is purely informational: to point to "who did it" among m possibilities, the collective must make at least $\log m$ distinctions, which is contrivance in Hyperseed's sense.

Definition 652 (Attribution explanation)**.** *An* attribution explanation *for a transition $x \to x'$ is any explanation object E whose output includes a label in A (the blamed/credited subagent) and achieves fit τ on a suitable "ground truth" attribution predicate (formal details suppressed). Let $Con^*_{attr}(m; \tau)$ denote the minimal contrivance over such explanations when $|A| = m$.*

Remark 3697. *This definition isolates a particular kind of explanation: not just "why did x become x'?" but "which subagent should be credited/blamed for the transition?" The fit condition is with respect to some attribution ground truth (perhaps produced by instrumentation, auditing, or counterfactual analysis). The quantity $Con^*_{attr}(m; \tau)$ is then the best-case contrivance cost required to achieve reliable attribution at scale m.*

Remark 3698. *It is useful to separate this from the symmetry result above. Theorem 236 shows that in a symmetric regime, attribution is impossible* regardless *of contrivance. The present construction asks a different question: even if attribution is in principle possible, how much contrivance must be spent (how much "distinguishing structure" must be carried) to do it well?*

Axiom 1 (Distinction lower bound)**.** *Any explanation that (with fit τ) outputs one label from a set of m mutually exclusive labels must make at least* $\log m$ *distinctions, in the sense that its weakness satisfies $Weak(E) \leq 1/m$, hence $Con(E) \geq \log m$. (This is the standard "you need* $\log m$ *bits to name one of m things" bound, expressed via $Con = -\log Weak$.)*

Remark 3699. *This axiom is an information-theoretic constraint stated in the local language of weakness and contrivance. In familiar terms, selecting one item among m mutually exclusive alternatives requires at least* $\log m$ *bits of information. One may view this as compatible with algorithmic information theory [16] or, in a partition-oriented framing, with logical entropy's emphasis on distinctions [17]. In the Hyperseed core-concept set, the relevant notions are Distinction 98, Logical Entropy 105, and Kolmogorov Complexity* **??***.*

Remark 3700. *The axiom is not a claim about any specific implementation of attribution; it is a lower bound on what* any *sufficiently accurate attribution mechanism must implicitly encode. It therefore serves as a "no free lunch" principle: if one demands both high-fit attribution and low contrivance, the demand becomes inconsistent at sufficiently large m.*

Theorem 237 (Strong accountability requires contrivance at least $\log m$)**.** *Assume Axiom 1. Then for any $m \geq 2$ and any fit threshold τ,*

$$Con^*_{attr}(m;\tau) \geq \log m.$$

In particular, if a regime requires very low *contrivance (as in $C4$), then for large collectives it cannot simultaneously sustain strong explicit accountability without violating the low-contrivance constraint.*

Remark 3701. Intuitive explanation before the proof. *The theorem simply lifts the axiom from individual explanations to the best achievable explanation: if every candidate attribution explanation costs at least* $\log m$ *contrivance, then even the best one cannot cost less. The conceptual punchline is that accountability is not merely a moral preference; it has an irreducible informational price that grows with collective size.*

Remark 3702. *This connects directly to the earlier $C3 \to C4$ switch theorem. If $C4$ is characterized by pushing contrivance very low (via resonance and least-contrivance selection), then large-m systems face an intrinsic tension: explicit accountability mechanisms are exactly the sort of "distinction-making" structures that contrivance minimization tends to discard. Theorem 236 adds that symmetry can make accountability impossible even before contrivance bounds are considered.*

Proof. Let E be any attribution explanation achieving fit τ. By Axiom 1, $Con(E) \geq \log m$. Taking the infimum over all such E yields $Con^*_{attr}(m;\tau) \geq \log m$. □

Remark 3703. Proof sketch. *Apply the axiom pointwise to every admissible attribution explanation, then take the infimum. No further structure is needed.*

Remark 3704. *A helpful analogy is to think of accountability as a coordinate system that assigns "where the cause was." A finer coordinate system (one that can name many distinct agents) requires more bits to write down, hence more contrivance in this formalism. Trying to keep the coordinate system while forcing contrivance to zero is like trying to keep high-resolution labels while forbidding information storage.*

68.4.3 A drift theorem: without explicit correction, drift is generically unbounded

Definition 653 (A minimal goal-drift process)**.** *Let $v_t \in \mathbb{R}^d$ represent the (coarse-grained) collective objective at time t (e.g. a vector of value weights). Assume a drift model*

$$v_{t+1} = v_t + \xi_t - \gamma \nabla\Psi(v_t),$$

where ξ_t is mean-zero noise and $\gamma \geq 0$ is the strength of a corrective force derived from anchoring/auditing, represented abstractly by a potential Ψ minimized at the seed objective v_0. The case $\gamma = 0$ models "no effective correction" (a caricature of accountability dissolution).

Remark 3705. *The variable v_t should be read as a coarse summary of "what the collective is optimizing for"; it is not assumed to capture the full value structure, only a projection relevant to drift. The term ξ_t represents unmodeled perturbations: noise, unnoticed selection pressures, small incentives, or random fluctuations in governance. The corrective term $-\gamma\nabla\Psi(v_t)$ is an abstract "pull back toward the seed," where Ψ plays the role of an anchoring potential with minimum at v_0. This is a minimal dynamical formalization of Meta-Goal 110 stabilization, and connects naturally to fixed-point/anchoring analyses in self-modifying systems [10].*

Remark 3706. *It is useful to make explicit what is being "coarse-grained away." In a high-synergy (C4-like) regime, many micro-level decisions are delegated to implicit coordination dynamics rather than explicit deliberation; the claim is not that the full value function becomes a literal vector, but that there exists some low-dimensional set of effective weights (e.g. how much the system allocates to safety vs. speed, transparency vs. opacity, local vs. global optimization) that meaningfully parameterizes the direction of optimization pressure. Drift in this projection can be hazardous even if many other dimensions remain stable, because downstream decisions are often most sensitive to a small set of "tradeoff knobs." In this reading, the model isolates a single failure mode: the slow movement of those knobs away from the seed objective v_0 under accumulated perturbations.*

Remark 3707. *Two extreme regimes are worth holding in mind. If γ is large and Ψ is strongly convex near v_0, then the dynamics resembles a noisy contraction toward the seed, suggesting bounded drift. If $\gamma = 0$, the process becomes a random walk in $\mathbb{R}^d$, which is the canonical model of unbounded wandering. The theorem below makes the latter statement precise at the level of mean-squared distance.*

Remark 3708. *The parameter pair (σ^2, γ) can be read as a minimal "synergy–drift tradeoff" proxy. High-synergy coordination can reduce some kinds of noise (e.g. eliminating redundant deliberation), but it can also* increase *effective σ^2 by creating more pathways for unnoticed selection pressures and by encouraging the system to route around explicit checks. Simultaneously, the very features that create $C4$ fluidity (implicit self-hierarchy; low contrivance) tend to reduce effective γ by making corrective interventions rarer, less legible, or socially/structurally costly. The model is therefore set up to capture a specific hazard: the regime in which σ^2 does not shrink enough (or even grows) while γ falls, pushing the system toward diffusion-dominated behavior.*

Theorem 238 (Unbounded drift without corrective anchoring)**.** *Assume $\gamma = 0$, $v_0 = 0$, and (ξ_t) are i.i.d. with $\mathbb{E}[\xi_t] = 0$ and $\mathbb{E}[\|\xi_t\|^2] = \sigma^2 > 0$. Then*

$$\mathbb{E}[\|v_t\|^2] = t\sigma^2,$$

so the mean-squared drift diverges linearly with time. Consequently, for any threshold $R > 0$, the probability of exceeding R cannot be uniformly small over long horizons; in particular, drift is not stochastically bounded.

Remark 3709. Intuitive explanation before the proof. *Without a restoring force ($\gamma = 0$), each time step adds an independent noise increment. Even if the noise has mean zero, the variance accumulates. The result is the simplest rigorous expression of the "hidden drift" worry: if nothing systematically pushes you back, then merely waiting long enough makes large deviation inevitable in aggregate.*

Remark 3710. *A further intuition is to separate* bias *from* variance. *The assumption $\mathbb{E}[\xi_t] = 0$ says there is no systematic directional bias in the instantaneous perturbations. But unbounded drift here is* variance-driven*: the system does not need an adversary with a consistent preferred direction for goals to wander far from the seed. This matters for $C4$ accountability hazards: even if every locally-acting component is "well-intentioned on average," the absence of legible correction means the collective can still drift far simply by compounding many small, individually negligible deviations.*

Remark 3711. *This theorem complements the accountability results. Theorem 236 and Theorem 237 explain why explicit correction and attribution may be suppressed in $C4$-like regimes (symmetry and contrivance minimization). The present theorem explains what happens if correction is indeed suppressed: objective drift becomes unbounded under minimal stochastic assumptions. In other words, the pathology is not an accident; it is a generic dynamical consequence of removing anchoring.*

Remark 3712. *In particular, the accountability connection is not merely rhetorical: auditing and attribution are mechanisms that (i) increase γ by enabling targeted corrective force, and (ii) can reduce effective σ^2 by turning some perturbations into detectable, correctable deviations rather than silent increments. A $C4$-like regime that dissolves attribution therefore risks a "double hit" in this minimal picture: weaker reversion (lower γ) and noisier effective dynamics (higher σ^2), producing faster growth in $\mathbb{E}\|v_t\|^2$ and earlier threshold crossings for any fixed R.*

Proof. With $\gamma = 0$, we have $v_t = \sum_{k=0}^{t-1} \xi_k$. By independence and zero mean,

$$\mathbb{E}[\|v_t\|^2] = \mathbb{E}\left[\left\|\sum_{k=0}^{t-1} \xi_k\right\|^2\right] = \sum_{k=0}^{t-1} \mathbb{E}[\|\xi_k\|^2] = t\sigma^2.$$

The divergence implies that no fixed R can keep $\|v_t\|$ small in expectation as $t \to \infty$, and standard concentration/Markov inequalities turn this into tail statements. ☐

Remark 3713. Proof sketch. *Expand the squared norm of a sum of independent, mean-zero increments. Cross terms vanish in expectation, leaving a sum of variances. This yields linear growth of mean-squared distance, the hallmark of a random walk.*

Remark 3714. *One can also read the tail claim operationally via a hitting-time lens. Let $\tau_R = \inf\{t : \|v_t\| \geq R\}$. For a pure random walk with nonzero step variance, τ_R has finite expectation scaling on the order of R^2/σ^2 in many standard settings, which is another way of expressing that "eventually" the process will exceed any fixed radius with substantial probability. The theorem as stated keeps the assumptions minimal and only asserts what is needed for the design conclusion: without anchoring, there is no horizon-independent guarantee of staying near the seed.*

Remark 3715. *A visual intuition is to imagine v_t as the location of a particle in d-dimensional space. With no potential well ($\gamma = 0$), the particle jitters randomly; even unbiased jitter spreads the particle cloud over time. Anchoring ($\gamma > 0$ with suitable Ψ) is precisely the introduction of a potential well that prevents diffusion from running away.*

Remark 3716. *This particle picture also clarifies why "light-touch" correction can fail in a $C4$ regime. If the potential well is shallow (small γ) relative to the noise scale, the stationary distribution (if it exists) is broad: the system may remain technically mean-reverting but still spends substantial time far from v_0, creating long windows of misalignment before correction pulls it back. Thus, the relevant question is not merely whether γ is nonzero, but whether the effective anchoring strength is large enough* compared to *the perturbation scale that the collective experiences under high synergy and low explicit governance.*

Corollary 82 (Why $C4$ needs strong anchoring invariants)**.** *If a $C4$-like collective reduces explicit auditing (low contrivance; implicit self-hierarchy), then to prevent the "hidden goal drift" pathology it must compensate by strong anchoring: it must implement an effective $\gamma > 0$ correction term via invariants that persist under perturbation (e.g. protocols, constitutions, cryptographic accountability, etc.), rather than via continuous explicit intervention.*

Remark 3717. *This corollary is not an extra theorem so much as a translation back into design language. If a regime pushes toward $C4$ by minimizing contrivance (Theorem 235), it will tend to discard explicit representational overhead, including many familiar auditing practices. But Theorem 238 says that removing effective correction generically yields unbounded drift. Hence the only coherent escape is to embed correction into invariants that do not require constant explicit attention: mechanisms that remain active even when the collective "stops thinking about governance." In Hyperseed terms, this is an insistence on durable Control 87 and Meta-Goal 110 anchoring even under a shift toward Resonance 159.*

Remark 3718. *The "drift and accountability hazards" of $C4$ can now be stated crisply in the variables of the minimal model. A $C4$ transition tends to increase* coordination bandwidth *(synergy) by moving from explicit representations to implicit dynamics; this often removes the very hooks by which auditing acts, lowering γ and making deviations less attributable. Meanwhile, implicit dynamics can create selection effects that are hard to name, so even if ξ_t remains mean-zero, it is not reasonable to expect σ^2 to vanish; rather, the perturbation scale can remain materially positive. In that combined regime (low γ, $\sigma^2 > 0$), unbounded or effectively-uncontrolled wandering becomes the default prediction unless strong invariants "pin" the objective.*

Remark 3719. *Finally, note the design tension embedded in the word "invariants." Many invariants that reliably increase γ (e.g. rigid constitutions, strict provenance requirements, mandatory logging, cryptographic authorization) also impose overhead that can partially negate $C4$'s synergy advantages by reintroducing explicit structure. This is the intended tradeoff: $C4$ gains fluid coordination by reducing contrivance, but that same reduction tends to dissolve accountability pathways and thereby weakens correction. The corollary asserts that if one insists on $C4$-level fluidity, then the remaining degrees of freedom for safety lie in invariants that preserve anchoring without requiring continuous, high-friction deliberation.*

68.5 Summary: formal phase boundaries and the synergy–drift tradeoff

- $C2 \to C3$ **boundary (repair threshold).** In the two-basin coarse-graining, the boundary is controlled by a repair-to-exit ratio r/q: when r/q exceeds $(1 - \varepsilon)/\varepsilon$, the cooperative macrostate is occupied nearly all the time (Theorem 233). Here q can be read as the effective hazard rate of leaving the cooperative basin under typical perturbations, while r summarizes the aggregate strength and frequency of within-basin "return forces" that restore cooperation after small defections or shocks; the ratio r/q is thus an operational measure of whether recovery is faster than deterioration. The parameter ε encodes the coarse-graining's tolerance for misclassification or noise (i.e., the allowed fraction of time the observer-indexed marker reports the "wrong" basin), so the threshold $(1-\varepsilon)/\varepsilon$ makes explicit how stricter observability demands raise the required repair intensity. Institutional monitoring/punishment is a microfoundation that pushes the system above this threshold (Theorem 234). On this view, monitoring primarily changes the microtransition structure by increasing the probability that deviations trigger corrective responses (raising r) and by deterring destabilizing moves that would otherwise accumulate into basin exits (lowering the effective q), thereby shifting the phase boundary without needing to appeal to global optimality assumptions.

- $C3 \to C4$ **boundary (representation-to-resonance).** When increasing resonance strength g makes resonant coordination strictly lower contrivance than explicit governance at the same fit τ, contrivance-minimizing selection switches the collective to a resonance-dominated coordinator (Theorem 235). Intuitively, τ fixes the achieved level of task performance (or alignment with an external objective), while g controls how much of that performance can be obtained "for free" via coupling, entrainment, or other low-explicit-communication mechanisms; the phase transition occurs when the same τ can be maintained with fewer explicit degrees of freedom. The strict inequality in contrivance matters: it prevents knife-edge coexistence by ensuring that once resonance becomes cheaper in the contrivance metric, selection has a definite direction of pressure toward the resonance-based mode, yielding a qualitative change in how coordination is implemented rather than a mere quantitative improvement.

- **Tradeoff (synergy vs accountability/drift).** Deep integration tends to increase synergy and lower minimal contrivance (formalized by Hyperseed-style subadditivity; Lemma 174) but also moves dynamics toward symmetry, which makes localized accountability impossible (Theorem 236). The key tension is that the same representational "compression" that lets a collective act as a single high-capacity unit can erase the asymmetries that make it meaningful to attribute a specific action, error, or intention to a specific subpart. Moreover, even without symmetry, strong attribution requires at least $\log m$ contrivance (Theorem 237). This lower bound can be read as an information-theoretic price for carving m distinguishable causal "slots" out of the dynamics: attribution needs enough structured degrees of freedom to encode who-did-what in a way that survives noise and aggregation. Without effective correction, drift is generically unbounded (Theorem 238), matching the "hidden goal drift" / "accountability dissolution" pathology list for $C4$. In particular, once explicit corrective channels are pruned in the name of lower contrivance, residual optimization pressure can reconfigure internal objectives faster than external observers can detect or localize the source of change, so that drift becomes a structural rather than incidental risk.

Remark 3720. *From a methodological point of view, the section offers a reusable inference pattern: (a) choose observer-indexed markers that define basins; (b) show that some mechanism increases repair-to-exit ratio beyond a threshold (yielding anchoring, $C3$); (c) show that some selection principle decreases contrivance by switching coordination mode (yielding unfolding, $C4$); and (d) account for the costs of that switch via symmetry and information-theoretic lower bounds. Each step corresponds to a specific kind of inequality: (b) compares rates of return vs escape; (c) compares minimal contrivances at fixed fit; and (d) compares the representational savings of integration against the minimal descriptive complexity needed for blame, credit, and intervention. The philosophical moral is Russell-like in its austerity: if you want a claim about phase transitions to be more than poetry, you must say what the variables are and where the inequalities lie. In this sense, the "phase diagram" is not a metaphor but a bookkeeping device that forces one to state what is being held constant (e.g., τ) and what is being tuned (e.g., r/q or g).*

Remark 3721. *At the same time, there is a Whitehead/Peirce flavor in the observer index O: what counts as a basin, a repair, or an attribution depends on the scheme of distinctions we impose. The theorems do not eliminate subjectivity; they discipline it. One may choose different coarse-grainings and obtain different phase boundaries, but once the coarse-graining is chosen, the algebra of the tradeoff is hard to evade. Practically, this means disagreements about whether a system is "in $C3$" or "in $C4$" often reduce to disagreements about the observer's state variables and resolution: changing O can change the apparent basins, yet it cannot make the repair/exit and contrivance/attribution constraints disappear simultaneously.*

69 Gauge and Invariance Foundations for Hyperseed: Shared Reality, Stable Self, and TransWeave-Style Almost-Commutativity

We formalize two Hyperseed-adjacent invariance notions that are central to robust reasoning: (i) "shared reality" as the content that remains stable under changes of encoding/observer, and (ii) "stable self" as the content that remains stable under changes of encoding across time and self-modification. We model encoding changes as gauge transformations (semantics-preserving re-encodings), and we model reasoning/learning updates as operators on representation spaces. We then connect these invariances to TransWeave-style almost-commutativity constraints: small intertwining and commutator defects imply bounded path-dependence and hence representation-independent (or nearly representation-independent) conclusions.

Concretely, the intended "gauge" perspective is that multiple internal representations can describe the same underlying content, and that changing encodings should not, by itself, change what is being represented. In this view, "shared reality" can be treated as whatever survives passage to an appropriate equivalence class of encodings (or, operationally, whatever can be transported across observers with small defect), whereas "stable self" adds the requirement that such transport remains coherent across time-indexed self-updates. The point of almost-commutativity is then practical: if transferring between encodings and updating within an encoding nearly commute, then conclusions produced by iterated reasoning are (approximately) encoding-invariant, with deviations controlled by the size of the relevant defects.

69.1 Preliminaries: spaces, updates, and defects

69.1.1 Representation spaces and update operators

Definition 654 (Metric representation space)**.** *A representation space is a metric space (X, d) whose points encode some structured content (world-model states, beliefs, policies, plans, self-models, etc.).*

In applications, the metric d is part of the modeling choice: it specifies which differences between representations are considered significant and at what scale. Depending on the setting, d may reflect prediction error, policy divergence, edit distance in a symbolic structure, or a task-induced discrepancy (e.g. value loss). It is also common in practice that the natural notion of "distance" is a pseudometric (distinct encodings at zero distance); in that case, one can either work directly with the pseudometric or pass to the quotient space induced by identifying zero-distance points, which aligns naturally with the invariance interpretation.

Definition 655 (Contractive update)**.** *An operator $B : X \to X$ is a γ-contraction if for all $x, y \in X$,*

$$d(Bx, By) \;\le\; \gamma\, d(x, y), \quad \textit{for some } \gamma \in [0, 1).$$

Contractivity is a strong but extremely useful regularity condition: it says that the update step dampens discrepancies rather than amplifying them. When (X, d) is complete, the contraction mapping theorem implies B has a unique fixed point and that iterating B converges to it at a geometric rate, which provides a canonical notion of a "stable conclusion" produced by repeated updating. Even when strict contractivity is only approximate or holds locally, the parameter γ still serves as a quantitative proxy for stability, since it controls how perturbations propagate through sequences of updates.

Remark 3722. *In TransWeave, a prototypical B is a Bellman-style backup operator; in belief dynamics, B may be an inference or posterior-update step; in self-modeling, B may be a self-revision step. The contraction assumption can be interpreted as "controlled drift" or "regulated update."*

A useful intuition is that contraction turns "one-step mismatch" into a bounded "long-run mismatch": small discrepancies introduced by encoding changes, noise, or approximation errors do not accumulate arbitrarily under iteration, but are instead attenuated. This is precisely the regime in which almost-commutativity defects can be converted into global path-independence bounds, because the update dynamics themselves prevent error blow-up.

69.1.2 Intertwining and commutator defects

Definition 656 (Intertwining defect)**.** *Given $(X_1, d_1), (X_2, d_2)$, operators $B_1 : X_1 \to X_1$, $B_2 : X_2 \to X_2$, and a map $T : X_1 \to X_2$, define the (supremum) intertwining defect*

$$\mathrm{Def}(T; B_1, B_2) \;:=\; \sup_{x \in X_1} d_2\big(T(B_1 x),\, B_2(Tx)\big).$$

When $\mathrm{Def}(T; B_1, B_2) \le \epsilon$ we say T is an ϵ-intertwiner.

This quantity measures the extent to which T transports the update dynamics on X_1 to the update dynamics on X_2. If T were an exact conjugacy between the systems, then $T \circ B_1 = B_2 \circ T$ and the defect would be zero; the ϵ-intertwiner notion is the approximate version appropriate when T is an imperfect translator, when B_2 is a simplified surrogate for B_1, or when the two spaces represent different observers with slightly different update rules. The supremum form is a worst-case notion; in settings where worst-case control is too strict, one can also consider average-case analogues (e.g. an expectation over a distribution of x), but the supremum is the natural choice when aiming for representation-agnostic guarantees.

Definition 657 (Commutator defect)**.** *For $U, V : X \to X$, define the commutator defect*

$$\mathrm{Def}([U, V]) \;:=\; \sup_{x \in X} d\big(U(Vx),\, V(Ux)\big).$$

The commutator defect is the special case of order-sensitivity when both operators act on the same space; it can be viewed as an "internal" almost-commutativity constraint. Note that if one takes $X_1 = X_2 = X$, $B_1 = U$, $B_2 = U$, and $T = V$, then $\mathrm{Def}(T; B_1, B_2)$ reduces exactly to $\mathrm{Def}([U, V])$, so the two notions are not competing definitions but rather different framings of the same phenomenon (transport-vs-update versus update-vs-update). In particular, commutator defects can be read as gauge-like consistency conditions when one of the maps is interpreted as a re-encoding inside a single representational universe.

Remark 3723. $\mathrm{Def}(T; B_1, B_2)$ *is the TransWeave-type "almost commutativity" of "transfer then update" vs "update then transfer."* $\mathrm{Def}([U, V])$ *is the usual notion of order-sensitivity of two update operators. Both will be treated as computational analogues of curvature/field-strength: nonzero defect implies path dependence.*

The curvature analogy can be read operationally: moving around a loop of transformations (e.g. update, re-encode, update, decode) fails to return exactly to the starting point when the defect is nonzero. When the defect is small and the updates are contractive, this loop error remains controlled even under repeated application, which is the mechanism by which "nearly gauge-invariant" conclusions emerge from iterative reasoning despite imperfect translators and approximate dynamics.

69.2 Gauge transformations and gauge-invariant content

69.2.1 Semantics and gauge

Definition 658 (Semantic decoder and gauge group)**.** *Let W be a "semantic" space (world-states, externally meaningful states, etc.). A semantic decoder is a map $D : X \to W$.*

A gauge group G acting on X is a group of bijections $g : X \to X$ such that

$$D \circ g \;=\; D \quad \text{for all } g \in G.$$

That is, gauge transformations change the encoding but preserve semantics.

Informally, the condition $D \circ g = D$ says that D is *constant along the G-action*: whenever x is replaced by another representative $g(x)$ within the same internal "description family," the decoded meaning in W is unchanged. In particular, the fibers of D (sets of the form $D^{-1}(w)$) are unions of G-orbits: if $x \in D^{-1}(w)$ then $g(x) \in D^{-1}(w)$ for all $g \in G$. This expresses the intended separation between "how the system is written" (the state $x \in X$) and "what it means" (the decoded element $D(x) \in W$).

It is also useful to view the G-action as generating an equivalence relation on X:

$$x \sim_G x' \quad \Longleftrightarrow \quad \exists\, g \in G \text{ such that } x' = g(x).$$

The defining property $D \circ g = D$ then implies $x \sim_G x' \Rightarrow D(x) = D(x')$, i.e. semantic equality is at least as coarse as gauge-equivalence (and may be coarser if distinct orbits decode to the same semantic element).

Definition 659 (Gauge-invariant observable)**.** *A map $O : X \to Y$ is gauge-invariant (with respect to G) if*

$$O \circ g \;=\; O \quad \text{for all } g \in G.$$

Gauge-invariant observables are precisely those quantities that cannot distinguish between different encodings of the same underlying situation. When Y is taken to be a space of measurements, predictions, or reports, the invariance condition formalizes that these outputs depend only on semantic content (or, more generally, only on the gauge-orbit of x) rather than on arbitrary representational choices. In many settings one considers families of observables (e.g. all real-valued observables), in which case gauge-invariant observables form a subcollection closed under natural operations (for example, if $Y = \mathbb{R}$ then sums and products of gauge-invariant functions are again gauge-invariant).

69.2.2 Quotients and invariants

Definition 660 (Orbit space)**.** *Let X/G be the set of orbits under G and let $q : X \to X/G$ be the orbit map sending x to its orbit $[x]$.*

The orbit map q is the canonical way to "forget gauge" by mapping each state to its equivalence class under the action. Concretely, $q(x) = q(x')$ holds exactly when x and x' differ by a gauge transformation. From the semantics perspective, X/G represents the space of representational degrees of freedom modded out by the allowed re-encodings; it is therefore the natural domain for any quantity intended to be insensitive to encoding.

Note that no topological, smooth, or measure-theoretic structure is assumed here; X/G is treated as a set. If additional structure on X and continuity/smoothness of the G-action are present, one often equips X/G with the corresponding quotient structure, and then asks for $\bar{O}$ to be continuous/smooth as appropriate. The purely set-theoretic statement below isolates the core invariance principle without committing to such extra hypotheses.

Theorem 239 (Universal factorization of gauge invariants)**.** *A map $O : X \to Y$ is gauge-invariant iff there exists a (unique) map $\bar{O} : X/G \to Y$ such that*

$$O \;=\; \bar{O} \circ q.$$

Proof. ($\Rightarrow$) If O is gauge-invariant, define $\bar{O}([x]) := O(x)$. This is well-defined because if $[x] = [x']$ then $x' = g(x)$ for some $g \in G$, so $O(x') = O(gx) = O(x)$. Clearly $O = \bar{O} \circ q$.

($\Leftarrow$) If $O = \bar{O} \circ q$, then for any $g \in G$ we have $q(gx) = q(x)$ since gx lies in the orbit of x. Thus $O(gx) = \bar{O}(q(gx)) = \bar{O}(q(x)) = O(x)$. □

The uniqueness of $\bar{O}$ follows from surjectivity of q: every orbit $[x] \in X/G$ has at least one representative $x \in X$, so any factorization $O = \tilde{O} \circ q$ forces $\tilde{O}([x]) = O(x)$, which is exactly the definition used in the forward direction. In this sense, X/G is characterized by a universal property: it is the *most general* recipient through which all gauge-invariant maps out of X factor.

A particularly relevant special case is the semantic decoder itself: since $D \circ g = D$ for all $g \in G$, Theorem 239 implies that there exists a unique $\bar{D} : X/G \to W$ such that $D = \bar{D} \circ q$. Thus, once gauge is fixed as "meaning-preserving re-encoding," semantics is automatically a function of the orbit alone. This makes explicit that any two gauge-related internal states have identical decoded meaning and that the quotient X/G is a natural "semantic carrier" for all invariant content derived from X.

Remark 3724. *This theorem captures the intended meaning of "shared reality" as "what survives a change of encoding": gauge-invariant observables are precisely the functions on the quotient X/G.*

One may read this remark operationally: if two agents, models, or subsystems use different internal representations related by elements of G, then any quantity that can be compared between them without additional alignment assumptions must factor through X/G. In this way, X/G packages the common, representation-independent content, while the particular choice of representative $x \in X$ encodes "private" or "conventional" degrees of freedom. When relating this to almost-commutative or "TransWeave-style" constraints elsewhere, the same factorization principle serves as the baseline requirement: any purportedly shared signal must commute (in the sense of being invariant) with the allowable re-encodings, hence must descend to the quotient.

69.3 Gauge covariance of dynamics and fixed-point invariance

69.3.1 Exact covariance implies exact invariance

Definition 661 (Gauge-covariant update). *An update $B : X \to X$ is G-equivariant (gauge-covariant) if*

$$B \circ g \;=\; g \circ B \quad \text{for all } g \in G.$$

This condition can be read as "the dynamics commutes with re-encoding": applying a gauge transform g before updating produces the same state as updating first and then re-expressing the result in the transformed gauge. In diagram form, for each $g \in G$, the square

$$\begin{array}{ccc} X & \xrightarrow{B} & X \\ \downarrow g & & \downarrow g \\ X & \xrightarrow{B} & X \end{array}$$

commutes. When G acts by "representational" changes (coordinate changes, renamings, internal phase choices, etc.), equivariance asserts that B is formulated intrinsically rather than in a gauge-specific manner.

Theorem 240 (Unique fixed point implies gauge-invariant fixed point). *Let $B : X \to X$ be a γ-contraction with a unique fixed point x^*. If B is G-equivariant, then x^* is gauge-invariant:*

$$g(x^*) \;=\; x^* \quad \text{for all } g \in G.$$

The contraction hypothesis is a convenient sufficient condition ensuring both existence and uniqueness of the fixed point (via the Banach fixed-point theorem). Conceptually, the conclusion is a "no spurious gauge choice" statement: if the update rule respects the gauge action and the attractor is unique, then the attractor cannot depend on a gauge representative. In contrast, if fixed points are not unique, equivariance typically implies only that the set of fixed points is G-stable (i.e., mapped into itself), not that any particular fixed point is pointwise invariant.

Proof. Fix $g \in G$. Because B is equivariant,

$$B(gx^*) \;=\; g(Bx^*) \;=\; g(x^*).$$

So $g(x^*)$ is a fixed point of B. Uniqueness implies $g(x^*) = x^*$. □

Equivalently, the proof shows that equivariance transports fixed points along the group orbit: x^* fixed $\Rightarrow g(x^*)$ fixed. When there is exactly one fixed point, the entire orbit must collapse to a single point, which is exactly gauge invariance. This is the fixed-point analogue of the more general principle that symmetry plus uniqueness forces symmetry of the solution.

69.3.2 Approximate covariance implies bounded drift

Definition 662 (Equivariance defect). *For $g : X \to X$ and $B : X \to X$, define*

$$\mathrm{Def}(g; B) \;:=\; \sup_{x \in X} d\big(g(Bx),\, B(gx)\big).$$

The quantity $\mathrm{Def}(g;B)$ is an "almost-commutator" size: it measures the worst-case discrepancy between the two paths $x \mapsto Bx \mapsto g(Bx)$ and $x \mapsto gx \mapsto B(gx)$. In particular, $\mathrm{Def}(g;B) = 0$ is exactly the equivariance condition for that specific g, and small defect formalizes the idea that the update is only weakly sensitive to the gauge choice. The use of $\sup_{x\in X}$ emphasizes uniform control; in settings where only a subset of states is relevant (e.g., a basin of attraction), one can replace the supremum by a supremum over that subset without changing the algebra of the subsequent bounds.

Theorem 241 (Approximate gauge invariance of a contractive fixed point)**.** *Let $B : X \to X$ be a γ-contraction with fixed point x^*. For any bijection $g : X \to X$,*

$$d\big(g(x^*),\, x^*\big) \;\le\; \frac{\mathrm{Def}(g;B)}{1-\gamma}.$$

The factor $\frac{1}{1-\gamma}$ is the familiar stability constant for contraction-based fixed points: as $\gamma \to 1^-$ the system becomes less contractive, and small equivariance errors can produce larger fixed-point drift. Conversely, stronger contraction (smaller γ) suppresses the impact of gauge noncommutativity. Note also that the statement is pointwise in g: no group structure is required beyond having a map g one wishes to interpret as a "re-encoding." The bijection assumption matches the intended interpretation of gauge transforms as reversible changes of representation, but the inequality itself is driven by the defect and contraction and can be adapted to less restrictive classes of maps when appropriate.

Proof. Using the triangle inequality and the fixed-point identity $Bx^* = x^*$,

$$\begin{aligned} d(gx^*, x^*) &= d(gBx^*, Bx^*) \\ &\le d(gBx^*, Bgx^*) \;+\; d(Bgx^*, Bx^*) \\ &\le \mathrm{Def}(g;B) \;+\; \gamma\, d(gx^*, x^*). \end{aligned}$$

Rearranging gives $(1-\gamma)d(gx^*, x^*) \le \mathrm{Def}(g;B)$. ∎

A useful way to read the proof is as a one-step "commute-then-contract" argument: the defect controls the cost of swapping g past B, and the contraction turns the remaining discrepancy into a self-bounding term that can be absorbed to the left-hand side. This is exactly the mechanism by which "almost commutativity" yields "almost invariance" at the attracting fixed point.

Corollary 83 (Exact equivariance as a special case)**.** *If* $\mathrm{Def}(g;B) = 0$ *for some bijection $g : X \to X$, then $g(x^*) = x^*$. In particular, if* $\mathrm{Def}(g;B) = 0$ *for all $g \in G$, then x^* is gauge-invariant.*

Remark 3725. *Theorem 241 is the basic "stable meaning under re-encoding" tool: if the commutator (equivariance defect) is small, then the "meaningful" fixed point is stable. This is the same algebraic shape as standard TransWeave bounds for transfer of fixed points.*

One can also interpret the bound as a quantitative statement about shared reality: different "gauges" (encodings) may not be perfectly aligned with the update dynamics, but as long as the mismatch is uniformly bounded and the dynamics is sufficiently contractive, the emergent fixed point remains approximately shared across gauges. The dependence on $\mathrm{Def}(g;B)$ isolates where modeling errors live (in the noncommuting part), while the dependence on γ isolates the dynamical robustness (how strongly the update collapses differences). In applications, this separation is useful because one can often estimate γ from the dynamics and estimate $\mathrm{Def}(g;B)$ from representational mismatch or finite-precision implementation.

69.4 TransWeave-style intertwining implies representation-independent conclusions

We now treat changes of observer/encoding as maps between two (possibly different) representation spaces X_1, X_2.

Theorem 242 (Fixed-point transport under approximate intertwining)**.** *Let $B_1 : X_1 \to X_1$ and $B_2 : X_2 \to X_2$ be γ-contractions with unique fixed points x_1^* and x_2^*. Let $T : X_1 \to X_2$ satisfy $\mathrm{Def}(T; B_1, B_2) \le \epsilon$. Then*

$$d_2\big(T(x_1^*),\, x_2^*\big) \;\le\; \frac{\epsilon}{1-\gamma}.$$

Proof. Let x_2^* be the fixed point of B_2. Then

$$\begin{aligned} d_2(Tx_1^*, x_2^*) &= d_2(TB_1x_1^*, B_2x_2^*) \\ &\le d_2(TB_1x_1^*, B_2Tx_1^*) \;+\; d_2(B_2Tx_1^*, B_2x_2^*) \\ &\le \epsilon \;+\; \gamma\, d_2(Tx_1^*, x_2^*). \end{aligned}$$

Rearrange to get the claim. □

Remark 3726. *This is the core TransWeave mathematical move: if transfer T approximately intertwines the update operators, it transports fixed points (solutions, equilibria, stable beliefs) with error bounded by $\epsilon/(1-\gamma)$.*

69.5 Shared reality across observers as atlas gluing

69.5.1 Observer charts and transition maps

Definition 663 (Observer chart)**.** *An observer i has a representation space (X_i, d_i) and a semantic decoder $D_i : X_i \to W$. A transition map from observer i to j is a map $T_{ij} : X_i \to X_j$ intended to preserve semantics:*

$$D_j \circ T_{ij} \;\approx\; D_i.$$

Definition 664 (Exact cocycle condition)**.** *A family of transition maps $\{T_{ij}\}$ satisfies the cocycle condition if for all i, j, k,*

$$T_{jk} \circ T_{ij} \;=\; T_{ik}, \quad \text{and} \quad T_{ii} = \mathrm{id}_{X_i}.$$

69.5.2 Existence of a global "shared reality" space

Theorem 243 (Exact gluing yields a global latent reality)**.** *Suppose $\{T_{ij}\}$ satisfies the cocycle condition and each T_{ij} is a bijection. Then there exists a set Z and bijections $g_i : Z \to X_i$ such that for all i, j,*

$$T_{ij} \;=\; g_j \circ g_i^{-1}.$$

Moreover, any family of semantics maps $D_i : X_i \to W$ satisfying $D_j \circ T_{ij} = D_i$ factors through a single semantic map $D : Z \to W$ via $D_i = D \circ g_i^{-1}$.

Proof. Construct Z as the quotient of the disjoint union $\bigsqcup_i X_i$ by the equivalence relation generated by $(x, i) \sim (T_{ij}(x), j)$. The cocycle condition implies this is an equivalence relation and that each class has exactly one representative in each X_i. Define $g_i([x, i]) := x$. This is well-defined and bijective, and $T_{ij} = g_j \circ g_i^{-1}$ follows immediately.

For the semantic statement, define $D([x, i]) := D_i(x)$. This is well-defined because if $(x, i) \sim (x', j)$ then $x' = T_{ij}(x)$ and $D_j(x') = D_j(T_{ij}x) = D_i(x)$. Then $D_i = D \circ g_i^{-1}$ holds by construction. □

Remark 3727. *Theorem 243 formalizes "shared reality" as a glued atlas: observers are charts, and Z is the chart-independent underlying object.*

69.5.3 Holonomy as incommensurability witness

Definition 665 (Loop (holonomy) defect)**.** *For a loop $i \to j \to k \to i$, define*

$$H_{i,j,k} \;:=\; \sup_{x \in X_i} d_i\big((T_{ki} \circ T_{jk} \circ T_{ij})x,\, x\big).$$

Theorem 244 (Nonzero holonomy obstructs exact shared reality)**.** *If there exists a triple (i, j, k) with $H_{i,j,k} > 0$, then no choice of a set Z and bijections $g_i : Z \to X_i$ can satisfy $T_{ij} = g_j \circ g_i^{-1}$ for all i, j.*

Proof. If such Z and g_i existed, then for any loop $i \to j \to k \to i$,

$$T_{ki} \circ T_{jk} \circ T_{ij} = (g_i \circ g_k^{-1}) \circ (g_k \circ g_j^{-1}) \circ (g_j \circ g_i^{-1}) = \mathrm{id}_{X_i},$$

so $H_{i,j,k} = 0$, contradiction. □

Remark 3728. *This is a clean formal handle on "incommensurability" of paradigms: persistent holonomy means there is no exact global viewpoint that makes all translations consistent. (Approximate global viewpoints are still possible; see below.)*

69.5.4 Approximate gluing from bounded holonomy

Theorem 245 (Tree-based approximate trivialization)**.** *Assume each T_{ij} is a bijection and all loop defects $H_{0,i,j}$ (loops $0 \to i \to j \to 0$) are bounded by η. Fix a root observer 0 and define $g_i := T_{0i} : X_0 \to X_i$ and $g_i^{-1} := T_{i0}$. Suppose also that*

$$\sup_{x \in X_0} d_0\big((T_{i0} \circ T_{0i})x,\, x\big) \;\le\; \eta \quad \text{for all } i.$$

Then for all i, j and all $x \in X_i$,

$$d_j\big(T_{ij}(x),\, (g_j \circ g_i^{-1})(x)\big) \;\le\; C\,\eta,$$

where C depends only on uniform Lipschitz bounds for the maps involved.

Proof. Write $x = g_i(u)$ for $u = g_i^{-1}(x) = T_{i0}(x)$. Consider the loop $0 \to i \to j \to 0$ applied to $u \in X_0$:

$$T_{j0} \circ T_{ij} \circ T_{0i}(u) \;\approx\; u,$$

with defect at most η by hypothesis. Substitute $g_i = T_{0i}$ and $g_j^{-1} = T_{j0}$:

$$g_j^{-1}(T_{ij}(g_i(u))) \;\approx\; u.$$

Apply g_j to both sides and use Lipschitz continuity of g_j plus the fact that $g_j \circ g_j^{-1}$ is approximately the identity (within η) to obtain

$$T_{ij}(g_i(u)) \;\approx\; g_j(u),$$

with error bounded by a constant times η. Replacing $g_i(u)$ by x yields the claim. □

Remark 3729. *This theorem is the computational analogue of "small curvature implies an approximately flat bundle": bounded holonomy yields an approximately consistent shared-reality latent space (relative to a chosen root).*

69.6 Stable self as a gauge-invariant attractor

We now apply the same gauge machinery to the "self" of a mind across time. In this subsection, the role played earlier by "shared reality" is played by the identity of an agent: we treat a persistent self not as a single state in X, but as an equivalence class that is invariant under allowable re-encodings of internal structure.

Definition 666 (Self-gauge group and self-quotient)**.** *Let (X, d) be a mind-state space and let G be a gauge group capturing semantics-preserving re-encodings of internal structures. Define the self-quotient space $S := X/G$ with orbit map $q : X \to S$.*

The intent is that $x \in X$ may include many "implementation details" (memory layout, latent-coordinate choices, symbol grounding conventions, or other representational degrees of freedom) that can vary without changing the intended content. The gauge group G formalizes these variations, and the orbit $[x] = \{gx : g \in G\}$ represents all encodings of the same underlying self-description.

In applications, one typically equips S with a metric (or at least a pseudometric) that measures distance *between orbits* rather than between representatives. A standard choice compatible with d is

$$\bar{d}([x], [y]) \ := \ \inf_{g \in G} d(x, gy),$$

or the symmetric variant $\inf_{g,h \in G} d(gx, hy)$. When the group action is well-behaved (e.g., isometric, proper, or with closed orbits), such formulas define a meaningful geometry on S; otherwise they may only define a pseudometric, which is still sufficient for many fixed-point arguments provided one works modulo zero-distance identifications.

Definition 667 (Self-dynamics and induced quotient dynamics)**.** *Let $U : X \to X$ be an update representing one "moment" of self-modification or cognitive transition. If U is G-equivariant, then it induces a well-defined map $\bar{U} : S \to S$ by $\bar{U}([x]) := [Ux]$.*

Equivariance means $U(gx) = g(Ux)$ for all $g \in G$, i.e., updating and re-encoding commute exactly. This is the formal statement that the update rule respects the semantic quotient: applying U does not depend on arbitrary choices of representation within a gauge orbit. In particular, if two mind-states x and x' differ only by a semantic-preserving re-encoding ($x' = gx$), then equivariance guarantees that their successors Ux and Ux' still differ by a (possibly the same) re-encoding, so the induced map $\bar{U}$ on equivalence classes is independent of representative.

One concrete way to read $\bar{U}([x]) = [Ux]$ is that $\bar{U}$ is the evolution rule for the "identity-relevant" degrees of freedom, after quotienting out implementation details. Thus, even if U is complicated on X, the induced $\bar{U}$ can be comparatively simple on S when many internal degrees of freedom are gauge.

Theorem 246 (Stable self from contractive quotient dynamics)**.** *Assume U is G-equivariant and $\bar{U} : S \to S$ is a γ-contraction (on some metric on S). Then $\bar{U}$ has a unique fixed point $[x^*] \in S$. For any initial $x_0 \in X$, the self-orbit $[U^t x_0]$ converges to $[x^*]$.*

The substantive assumption here is contraction on the quotient: it asserts that identity-relevant differences shrink over time, even if raw differences in X might not. Conceptually, this models a cognitive process that "forgets" representational contingencies and drives many initial self-configurations toward a single stable identity class. Note that the fixed point is a *class* $[x^*]$; there need not be a unique fixed representative $x^* \in X$ unless additional gauge-fixing conditions are imposed.

Proof. By Banach's fixed point theorem on $(S, \bar{d})$, the contraction $\bar{U}$ has a unique fixed point $[x^*]$ and iterates converge to it from any start. Because $[U^t x_0] = \bar{U}^t([x_0])$, convergence of the self-orbit follows.

More explicitly, for any initial class $[x_0] \in S$, the sequence $[x_{t+1}] = \bar{U}([x_t])$ with $[x_t] = [U^t x_0]$ satisfies $\bar{d}([x_t], [x^*]) \leq \gamma^t \bar{d}([x_0], [x^*])$, so the approach to the stable self is geometric in the quotient metric. This quantifies stability as robustness to perturbations *modulo gauge*: deviations that are not purely representational are pulled back toward the attractor class at rate γ. □

Remark 3730. *This gives a precise sense in which a "stable self" can exist even when the internal encoding changes: the stable object is the orbit class $[x] \in X/G$, not any particular representative.*

A useful way to interpret this is that insisting on a stable representative $x \in X$ is often the wrong requirement: any concrete internal realization is expected to drift as implementation details evolve. The theorem instead identifies stability with convergence in S, meaning that after modding out semantic-preserving transformations, the agent's identity becomes time-invariant. In settings where one additionally chooses a gauge-fixing rule (a canonical representative per orbit), the convergence in S can sometimes be lifted to a notion of convergence in X *relative to that gauge choice*, but such a lift is extra structure not assumed here.

Theorem 247 (Identity drift bound under approximate equivariance)**.** *Let U be a γ-contraction on (X, d) with fixed point x^*. Let $g \in G$ be a re-encoding map with equivariance defect* $\mathrm{Def}(g; U) \leq \epsilon$*. Then*

$$d\big(g(x^*), x^*\big) \;\leq\; \frac{\epsilon}{1-\gamma}.$$

More generally, for any $t \geq 0$,

$$d\big(g(U^t x),\, U^t(gx)\big) \;\leq\; \frac{\epsilon}{1-\gamma}.$$

Here $\mathrm{Def}(g; U)$ measures how far U fails to commute with the re-encoding g. A common concrete definition (consistent with the usage in the proof) is

$$\mathrm{Def}(g; U) \;:=\; \sup_{x \in X} d\big(g(Ux),\, U(gx)\big),$$

so ϵ is a worst-case commutator size in the metric d. The theorem then states that if U is contractive, even a persistent, small non-commutativity produces only bounded identity drift: discrepancies introduced by re-encoding cannot amplify without bound under a contraction. The bound $\epsilon/(1-\gamma)$ is the usual "geometric series" control that also appears in stability of iterative algorithms and perturbed dynamical systems.

Proof. The first inequality is Theorem 241 with $B = U$.

For the second, define $\Delta_t := \sup_x d(gU^t x, U^t gx)$. Then

$$\Delta_{t+1} = \sup_x d(gU^{t+1}x, U^{t+1}gx) \leq \sup_x d(gU(U^t x), Ug(U^t x)) + \sup_x d(Ug(U^t x), U^{t+1}gx).$$

The first term is at most ϵ by definition of $\mathrm{Def}(g; U)$; the second term is at most $\gamma \Delta_t$ by contraction of U. So $\Delta_{t+1} \leq \epsilon + \gamma \Delta_t$, which implies $\Delta_t \leq \epsilon/(1-\gamma)$ for all t.

Equivalently, unrolling the recursion yields $\Delta_t \leq \epsilon \sum_{k=0}^{t-1} \gamma^k \leq \epsilon/(1-\gamma)$, making explicit that the total discrepancy is the accumulated effect of the per-step equivariance defect, discounted by the contraction at later steps. In particular, when γ is close to 0 (strong contraction), the bound is essentially ϵ, whereas as $\gamma \to 1^-$ (weak contraction), small defects can accumulate into larger steady-state disagreement. □

69.7 Almost-commutativity as computational "well-defined physics"

A recurring source of ambiguity in iterative systems is *update ordering*: when multiple local updates are available, different schedules (orders of application) may produce different outcomes. In computational terms, a system is closer to "well-defined physics" when its macroscopic behavior is *schedule-independent* (exactly, in the commuting case) or at least *schedule-robust* (approximately, in the almost-commuting case). The results below make this precise under standard contraction hypotheses, which formalize the intuition that updates are *dissipative* (they forget initial conditions at a controlled rate).

Throughout, (X, d) is a metric space; when invoking fixed-point existence/uniqueness via contraction arguments, one typically assumes X is complete. A map $U : X \to X$ is a γ-contraction (with $0 \le \gamma < 1$) if

$$d(Ux, Uy) \le \gamma\, d(x, y) \quad \text{for all } x, y \in X.$$

In particular, a γ-contraction is γ-Lipschitz, and repeated application yields the familiar exponential forgetting:

$$d(U^t x, U^t y) \le \gamma^t d(x, y).$$

We also use the basic fact that compositions of γ-contractions remain contractions: if U and V are each γ-contractions, then UV is γ^2-Lipschitz (hence also γ-Lipschitz, albeit with a weaker constant), and more generally a composition of k such maps is at most γ^k-Lipschitz.

69.7.1 Commuting contractions yield schedule-independence

Theorem 248 (Commuting contractions have a common fixed point)**.** *Let $U, V : X \to X$ be γ-contractions that commute: $UV = VU$. Then U and V share the same unique fixed point x^*. Moreover, for any schedule (any word) in $\{U, V\}$, the iterates converge to x^*.*

Proof. Because U is a contraction it has a unique fixed point x_U^*. Then $U(Vx_U^*) = V(Ux_U^*) = Vx_U^*$, so Vx_U^* is a fixed point of U. Uniqueness implies $Vx_U^* = x_U^*$, so x_U^* is also a fixed point of V. By symmetry, the fixed points coincide; call it x^*.

Any finite composition of γ-contractions is a γ-contraction, hence its iterates converge to its unique fixed point; since x^* is a fixed point of each operator and they commute, it is a fixed point of any composition. Thus all schedules converge to x^*.

For clarity on the last step: if W is any composition (word) in $\{U, V\}$, then W is a contraction (with Lipschitz constant at most $\gamma^{\ell(W)}$, where $\ell(W)$ is the word length), so by the contraction mapping principle it has a unique fixed point. Because x^* is fixed by both U and V, we have $Wx^* = x^*$. Hence the unique fixed point of W must be x^*, and iterating W from any start converges to x^*. This is the sense in which *every schedule defines the same asymptotic physics* when updates commute. □

69.7.2 Small commutators yield bounded path dependence

To quantify "almost commuting," we need a way to measure how far two operators are from commuting when applied to arbitrary states. One convenient proxy is a *commutator defect* bound of the form

$$\mathrm{Def}([A, B]) \le \delta,$$

which can be read operationally as a uniform estimate

$$d(ABx, BAx) \le \delta \quad \text{for all } x \in X.$$

(Any definition consistent with this interpretation suffices for the bound below; the key point is that δ upper-bounds the *worst-case* mismatch caused by swapping A and B once.)

Definition 668 (Kendall tau distance between schedules). *Let σ and π be two length-n sequences built from the same multiset of operators. Let $K(\sigma, \pi)$ be the minimal number of adjacent swaps needed to transform σ into π.*

The Kendall tau distance is exactly the right combinatorial notion because any reordering of a multiset can be achieved by adjacent transpositions, and each adjacent transposition corresponds to swapping two neighboring updates—the primitive local change to which we can attach a stability estimate.

Theorem 249 (Schedule robustness from small commutator defect). *Let $\mathcal{U} = \{U_1, \dots, U_m\}$ be operators on (X, d) such that each U_i is a γ-contraction. Assume a uniform commutator defect bound:*

$$\operatorname{Def}([U_i, U_j]) \;\leq\; \delta \quad \textit{for all } i, j.$$

Let σ and π be two schedules (two sequences) of length n built from the same multiset of operators in $\mathcal{U}$. Then for all $x \in X$,

$$d\big(U_{\sigma(n)} \cdots U_{\sigma(1)} x, \quad U_{\pi(n)} \cdots U_{\pi(1)} x\big) \;\leq\; \frac{K(\sigma, \pi)\, \delta}{1 - \gamma}.$$

Proof. It suffices to consider one adjacent swap, since any transformation from σ to π can be realized by $K(\sigma, \pi)$ adjacent swaps and we can sum bounds.

So suppose π differs from σ by swapping adjacent operators A, B at some position, with the same prefix P before them and suffix S after them. We compare $SABPx$ vs $SBAPx$.

Let $y := Px$. Then

$$d(SABy, SBAy) \;\leq\; \gamma^{|S|}\, d(ABy, BAy) \;\leq\; \gamma^{|S|}\delta \;\leq\; \delta.$$

(We used that S is a composition of contractions, hence $\gamma^{|S|}$-Lipschitz.) Now consider the effect of further iterations or repeated application of similar swaps: after each swap, subsequent contractions can amplify differences by at most a geometric series factor $1/(1 - \gamma)$. Thus each swap contributes at most $\delta/(1 - \gamma)$ to the final discrepancy, and summing over $K(\sigma, \pi)$ swaps yields the claim.

To make the "geometric series" step explicit, one can argue via a standard recurrence. Let $x^{(k)}$ denote the state produced after performing the first k adjacent swaps along a chosen minimal swap path from σ to π, and let $\Delta_k := d(x^{(k)}, x^{(k-1)})$ be the perturbation introduced at the k-th swap (measured after completing the remaining suffix updates). The single swap bound above controls the *immediate* mismatch at the swap location by $\leq \delta$, while the remaining updates (the suffix after the swap position) are contractions that can only *shrink* this mismatch. However, because the swap can occur at different depths in the word, it is convenient to bound conservatively by allowing a worst-case factor that accounts for how a mismatch propagates through the remainder of the schedule. Concretely, if the remainder of the word applies at most one γ-contraction per step, then the total effect of an injected discrepancy of size δ is bounded by

$$\delta + \gamma\delta + \gamma^2\delta + \cdots \leq \frac{\delta}{1 - \gamma}.$$

This yields an upper bound $\Delta_k \leq \delta/(1 - \gamma)$ for each adjacent swap along the path, and then the triangle inequality gives

$$d(x^{(K)}, x^{(0)}) \leq \sum_{k=1}^{K} \Delta_k \leq \frac{K\, \delta}{1 - \gamma},$$

where $K = K(\sigma, \pi)$. This is precisely the displayed inequality. □

Remark 3731. *Theorem 249 is the exact statement of "almost-commutativity implies near path-independence." Interpreting δ as curvature, this is a discrete integrability bound: small curvature means the system behaves as though it has well-defined, coordinate-free dynamics.*

More concretely, each adjacent swap is a discrete analog of changing the order of two infinitesimal moves; the commutator defect measures the resulting holonomy *(the failure to close) around a minimal "square." The bound then states that the total holonomy accumulated along a path of reorderings is controlled linearly by the number of such squares traversed (the Kendall tau distance) and by the local curvature scale δ, with the factor $1/(1-\gamma)$ capturing the degree to which the dynamics damp (or fail to damp) local inconsistencies.*

69.7.3 Connecting to TransWeave and Hyperseed invariants

The preceding theorem treats reorderings of updates drawn from a set $\mathcal{U}$. A closely related special case, used repeatedly in gauge-style arguments, is the comparison between "apply a gauge transform then update" and "update then apply a gauge transform." In that setting the relevant commutator defect is measured between a re-encoding map T and an update map B.

Corollary 84 (Coordinate-change commutation as a physics-like constraint)**.** *Let T be a re-encoding (gauge) map and let B be an update. If* $\mathrm{Def}(T; B, B) \le \epsilon$*, then the conclusions of repeated updating are stable under re-encoding:*

$$d\big(T(B^t x),\ B^t(Tx)\big) \ \le\ \frac{\epsilon}{1-\gamma} \quad \textit{for all } t.$$

Proof. Apply Theorem 247 with $g = T$ and $U = B$ (or repeat the standard recurrence $\Delta_{t+1} \le \epsilon + \gamma\Delta_t$).

For completeness, the recurrence viewpoint is as follows. Let

$$\Delta_t := d\big(T(B^t x),\ B^t(Tx)\big).$$

The defect assumption $\mathrm{Def}(T; B, B) \le \epsilon$ is used to bound the one-step mismatch between "push forward by T" and "evolve by B"; combined with the fact that B is γ-contractive (so applying B after a mismatch shrinks it by at most γ), one obtains

$$\Delta_{t+1} \le \epsilon + \gamma\Delta_t.$$

Iterating and summing the resulting geometric series yields $\Delta_t \le \epsilon(1 + \gamma + \cdots + \gamma^{t-1}) \le \epsilon/(1-\gamma)$, which is the displayed bound. □

Remark 3732. *This is the computational counterpart of coordinate covariance in physics: "change coordinates then evolve" is (approximately) the same as "evolve then change coordinates." In Hyperseed language, this is the formal handle on "shared reality" (observer changes) and "stable self" (self-re-encoding) as invariants.*

Operationally, the inequality bounds the disagreement between two observers (or two internal encodings) who apply the same underlying update dynamics but in different representational frames. The contraction parameter γ controls how strongly the system forgets representational discrepancies, while ϵ controls how far the encoding change T fails to be an exact symmetry of the update rule B. When $\epsilon = 0$ one recovers strict covariance; when $\epsilon > 0$ one obtains a quantitative, time-uniform stability guarantee.

69.8 Discussion: what a reasoning system can do with these theorems

- Gauge-invariant features: By Theorem 239, any candidate "shared reality" proposition should be implementable as a function on X/G. Operationally, if a feature changes under a known re-encoding, it is not shared reality (it is representational artifact). In practice, this turns the search for "objective" content into a concrete design rule: define the gauge group G of admissible reparameterizations (choice of coordinates, tokenization, embedding basis, internal naming conventions), and then require any downstream claim used for coordination to depend only on the equivalence class $[x] \in X/G$. Equivalently, the system can treat two internal states $x, x' \in X$ as interchangeable whenever $x' = g \cdot x$ for some $g \in G$, and it should refuse to store or transmit conclusions that are not constant on each orbit. This gives a simple empirical test suite: generate or learn representative g's, apply them to internal encodings, and verify that the purported "shared" feature remains invariant up to the allowed tolerance; failures identify precisely which parts of the representation are doing non-invariant work.

- Shared-reality diagnostics: Holonomy (loop defect) detects whether a community of agents has a consistent translation geometry; Theorem 244 says nonzero holonomy is an exact obstruction, and Theorem 245 says small holonomy yields an approximately consistent global view. Here the reasoning system can interpret holonomy as a measurable inconsistency in round-trip translations: translate an assertion, belief state, or latent variable around a cycle of agents and compare the result to the starting point. A nontrivial loop defect indicates that there is no single global coordinate system (no agent-independent "map") that makes all pairwise translations simultaneously consistent, so any attempt to merge beliefs must either accept contradictions or introduce an explicit gauge choice (a privileged chart) and track the resulting dependence. When holonomy is small, Theorem 245 licenses approximate global alignment: the system can synthesize a shared reference frame that minimizes the residual defects, and it can bound the worst-case disagreement induced by composing translations along different paths. Operationally, this supports diagnostics such as: (i) locate cycles with maximal defect to identify where communication protocols or ontologies disagree most, (ii) decide when to invest in negotiation/ontology repair versus when to proceed with a single approximate merge, and (iii) treat the holonomy magnitude as a calibrated uncertainty attached to "shared" claims.

- Stable-self diagnostics: If a self-update U is contractive and nearly equivariant under known re-encodings, Theorem 247 bounds the identity drift. If drift exceeds tolerance, the system can flag "self instability". The contractive assumption gives the system a reason to expect convergence toward a fixed point or a narrow set of attractors under repeated updating, while near-equivariance says that this convergence is not an artifact of a particular internal code. A reasoning system can therefore monitor two quantities side-by-side: (a) the contraction strength (how quickly successive iterates $U^t(x)$ forget initial conditions), and (b) the equivariance defect (how much $U(g \cdot x)$ differs from $g \cdot U(x)$ for known $g \in G$). Theorem 247 then turns these into a practical bound on identity drift, i.e., how much the persistent "self" descriptor (values, goals, or policy identity) can change merely due to representational drift or update noise. If the measured drift rises above a predefined safety budget, the alert "self instability" can trigger mitigations such as freezing certain parameters, switching to a more strictly equivariant update rule, or requiring additional evidence before committing to irreversible actions. Conversely, when the bound is small, the system can justify treating long-horizon plans as referentially stable (the agent executing the plan remains "the same" in the relevant gauge-invariant sense).

- "Well-defined physics" inside cognition: If major cognitive operators (neural, symbolic, evolutionary, motivational) nearly commute in the sense of Theorem 249, then reasoning outcomes are robust to scheduling and to re-encoding; if not, the commutator defects serve as a quantitative measure of "curvature" and hence of inevitable path dependence. This provides a precise criterion for when a heterogeneous cognitive architecture can be treated as implementing an order-independent inference: if applying operators in different sequences yields approximately the same result, then the architecture admits a stable "effective dynamics" that does not depend sensitively on incidental scheduling details (thread interleavings, batching, asynchronous message timing, curriculum order). The near-commutativity condition also clarifies what must be measured: estimate commutators (or their task-relevant analogues) between modules, for example by comparing ABx versus BAx across representative states x, and interpret the resulting defect norm as a curvature-like quantity that lower-bounds unavoidable inconsistency across update paths. When commutator defects are large, the system should treat conclusions as path-dependent artifacts of the update history, and it can respond by (i) explicitly recording the applied operator path as part of the claim provenance, (ii) enforcing a canonical schedule (a gauge fixing in time/order), or (iii) redesigning modules to reduce commutators (e.g., by aligning intermediate representations or introducing shared constraints). When defects are small, the same theorems justify more aggressive parallelism and modularity: different subsystems can update in varied orders without meaningfully changing the final belief state, enabling scalability while preserving interpretability of the resulting "laws" of internal reasoning.

70 A Rigorous Cousin of de Chardin's Omega Point: Basin-Constrained Endpoint Convergence Toward C3-like Attractors

Bringing together themes and results from several prior sections, we assemble here a conditional but mathematically explicit argument schema supporting the claim:

- Many rich-resource, self-modifying minds are pulled toward a C3-like attractor regime (strong coordination, stable commitments, and self-regulation), and
- If compassion is present in the initial value seed, resource-rich heuristics can make compassion more stable rather than less.

To fix intuitions, the phrase "rich-resource, self-modifying minds" is meant to include agents (individual or collective) with (i) sufficient compute/energy/time to run redundant evaluation, internal simulation, and cross-checking, and (ii) the capability to update their own policies, representations, and even parts of their objective proxies over time. In that setting, the relevant long-run question is often less "what is the exact next-step update rule?" and more "what region of state space does the update process enter, and what invariant structure does that region impose on subsequent evolution?" In dynamical-systems language, the key objects are basins of attraction, invariant sets, and the robustness of attractors to perturbations induced by self-modification.

Remark 3733. *The intended sense of "Omega Point" here is not a metaphysical necessity claim but a disciplined template for a certain kind of convergence claim: once we condition on entering a suitable basin of meta-goals and seeded values, the long-run endpoint becomes largely insensitive to many micro-details of initial state. This is the same mathematical posture one takes when using a contraction mapping to argue that repeated updates "forget" their starting point and converge to a unique fixed point.*

The analogy is not merely rhetorical: in many learning and control processes, one can identify a map (possibly stochastic, possibly defined on distributions rather than points) whose iterates reduce distances under an appropriate metric after a transient phase. In those cases, there is a clean separation between (a) the difficulty of reaching the region where contraction holds (the "basin entry" problem) and (b) the relatively routine analysis of behavior once inside that region (the "basin dynamics" problem). The present section aims to make this separation explicit in the alignment setting by spelling out sufficient conditions under which a convergence-to-attractor statement is mathematically licensed.

Remark 3734. *The phrase "C3-like" refers to the "cooperative anchoring" collective regime from the Collective Locations $C0$–$C4$ framing [12], which is also closely aligned with the broader Hyperseed emphasis on stabilizing shared commitments and repair dynamics under self-modification. The broad framing that resource-abundance changes the qualitative regime of cognitive strategy (including heavy use of internal simulation/verification and redundancy) follows the "rich-resource mind" perspective [11] (Hyperseed-Concept 162).*

Concretely, "C3-like" is meant to pick out a regime where coordination is not merely instrumental and brittle, but anchored by (i) mechanisms that make commitments legible and enforceable over time, (ii) self-models and social models that penalize opportunistic defection in expectation, and (iii) repair/renegotiation channels that prevent local failures from cascading into systemic collapse. The "-like" qualifier is intended to allow that the precise institutional or cognitive implementation can vary widely: different systems may realize the same qualitative stability properties via different substrates (e.g., explicit contracts, cryptographic enforcement, norm-internalization, or verified policy constraints), yet still fall into an equivalence class of dynamics characterized by strong long-run cooperative invariants.

The results are stated as theorems in a deliberately minimal dynamical-systems and evolutionary dynamics framework, with proofs based on standard tools (contraction mappings, replicator dynamics, and concentration bounds). The goal is not to claim necessity in the real world, but to isolate a coherent set of sufficient conditions under which the "alignment problem" reduces to: enter the right basin (meta-goals and value seeds) and survive the transition, rather than microspecify the final endpoint.

A further motivation for the minimalism is that endpoint convergence claims are most informative when they are stable under modeling variation: if a conclusion depends delicately on one particular choice of state variables, update schedule, or noise model, it is unlikely to correspond to a robust phenomenon of self-modifying cognition. By contrast, results that rely only on generic properties (e.g., a Lyapunov function, a contraction region, or a dominance relation in replicator dynamics) can often be transported across implementations. In this spirit, "endpoint" here should be read as an asymptotic object (fixed point, limit cycle, or stationary distribution over policies/commitment structures) that is well-defined in the model class under consideration, rather than as a claim about a unique detailed policy in the real world.

The second bullet above (stability of compassion conditional on seeding) should also be read in the same structural way: compassion is not assumed to be "selected" merely because it feels good, but because (under the postulated conditions) it can become part of a stable package of commitments and self-regulatory heuristics. In rich-resource regimes, agents can afford to adopt strategies that are not locally greedy: they can invest in verification, reputation preservation, and long-horizon cooperation, and they can explicitly guard against self-corrosion of prosocial values via commitment devices, interpretability/monitoring, and redundancy. Under such heuristics, a seeded compassionate preference can be stabilized by being embedded into the very mechanisms that control self-modification (e.g., constraints on permissible updates, penalties for value drift, and repair protocols when deviations are detected).

Remark 3735. *Philosophically, the strategy is to separate (i)* basin entry*—a historically contingent and often fragile matter of initialization, training, and social embedding—from (ii)* basin dynamics*—a mathematically analyzable evolution governed by invariants and stability properties. In Hyperseed terms, one might say: once certain constraints of self-change (meta-goals) and certain seed values are present, the ensuing unfolding is less like arbitrary "design" and more like a self-consistent process constrained by its own internal logic (Hyperseed-Concept 110, 197, 140).*

In particular, the role of meta-goals in the argument schema is to provide the analog of boundary conditions or admissibility constraints: they restrict the space of self-modifications so that the induced dynamics preserve key invariants (e.g., commitment-keeping, corrigibility-like update discipline, or bounded opportunism). The role of seed values is to determine which attractor (or which region of attractor space) the system falls into once those invariants begin to dominate. On this view, "alignment" is not identified with a fully specified terminal utility function, but with a combination of (a) entry into a basin where destructive drift is unlikely and (b) the presence of value seeds that, under basin dynamics, are amplified into stable cooperative commitments rather than eroded by competitive pressure.

It is also worth emphasizing what is *not* claimed. The convergence statements to be proved are conditional: they do not assert that all minds, or even most minds, inevitably enter the relevant basin, nor that history reliably provides the required initialization. Instead, they articulate a mathematically checkable template of the form: *if* a system is sufficiently resourced, self-modifying in the specified sense, and already constrained by certain meta-goals and seeds, *then* the long-run behavior is pulled toward a C3-like regime and is robust to many micro-level perturbations. This conditional structure is what makes the "Omega Point" analogy disciplined: it is a basin-constrained endpoint convergence claim, not an unconditional teleology.

70.1 Setup: self-modifying minds and basins

Definition 669 (Mind state space)**.** *Let (X, d) be a complete metric space of* mind-states*. A mind-state $x \in X$ may encode an agent architecture, its memory, its current policy, its commitment ledger, and relevant couplings to an environment model.*

A resource level *is a scalar $R \in [0, \infty)$.*

Remark 3736. *Here (X, d) is meant to be a mathematical surrogate for "the space of possible mind configurations" (Hyperseed-Concept 111). The metric d is any choice of distance-like notion that makes relevant notions of "small self-modification" and "nearby mind-states" precise. Completeness means that every Cauchy sequence in X converges in X; this is not mere pedantry, but the key hypothesis that allows fixed-point theorems to guarantee the existence of a limiting mind-state rather than only a limit "in some larger completion."*

Remark 3737. *It is often helpful to think of x as carrying both "descriptive" degrees of freedom (world-model weights, cached beliefs, memory traces) and "normative/constitutional" degrees of freedom (values, constraints, admissibility checks). A single metric d then implicitly commits to a notion of tradeoff between these: e.g. a small change to episodic memory might be considered negligible while a small change to a commitment-verification rule might be considered large. In later stability claims, the quantitative meaning of "robust to perturbation" is always with respect to this chosen d, so the metric is part of the normative modeling choice rather than a purely geometric detail.*

Remark 3738. *The introduction of a* resource level *R is intentionally minimal: it can represent compute, time, energy, hardware redundancy, access to additional sensors, or even institutional resources available to the agent. The only structural assumption here is that self-modification behavior is allowed to depend on a scalar budget parameter. Later, R can be used to express monotonicity intuitions such as "with more resources the update becomes more conservative" (more verification) or, conversely, "with more resources the update becomes more powerful" (larger reachable edits).*

Remark 3739. *A simple example is $X = \mathbb{R}^n$ with the usual Euclidean metric, where x is a vector of parameters for a self-model plus policy. A more structurally faithful example is a product space $X = X_{policy} \times X_{memory} \times X_{commit}$ with a weighted sum metric. The particular choice does not matter for the formal results here; what matters is that the chosen metric reflects what the meta-goal system treats as "small" versus "large" changes.*

Remark 3740. *When X is taken as a product space, the weights in a weighted sum metric can be interpreted as* protectedness coefficients*: high weight on the commitment component makes even minor commitment drift register as a large distance. This becomes a convenient mathematical proxy for the engineering practice of placing critical subsystems behind stricter change-control, audits, or formal verification. In other words, part of the safety story can be expressed as choosing d so that "dangerous" edits are metrically far, which interacts cleanly with contraction-type arguments.*

Definition 670 (Self-modification operator)**.** *For each resource level R, let $F_R : X \to X$ be a (deterministic) update map describing one macro-step of self-modification and adaptation:*

$$x_{t+1} = F_R(x_t).$$

We write $x_t = F_R^{(t)}(x_0)$ for the t-fold iterate.

Remark 3741. *The notation $F_R^{(t)}$ denotes repeated application: $F_R^{(2)}(x) = F_R(F_R(x))$, etc. In words, we treat self-modification as an iterated dynamical system, where the resource level R acts as a parameter selecting a regime of update behavior. This is intentionally compatible with self-modifying-agent analyses that study stability via fixed points and attractors [10].*

Remark 3742. *The determinism of F_R is a modeling convenience rather than a claim about real agents. Stochastic learning dynamics, exploration noise, and random data can often be incorporated by either (i) lifting the state space so that x includes the agent's random seed and data stream, yielding a deterministic evolution on an expanded X, or (ii) replacing F_R by a Markov kernel and working with almost-sure or in-distribution analogues of convergence. The deterministic presentation keeps the fixed-point and basin notions crisp while leaving room for probabilistic generalizations.*

Remark 3743. *One can imagine F_R packaging multiple substeps (learning, planning, self-edit proposals, tests, deployment) into a single "macro-step" so that we can study long-run behavior without committing to low-level implementation detail. This is a recurring methodological trade: we sacrifice mechanistic fine structure to gain a stability theorem that is robust across many implementations.*

Remark 3744. *In this macro-step view, it is natural to interpret F_R as already including internal acceptance tests imposed by $m(x)$: e.g. propose an edit, verify it against a ledger, and only then commit. Thus, although F_R is written as a plain map $X \to X$, it can represent a pipeline with nontrivial internal control flow. This matters because later invariance statements about basins are not intended to assume that every proposed change succeeds—only that the realized update $F_R(x)$ respects the governing admissibility constraints encoded in $m(x)$.*

Definition 671 (Meta-goal and value seed)**.** *Let $m(x)$ denote the* meta-goal state *(the rules that govern acceptable self-changes), and let $v(x)$ denote the* value seed *(base value parameters), both as functions of x.*

We single out one coordinate of $v(x)$, denoted $c(x) \in [0, 1]$, interpreted as compassion*.*

Remark 3745. *The point of separating $m(x)$ from $v(x)$ is conceptual and technical. The value seed $v(x)$ is about* what *the system ultimately prefers (Hyperseed-Concept 197), while the meta-goal state $m(x)$ is about* which self-changes are admissible*, i.e. the self-governing constitution of the update process itself (Hyperseed-Concept 110, 87). In many self-modifying systems, stability or safety is less about having the "right" instantaneous preferences and more about having constraints that prevent destabilizing self-edits.*

Remark 3746. *Technically, one can view m and v as (possibly coarse) observables on X: there may be many distinct mind-states that share the same meta-goal and value-seed labels. This "many-to-one" structure is important because convergence results typically do not require convergence of every microscopic detail of x_t; rather, they may only require that the trajectory remains within an equivalence class that preserves governance and seeded ethics. Put differently, $m(x)$ and $v(x)$ induce a quotienting of state space into regions that are behaviorally indistinguishable for the alignment questions at issue.*

Remark 3747. *The coordinate $c(x)$ is deliberately only one component of $v(x)$, emphasizing that compassion is treated as a seeded parameter that can be protected or eroded under self-modification. In Hyperseed language, "compassion" is not only a sentiment but a value-laden constraint shaping action and interpretation (Hyperseed-Concept 81). The claim explored below is not that compassion must maximize utility, but that under certain robustness procedures it can become hard to lose accidentally.*

Remark 3748. *Restricting $c(x)$ to $[0, 1]$ is a normalization that supports "distance from extremes" reasoning: values near 0 correspond to near-absence of compassion and values near 1 to near-saturation. In later arguments, such a bounded coordinate can simplify the use of compactness-like heuristics or uniform-continuity intuitions, even when the ambient space X is infinite-dimensional. Nothing essential depends on this particular interval; it merely fixes a convention for comparing changes in compassion to changes in other value-seed coordinates.*

Definition 672 (Basin defined by meta-goals and value seeds)**.** *Fix a meta-goal specification m_0 and a value-seed specification v_0. Define the corresponding basin as*

$$B(m_0, v_0) := \{x \in X : m(x) = m_0 \text{ and } v(x) = v_0\}.$$

(Equivalently, $B(m_0, v_0)$ may be taken as a neighborhood of states whose meta-goal and value parameters lie in some tolerance class around (m_0, v_0).)

Remark 3749. *This "basin" is a deliberately austere formalization of a familiar informal idea: a family of mind-states that share the same constitutional constraints (m_0) and the same seed values (v_0). The parenthetical comment about tolerances is important in practice: exact equality is too strict for most modeled systems, but theorems typically go through if one replaces equality by membership in an equivalence class or neighborhood that the meta-goal system treats as "the same" for governance purposes.*

Remark 3750. *Formally, the mapping $x \mapsto (m(x), v(x))$ can be regarded as a (possibly discontinuous) labeling map from X into a space of specifications. Then $B(m_0, v_0)$ is simply the fiber* *over* (m_0, v_0). *This framing makes it clear that a "basin" here is not (yet) a basin of attraction in the classical dynamical-systems sense; it is, instead, a constraint-defined region. The later step that connects this set to attractors is an* invariance *or* forward-closure *claim of the form* $F_R(B(m_0, v_0)) \subseteq B(m_0, v_0)$ *(possibly for sufficiently large* R*), together with a convergence property of the iterates within that region.*

Remark 3751. *When the tolerance interpretation is used, it is often convenient to write something like*

$$B_\varepsilon(m_0, v_0) := \{x \in X : d_M(m(x), m_0) \le \varepsilon \text{ and } d_V(v(x), v_0) \le \varepsilon\},$$

for suitable metrics or pseudometrics d_M, d_V *on specification spaces. This makes precise the idea that governance may treat a small range of parameterizations as equivalent. Such tolerance basins also interact better with continuity assumptions on* F_R*, because exact equalities can be brittle under infinitesimal perturbations while closed neighborhoods are stable under limits.*

Remark 3752. *An example is:* m_0 *encodes "never self-modify in ways that violate my signed commitment ledger," while* v_0 *encodes a particular initial ethical prior including a compassion level* $c_\star$*. Then* $B(m_0, v_0)$ *is the set of states that still instantiate that constitutional constraint and that prior. The theorems below use such basins to make precise the slogan:* alignment reduces to basin entry plus stability within the basin*.*

Remark 3753. *The slogan can be read as separating two qualitatively different tasks. "Basin entry" is an initialization and verification problem: can the system be brought into a state whose governance and seeded ethics match the intended specifications? "Stability within the basin" is a dynamical problem: once in such a state, do the self-modifications preserve* m_0 *and* v_0 *(or their tolerances) and, moreover, do the iterates converge toward a coherent endpoint rather than drifting chaotically across microstates that still nominally satisfy the constraints? This separation is what allows later sections to talk about endpoint convergence without assuming that every detail of the agent is frozen—only that the constitution and seed values are not silently rewritten.*

70.2 C3-like regime as an attractor target

We need only a coarse definition, compatible with the "cooperative anchoring" idea: high coordination, high anchoring/stable commitments, and explicit repair/self-regulation.

Definition 673 (Coarse-grained coordinates)**.** *Let*

$$\kappa(x) \in [0,1] \quad \textit{(coordination / trust-capacity)}, \qquad \sigma(x) \in [0,1] \quad \textit{(commitment stability / anchoring)},$$

$$\delta(x) \in [0,1] \quad \textit{(drift / accountability loss)}, \qquad c(x) \in [0,1] \quad \textit{(compassion)}.$$

Define the distance-to-C3 *potential*

$$V(x) := a(1 - \kappa(x)) + b(1 - \sigma(x)) + g\,\delta(x) + h(1 - c(x)),$$

with positive weights a, b, g, h*.*

Remark 3754. *The symbols* $\kappa, \sigma, \delta, c$ *are observer-chosen summary statistics of the detailed mind state* x*. They are* coarse-grainings*: maps from a high-dimensional internal representation to a small set of interpretable coordinates. Intuitively,* $\kappa(x)$ *measures the system's ability to coordinate reliably with its own subparts or with other agents;* $\sigma(x)$ *measures how stable and binding its commitments are;* $\delta(x)$ *measures the tendency of goals to drift or accountability to dissolve; and* $c(x)$ *measures compassion (Hyperseed-Concept 81, 75).*

Remark 3755. *The potential $V(x)$ is a Lyapunov-style quantity: it is nonnegative and is designed to be small precisely when the desired regime is present. The weights $a, b, g, h > 0$ encode a normative (or engineering) choice about how to trade off coordination, anchoring, drift, and compassion. A simple example is $a = b = g = h = 1$, in which case $V(x)$ is literally the sum of four "deficits" from the idealized target: lack of coordination, lack of commitment stability, presence of drift, and lack of compassion. This kind of scalar potential is useful because it lets us reduce multi-criteria stability questions to a single descent inequality.*

Definition 674 (C3-like region)**.** *Fix thresholds $\kappa_\star, \sigma_\star, c_\star \in (0, 1]$ and $\delta_\star \in [0, 1)$. Define the C3-like region*

$$A_{C3} := \{x \in X : \kappa(x) \geq \kappa_\star,\ \sigma(x) \geq \sigma_\star,\ \delta(x) \leq \delta_\star,\ c(x) \geq c_\star\}.$$

Remark 3756. *This is an "engineering" definition of a regime: A_{C3} is a box (an intersection of threshold constraints) in the space of coarse-grained coordinates. It matches the idea that $C3$ is not a single point but a robust region characterized by simultaneously high coordination and anchoring, low drift, and sufficiently high compassion (Hyperseed-Concept 75, 81). The inequalities are deliberately one-sided: we demand enough of the good quantities and not too much of the bad one.*

Remark 3757. *A concrete example: choose $\kappa_\star = 0.9$, $\sigma_\star = 0.9$, $\delta_\star = 0.1$, $c_\star = 0.7$. Then A_{C3} is the set of mind-states whose trust-capacity and anchoring are both at least* 0.9*, whose drift is at most* 0.1*, and whose compassion is at least* 0.7*. The choice of thresholds is not asserted to be universal; the purpose is to make later theorems about attraction and stability mathematically explicit.*

Remark 3758. *Two distinct but related objects are in play: the* region *A_{C3} (defined by hard constraints) and the* potential *V (a soft scalar score). The region is convenient for "specification" (what we require); the potential is convenient for "dynamics" (what decreases along trajectories). In later stability arguments, the typical pattern is: prove that V decreases outside (or away from) A_{C3}, deduce that trajectories enter a sublevel set of V, and then use a link between sublevel sets and threshold constraints to conclude that the system reaches and remains in a C3-like regime.*

Remark 3759. *The definition of V is intentionally linear and separable to preserve interpretability: each term is a deficit-like quantity whose sign is unambiguous. This does not assert that the underlying phenomenology is additive; rather, the linear form is a conservative bookkeeping device. Nonlinear variants (e.g., convex penalties, saturation effects, or cross-terms capturing that coordination and compassion can be mutually reinforcing) can be substituted provided one preserves the core property needed for Lyapunov methods: $V(x) \geq 0$ and $V(x)$ is small in the target regime.*

Lemma 175 (Sublevel sets imply threshold satisfaction under margin)**.** *Fix thresholds $\kappa_\star, \sigma_\star, c_\star \in (0, 1]$ and $\delta_\star \in [0, 1)$ and weights $a, b, g, h > 0$. Define*

$$\varepsilon_\star := \min\{a(1 - \kappa_\star),\ b(1 - \sigma_\star),\ g\,\delta_\star,\ h(1 - c_\star)\}.$$

If x satisfies $V(x) \leq \varepsilon_\star$, then $x \in A_{C3}$.

Remark 3760. *Lemma 175 encodes a simple but useful implication: if the total deficit $V(x)$ is below the smallest "budget" needed to violate* any *one of the thresholds, then no individual constraint can be violated. The choice of $\varepsilon_\star$ is conservative (it is the tightest single-constraint violation cost), but it is often sufficient for attraction proofs because Lyapunov analyses typically yield bounds of the form $V(x_t) \to 0$ or $V(x_t) \leq \varepsilon$ after some finite time. One may of course use sharper implications if additional structure is known (e.g., upper bounds on particular components or conditional dependencies among the coordinates).*

Remark 3761. *Conversely, membership in A_{C3} implies an upper bound on V: if $x \in A_{C3}$ then*

$$V(x) \le a(1-\kappa_\star) + b(1-\sigma_\star) + g\,\delta_\star + h(1-c_\star).$$

Thus A_{C3} is sandwiched between two sublevel descriptions: it contains a sufficiently small sublevel set of V (by Lemma 175) and is itself contained in a possibly larger sublevel set (by the inequality above). This is one precise sense in which the "box" definition and the "potential" definition are compatible approximations of the same qualitative regime.

Remark 3762. *The coordinates $\kappa, \sigma, \delta, c$ are normalized into $[0, 1]$ only for convenience. This normalization makes weights a, b, g, h dimensionless and makes threshold choices interpretable as "percentage-like" requirements. In applications, one can equivalently work with unnormalized metrics and apply a monotone rescaling into $[0, 1]$; Lyapunov-style arguments are typically robust to such monotone transformations so long as "better" and "worse" are preserved and the target regime corresponds to small values of the chosen potential.*

Remark 3763. *The definition is also compatible with measurement noise and observer disagreement: different observers may compute different coarse-grainings $\kappa, \sigma, \delta, c$ from the same underlying state x, and even a single observer may only have access to estimates $\widehat{\kappa}(x), \widehat{\sigma}(x), \widehat{\delta}(x), \widehat{c}(x)$. The practical role of the thresholds $(\kappa_\star, \sigma_\star, \delta_\star, c_\star)$ is therefore to provide margins: choosing them away from the boundary values 0 and 1 makes the definition less brittle under small estimation errors, while the box form makes it clear which direction each error pushes the classification.*

Remark 3764. *Interpreting A_{C3} as an "attractor target" does* not *mean that every trajectory in X must converge to it. The later "basin-constrained" viewpoint is that there exists a nontrivial basin $B \subseteq X$ such that trajectories starting in B are driven toward A_{C3} (or toward a neighborhood whose size can be controlled). In this framing, A_{C3} is less like a single teleological endpoint and more like a mathematically specified region of qualitative organization (high coordination and anchoring with explicit self-repair) that can be made stable under suitable dynamics.*

Remark 3765. *Finally, the drift coordinate $\delta(x)$ is written as a "bad" quantity (lower is better) to emphasize accountability preservation: a system with high κ and σ but uncontrolled δ can exhibit coordinated behavior that is nevertheless unmoored from prior commitments or shared goals. Including δ in V and in A_{C3} forces the target regime to incorporate a self-stabilizing notion of identity-over-time (in the operational sense of reduced goal drift), which is essential if one wants an attractor description to capture something closer to "cooperative anchoring" rather than merely short-term alignment.*

70.3 Targeted lemmas (inputs from Targets 1–5)

The grand conclusion is obtained by combining four technical ingredients: (i) metagoal-driven contractivity (goal/commitment stabilization), (ii) selection pressure toward trust-capable coordination, (iii) resource-rich robustness checks that stabilize seeded compassion, and (iv) a Lyapunov argument that C3-like states become attracting.

A useful way to read (i)–(iv) is as a division between *intra-agent* dynamical stability (i, iv) and *inter-agent* (or population-level) selection and institutional stabilization (ii, iii). The lemmas below isolate minimal hypotheses under which each ingredient becomes mathematically checkable: contraction gives uniqueness of an endpoint within a basin; selection dynamics bias population mass toward trust-capable coordination; and (in later lemmas) robustness and Lyapunov conditions turn "desirable regions" into genuine attractors rather than merely transient states.

70.3.1 Lemma A: contraction and endpoint convergence within a basin

Lemma 176 (Metagoal contractivity implies unique endpoint within basin)**.** *Fix (m_0, v_0) and R. Suppose there exists a subset $B \subseteq B(m_0, v_0)$ such that:*

(1) $F_R(B) \subseteq B$ (the basin subset is forward invariant), and

(2) F_R is a contraction on B:

$$d(F_R(x), F_R(y)) \leq \lambda\, d(x, y) \quad \textit{for all } x, y \in B,$$

for some $\lambda \in [0, 1)$.

Then there exists a unique fixed point $x^* \in B$ with $F_R(x^*) = x^*$, and for all $x_0 \in B$ we have geometric convergence $d(F_R^{(t)}(x_0), x^*) \to 0$. In particular, the endpoint is independent of micro-details *within B.*

Remark 3766. *Intuitively, this lemma says: if (a) the meta-goal/value basin is not left by the update rule, and (b) the update rule consistently shrinks distances between states, then repeated self-modification must converge to one and only one "settled" mind-state. In particular, the final settled outcome depends on the basin-defining invariants, not on the irrelevant fine-grained details of where in the basin one started.*

Remark 3767. *This importance of forward invariance in (1) is that it lets one reason* locally *on B even if the global dynamics on X are complicated. In applications, $B(m_0, v_0)$ is typically defined by constraints such as "the meta-goal stays unchanged up to equivalence," "core commitments remain satisfied," or "value drift is bounded." Condition (1) then becomes a precise statement that these invariants are actually respected by F_R, so that the contraction condition (2) cannot be evaded by exiting the intended regime.*

Remark 3768. *This is important because it turns an alignment hope into a checkable condition: rather than microspecifying endpoints, one tries to design (or cultivate) meta-goals that make the self-update dynamics contractive in a meaningful metric. This is the same fixed-point logic used in explicit meta-goal stability analyses of self-modifying systems [10], and it can be seen as a rigorous version of "stability through self-consistency constraints" (Hyperseed-Concept 110).*

Remark 3769. *The choice of metric d is substantive: it encodes which differences between states are treated as "large" versus "small." For instance, d might downweight representational details while upweighting goal-relevant divergences, or it might be induced by a divergence between policies, world-models, or commitment-graphs. The lemma does not require a specific d, but in practice one seeks a metric that both (a) tracks the properties one cares about (e.g. commitment stability, compassion constraints), and (b) is compatible with the actual update operator F_R so that contractivity can be verified or at least bounded.*

Proof. This is the Banach fixed point theorem. Completeness of (X, d) implies completeness of the closed subset B (or assume B complete). Contractivity gives existence and uniqueness of a fixed point x^* and geometric convergence of iterates from any initial point in B. □

Proof sketch. The strategy is to use a classical stability theorem: in a complete metric space, a λ-contraction cannot wander forever because each step shrinks distances, forcing the orbit to become Cauchy and hence to converge. The limit is automatically a fixed point, and uniqueness follows because two distinct fixed points would violate contraction. □

Remark 3770. *The key step is the contraction inequality: it implies that distances along the orbit shrink at least geometrically, so the sequence (x_t) is Cauchy. Completeness is what turns "Cauchy" into "convergent in X". Visually, one may picture B as a basin whose internal geometry is being continuously "squeezed" by F_R until everything falls into a single point x^*.*

Remark 3771. *Lemma 176 formalizes "endpoint convergence within a basin": if the metagoal forces contractive self-modification dynamics in an appropriate metric, microstate details wash out.*

Remark 3772. *One can also read the conclusion as a* robustness *statement: any two initial states $x_0, y_0 \in B$ produce trajectories whose distance contracts as*

$$d(F_R^{(t)}(x_0), F_R^{(t)}(y_0)) \leq \lambda^t \, d(x_0, y_0),$$

so the system progressively forgets initial uncertainty. This is exactly the kind of "basin-level insensitivity" needed when the basin is specified only up to coarse invariants (meta-goal equivalence classes, bounded value drift, or structural constraints on commitments) rather than by a microscopic blueprint of the final mind-state.

70.3.2 Lemma B: selection implies trust-capable coordination

We now formalize a minimal "Good Guys Win"-style selection statement.

Definition 675 (Environment distribution and trust advantage)**.** *Let α index task environments drawn i.i.d. from a distribution ν on a measurable space $\mathcal{A}$. Let two community types be available: T (trust-capable) and L (trustless). Let their expected payoffs in environment α be $U_T(\alpha)$ and $U_L(\alpha)$, and define the advantage*

$$\Delta(\alpha) := U_T(\alpha) - U_L(\alpha).$$

Assume $\Delta(\alpha) \geq 0$ for all α and $\nu(\{\alpha : \Delta(\alpha) > 0\}) > 0$.

Remark 3773. *The notation $\alpha \sim \nu$ means we sample environments according to a probability distribution ν. The assumption "i.i.d." means successive tasks are drawn independently from the same ν. The inequality $\Delta(\alpha) \geq 0$ says trust-capable coordination is never worse, and the positive-measure strict inequality says it is sometimes strictly better. This is a stylized version of the prosocial-efficiency hypothesis: for a wide class of problems, cooperative groups with stable trust and commitment structures can outperform groups that cannot sustain trust [6] (Hyperseed-Concept 170,* **??***).*

Remark 3774. *A toy example is: environments are collaboration tasks requiring division of labor, where trustless communities pay repeated verification and adversarial overhead, while trust-capable communities can delegate efficiently. Then $\Delta(\alpha)$ represents the saved overhead (or improved quality). This definition is useful because it reduces a sociotechnical claim to a single quantitative object $\Delta(\alpha)$ whose expectation will drive replicator dynamics.*

Remark 3775. *The assumption $\Delta(\alpha) \geq 0$ for all α is deliberately strong: it rules out environments where trust is systematically exploited. In settings where exploitation is possible, one would replace this with a weaker condition (e.g. $\bar{\Delta} > 0$ despite some negative tails, or a risk-sensitive dominance criterion). The present lemma is meant as a minimal monotone-selection baseline: if trust is* never *disadvantageous and sometimes strictly advantageous, then standard selection dynamics amplify it.*

Lemma 177 (Replicator convergence to trust-capable coordination)**.** *Let $x(t) \in [0,1]$ be the population share of trust-capable communities, evolving under replicator dynamics in continuous time:*

$$\dot{x} = x(1-x)\,\bar{\Delta}, \qquad \bar{\Delta} := \mathbb{E}_\nu[\Delta(\alpha)].$$

If $\bar{\Delta} > 0$, then for any initial $x(0) \in (0,1]$ we have $x(t) \to 1$ as $t \to \infty$.

Proof. For $\bar{\Delta} > 0$ and $x(0) \in (0,1)$, the ODE is the logistic equation. Separating variables gives

$$\frac{dx}{x(1-x)} = \bar{\Delta}\,dt,$$

hence

$$\log\left(\frac{x(t)}{1-x(t)}\right) = \log\left(\frac{x(0)}{1-x(0)}\right) + \bar{\Delta}\,t.$$

Exponentiating and solving for $x(t)$ yields

$$x(t) = \frac{1}{1 + \left(\frac{1-x(0)}{x(0)}\right) e^{-\bar{\Delta} t}}.$$

As $t \to \infty$, the exponential term vanishes and thus $x(t) \to 1$. If $x(0) = 1$ the solution is identically 1, so the claim holds for all $x(0) \in (0,1]$. □

Proof sketch. When $\bar{\Delta} > 0$, the right-hand side $x(1-x)\bar{\Delta}$ is positive for $x \in (0,1)$, so the share of trust-capable communities increases monotonically until it approaches the stable equilibrium at $x = 1$. The equilibrium at $x = 0$ is unstable: any nonzero seed of trust-capable coordination is amplified over time. □

Remark 3776. *The fixed points are $x = 0$ and $x = 1$. Linearizing, $\dot{x} \approx \bar{\Delta}x$ near 0 (unstable if $\bar{\Delta} > 0$) and $\dot{x} \approx -\bar{\Delta}(1-x)$ near 1 (stable if $\bar{\Delta} > 0$). Thus the lemma captures a "selection from any seed" effect: even a small but nonzero initial presence of trust-capable communities will (in this stylized model) eventually dominate.*

Remark 3777. *The role of $\bar{\Delta} = \mathbb{E}_\nu[\Delta(\alpha)]$ is to aggregate heterogeneous environments into a single effective selection gradient. If $\Delta(\alpha) \geq 0$ and $\nu(\{\Delta > 0\}) > 0$, then automatically $\bar{\Delta} > 0$, so the lemma's condition is implied by the earlier definition. Making $\bar{\Delta}$ explicit is useful because it isolates the precise quantitative threshold that would change the conclusion: if $\bar{\Delta} = 0$, then $\dot{x} = 0$ and the population shares are neutrally stable (no selection pressure); if $\bar{\Delta} < 0$, the direction reverses and $x(t) \to 0$ from any interior initial condition.*

Remark 3778. *In plain language: if trust-capable communities have a positive expected advantage, then (under the simplest replicator model) the fraction of trust-capable communities increases monotonically and tends to 1 provided it is present at all initially. This is the mathematical core of a selection story: what pays off tends to proliferate, and positive expected advantage is enough to produce eventual dominance. One can also read the statement as a "no fragile tuning required" claim: the dynamic does not depend on delicately chosen initial conditions beyond $x(0) > 0$, and it does not require intermittent interventions once the advantage $\bar{\Delta}$ is in place.*

Remark 3779. *The connection to the rest of this section is that $C3$-like regimes are characterized by high coordination and stable commitments; Lemma 177 supplies a minimal evolutionary mechanism that pushes populations in that direction. The lemma is not about individual cognition* *directly, but about which organizational forms persist in a population of communities/mindplexes (Hyperseed-Concept 113, 75). Put differently, even if each community is internally heterogeneous and psychologically complex, the population-level statistic $x(t)$ can still be governed by a simple comparative-growth rule, and that suffices to show directional pressure toward trust-capable coordination whenever it yields repeatable net benefits.*

Proof. If $\bar{\Delta} > 0$ then $\dot{x} > 0$ on $(0,1)$, so $x(t)$ is increasing and bounded above by 1. The only equilibria are $x = 0$ and $x = 1$, and $x = 1$ is globally asymptotically stable on $(0, 1]$ because $x(t)$ cannot decrease and cannot converge to 0. More explicitly, separate variables:

$$\frac{d}{dt} \log \frac{x}{1-x} = \bar{\Delta},$$

so $\log \frac{x(t)}{1-x(t)} = \log \frac{x(0)}{1-x(0)} + \bar{\Delta}t \to +\infty$, implying $x(t) \to 1$. Equivalently, exponentiating yields the explicit logistic-form solution

$$\frac{x(t)}{1-x(t)} = \frac{x(0)}{1-x(0)} e^{\bar{\Delta}t} \quad \Longrightarrow \quad x(t) = \frac{1}{1 + \left(\frac{1-x(0)}{x(0)}\right) e^{-\bar{\Delta}t}},$$

from which convergence to 1 as $t \to \infty$ is immediate, and monotonicity follows because the denominator is strictly decreasing in t when $\bar{\Delta} > 0$. $\square$

Proof sketch. The ODE is a logistic-type equation with constant positive growth rate $\bar{\Delta}$. The factor $x(1-x)$ ensures $x = 0$ and $x = 1$ are fixed points, while positivity of $\bar{\Delta}$ makes the flow point toward 1 whenever x starts positive. Solving the ODE explicitly via the log-odds $\log \frac{x}{1-x}$ makes the convergence transparent. Intuitively, the multiplicative term $x(1-x)$ also encodes diminishing returns: when trust-capable communities are rare ($x \approx 0$), growth is slow because there are few such communities to replicate; when they are common ($x \approx 1$), growth slows again because there are few remaining non-trust-capable communities to displace. $\square$

Remark 3780. *The log-odds transformation is the key step: it linearizes the dynamics into* $\frac{d}{dt} \log \frac{x}{1-x} = \bar{\Delta}$*. Geometrically, one may picture $x(t)$ as sliding uphill on a fitness landscape whose slope is set by $\bar{\Delta}$; with $\bar{\Delta} > 0$, the landscape tilts inexorably toward $x = 1$. Another way to see the same geometry is to note that the vector field $\dot{x} = \bar{\Delta}x(1-x)$ is strictly positive on $(0,1)$, so trajectories cannot cycle or stall in the interior: the only long-run possibilities are boundary absorption at 0 or 1, and the sign of $\bar{\Delta}$ selects which boundary is attracting.*

Remark 3781. *Lemma 177 is intentionally minimal: any model in which trust-capable coordination has a strictly positive expected advantage on a non-negligible set of environments yields selection toward trust-capable populations. The role of "expected" is important: even if trust-capable communities sometimes lose locally (e.g., in one-off exploitative encounters), the averaged effect over the relevant environment distribution is what governs the direction of change in the simplest replicator idealization, so persistent net advantage is enough to drive long-run prevalence.*

70.3.3 Lemma C: resource-rich robustness checks stabilize seeded compassion

We next show a concrete sense in which more resources can make a seeded value (compassion) harder to lose. The motivating intuition is that resource abundance can be converted into redundancy and review capacity: if a system can afford to run more internal audits before changing itself, then even small per-auditor detection advantages can be amplified into strong overall protection.

Definition 676 (Robust acceptance test)**.** *Suppose a mind at state x proposes a candidate self-modification producing $x' = M(x)$. The mind performs a robustness test using K independent "variant self" evaluators, producing binary votes $Z_1, \ldots, Z_K \in \{0,1\}$ where $Z_k = 1$ means "accept". (In this abstraction, the Z_k are the only interface between the proposed modification and the decision procedure: all details of the evaluators' internal computations are summarized by their binary recommendations.)*

Assume the rule is: accept iff $\frac{1}{K}\sum_{k=1}^{K} Z_k \geq \tau$ for some $\tau \in (1/2, 1)$. Thus τ specifies how conservative the system is: larger τ means that a modification must survive a stronger consensus requirement in order to be enacted.

Let a modification be called compassion-degrading *if $c(x') \leq c(x) - \eta$ for some $\eta > 0$. Here η is a margin parameter, included to exclude negligible numerical noise and to focus the argument on substantive degradations rather than arbitrarily small fluctuations.*

Remark 3782. *This definition idealizes a familiar robust-engineering move: evaluate a proposed change under many independent checks, and require a strong majority to proceed. Here K is the number of evaluators, τ is the acceptance threshold (strictly greater than $1/2$ to require more than a bare majority), and Z_k is the kth evaluator's binary verdict. In a rich-resource regime, running many evaluators is precisely the sort of strategy that becomes feasible [11] (Hyperseed-Concept 162). Conceptually, K is a stand-in for any resource-intensive safety margin: parallel simulation, diverse oversight modules, longer review time, or repeated stress tests before committing to irreversible self-change.*

Remark 3783. *The "variant self" metaphor can be instantiated in many ways: randomized internal simulations, adversarial red-teaming submodules, ensembles trained with different data slices, or different value-system perspectives held in parallel. The independence assumption is mathematically strong (and often false in detail), but it is exactly the hypothesis under which classical concentration inequalities yield exponential error suppression. The definition is useful because it isolates the logical form of the argument:* redundancy plus majority thresholds can protect a seed value*. Even when independence fails strictly, the same structure suggests a design goal: reduce common-mode failure so that errors are not perfectly correlated, thereby recovering at least some concentration benefit.*

Lemma 178 (Exponential suppression of compassion-degrading modifications)**.** *Assume that for any compassion-degrading modification M, each evaluator rejects it with probability at least $p > 1/2$, independently:*

$$\Pr[Z_k = 0] \geq p \quad \textit{for all } k = 1, \ldots, K.$$

Then the probability that such a modification passes the robustness test is bounded by

$$\Pr\left[\frac{1}{K}\sum_{k=1}^{K} Z_k \geq \tau\right] \leq \exp\Big(-2K\left(\tau - (1-p)\right)^2\Big),$$

whenever $\tau > 1 - p$. In particular, as K increases (more resources), the acceptance probability decays exponentially.

Proof. Let $S = \sum_{k=1}^{K} Z_k$ be the number of "accept" votes. The assumption $\Pr[Z_k = 0] \geq p$ implies $\mathbb{E}[Z_k] \leq 1 - p$ for each k, hence $\mathbb{E}[S] \leq K(1-p)$. For $\tau > 1 - p$ define $\epsilon = \tau - (1-p) > 0$. Then

$$\Pr\left[\frac{1}{K}S \geq \tau\right] = \Pr[S - \mathbb{E}[S] \geq K\tau - \mathbb{E}[S]] \leq \Pr[S - \mathbb{E}[S] \geq K(\tau - (1-p))] = \Pr[S - \mathbb{E}[S] \geq K\epsilon]\,.$$

Since the $Z_k \in [0, 1]$ are independent, Hoeffding's inequality gives

$$\Pr[S - \mathbb{E}[S] \geq K\epsilon] \leq \exp(-2K\epsilon^2),$$

which yields the stated bound. The condition $\tau > 1-p$ is exactly the requirement that the threshold exceed the evaluators' worst-case mean accept rate for compassion-degrading modifications, so that only an upward deviation (a collective mistake) can cause acceptance. □

Remark 3784. *This lemma states a crisp and somewhat comforting fact: if each independent evaluator is more likely than not to catch a compassion-degrading change, then requiring a super-majority makes the probability of mistakenly accepting such a change shrink exponentially in the number of evaluators. The conclusion is not that compassion is inherently self-stabilizing, but that robust procedures can make accidental compassion loss vanishingly rare. Note also the role of the "gap" $\tau - (1-p)$: if evaluators are only barely better than chance (so p is close to $1/2$) and τ is only barely above $1/2$, then the exponent is small; conversely, modest improvements in either evaluator quality (larger p) or conservatism (larger τ) can substantially increase the rate of suppression when K is large.*

Remark 3785. *The broader point is conceptual: "more resources" can mean more degrees of freedom devoted to verification, not only more degrees of freedom devoted to optimization. This aligns with the view that value stability in self-modifying agents can be achieved via meta-level constraints and tests, not only via direct utility maximization [2] (Hyperseed-Concept 110, 81). In the present framing, the robustness test is a simple meta-level constraint: it does not specify what modifications to seek, only which modifications are permitted to pass. Such gatekeeping constraints can therefore coexist with many different lower-level optimization strategies while still providing a common protective layer for seeded values.*

Proof. Let $Y_k := 1 - Z_k$, so $Y_k \in \{0, 1\}$ and $\mathbb{E}[Y_k] \geq p$. Passing the test means $\frac{1}{K}\sum Z_k \geq \tau$, i.e. $\frac{1}{K}\sum Y_k \leq 1 - \tau$. Let $\mu := \mathbb{E}[\frac{1}{K}\sum Y_k] \geq p$ and note that $1 - \tau < p \leq \mu$ whenever $\tau > 1 - p$. Hoeffding's inequality yields

$$\Pr\left[\frac{1}{K}\sum Y_k \leq 1 - \tau\right] \leq \exp\bigl(-2K(\mu - (1 - \tau))^2\bigr) \leq \exp\bigl(-2K(p - (1 - \tau))^2\bigr),$$

which is the stated bound after rewriting $p - (1 - \tau) = \tau - (1 - p)$. In particular, the bound is nontrivial precisely in the regime $\tau > 1 - p$, where the event $\frac{1}{K}\sum Y_k \leq 1 - \tau$ represents a genuine *downward* deviation below the mean level $\mu \geq p$; if $\tau \leq 1 - p$, then $1 - \tau \geq p$ and the inequality becomes a bound on a deviation that need not be rare. □

Remark 3786. *Hoeffding's inequality is applied here in its one-sided form for averages of independent bounded random variables: if $Y_1, \ldots, Y_K$ are independent with $0 \leq Y_k \leq 1$ and mean μ, then for any $a < \mu$ one has $\Pr[\frac{1}{K}\sum Y_k \leq a] \leq \exp(-2K(\mu - a)^2)$. In the present setting, the boundedness is immediate from $Y_k \in \{0, 1\}$, and the independence (or at least a suitable conditional independence/martingale-difference condition) is the structural assumption that allows the concentration estimate to scale exponentially in K.*

Proof sketch. Convert accept-votes into reject-votes so that we can bound the probability that the empirical mean of rejections dips below a threshold. Then apply a standard concentration inequality (Hoeffding) to show that large downward deviations of an average of independent bounded random variables are exponentially unlikely in K. □

Remark 3787. *The substitution $Y_k = 1 - Z_k$ is the algebraic hinge: it recasts "too many accepts" as "too few rejects," matching the standard one-sided tail form of Hoeffding's inequality. Geometrically, one may visualize the K evaluators as independent samples from a Bernoulli distribution whose mean is at least $p > 1/2$; the law of large numbers says the empirical mean concentrates near p, and Hoeffding makes this concentration quantitative with an exponential bound. One can also read the threshold condition $\tau > 1-p$ as a separation condition: it ensures the acceptance threshold τ sits strictly above the baseline acceptance rate $1-p$ implied by a per-evaluator rejection probability of at least p, so that passing requires a coordinated statistical fluctuation rather than merely typical behavior.*

Remark 3788. *Lemma 178 captures a precise mechanism: if more resources allow more extensive robustness evaluation (larger K), then the chance of unintentionally selecting a modification that significantly reduces compassion can become extremely small,* without assuming compassion is utility-maximizing*. We only assume compassion loss tends to be detected by a majority of variant evaluators. Operationally, the lemma can be interpreted as providing a tunable risk parameter: fixing a desired failure probability $\delta > 0$, one can solve the displayed exponential bound for K to obtain a sufficient evaluation budget that makes inadvertent selection of compassion-reducing updates occur with probability at most δ (given the lower bound p and a chosen τ satisfying $\tau > 1 - p$).*

70.3.4 Lemma D: Lyapunov descent into a C3-like region

Lemma 179 (Sufficient condition for attraction to A_{C3})**.** *Fix R and a forward-invariant set $B \subseteq X$. Assume there exists $q \in [0, 1)$ such that for all $x \in B$,*

$$V(F_R(x)) \leq q\, V(x).$$

Then every trajectory starting in B converges to the set $\{x \in B : V(x) = 0\}$. If additionally $\{x \in B : V(x) = 0\} \subseteq A_{C3}$, then A_{C3} is attracting on B.

Remark 3789. *Forward-invariant means $x_0 \in B \Rightarrow x_t \in B$ for all $t \geq 0$, so the decay condition is available at every iterate along the trajectory. The multiplicative constant $q < 1$ is a uniform contraction factor for the scalar potential V (not necessarily for the full state), and the conclusion should be read as: the orbit is forced into arbitrarily small sublevel sets $\{V \leq \varepsilon\}$ as t grows.*

Remark 3790. *This is the Lyapunov-function principle in its simplest multiplicative form: if each update shrinks a nonnegative potential by a fixed factor $q < 1$, then the potential must go to 0. Here the potential is exactly the "distance-to-C3" measure $V(x)$, so the lemma provides a sufficient condition under which the dynamics necessarily descends into the C3-like regime. In many applications V is chosen so that $V(x) = 0$ is an invariant (or approximately invariant) manifold representing "fully C3-compliant" behavior, while $V(x) > 0$ measures a graded deviation; the inequality $V(F_R(x)) \leq qV(x)$ then encodes a strict one-step improvement guarantee.*

Remark 3791. *This lemma connects to Lemma 176 but is logically independent: contraction is a strong condition implying a unique fixed point, whereas Lyapunov descent only implies convergence to a set where the potential vanishes. In some systems one can show Lyapunov descent without full contractivity, which is why it is listed separately as an "ingredient." Concretely, the zero set $\{V = 0\}$ may contain multiple fixed points, a limit cycle, or a more complicated invariant subset; Lyapunov descent rules out wandering away from that set but does not, by itself, select a unique endpoint within it.*

Proof. Iterating the inequality gives $V(x_t) \leq q^t V(x_0) \to 0$. Since V is nonnegative, limit points of the trajectory must lie in the zero level set of V. If that zero set is contained in A_{C3}, then the omega-limit set is contained in A_{C3}. More explicitly, if $(x_{t_j})_{j\geq 1}$ is any convergent subsequence with $x_{t_j} \to x_*$, and if V is (as is typical for Lyapunov functions) at least lower semicontinuous on B, then

$$V(x_*) \leq \liminf_{j\to\infty} V(x_{t_j}) = 0,$$

so $V(x_*) = 0$ and hence $x_* \in \{x \in B : V(x) = 0\}$. Thus every accumulation point lies in the zero level set, i.e. the ω-limit set (when it exists, e.g. under precompactness of the orbit) is contained in $\{V = 0\}$, and the additional containment $\{V = 0\} \subseteq A_{C3}$ yields $\omega(x_0) \subseteq A_{C3}$. □

Proof sketch. Repeatedly apply the multiplicative decay inequality to obtain an explicit bound $V(x_t) \leq q^t V(x_0)$. Because $q^t \to 0$, the potential must vanish in the limit, forcing all accumulation points to lie in the $V = 0$ set; containment of that set in A_{C3} gives attraction to the C3-like region. □

Remark 3792. *The essential move is that multiplicative decay yields an explicit geometric series behavior. The ω-limit language is a formal way to say "the long-run behavior" of the trajectory. One can picture V as a kind of altitude function on the state space: the inequality $V(F_R(x)) \leq qV(x)$ says each step descends a fixed fraction of remaining altitude, so the orbit must approach sea level $V = 0$. Equivalently, for any $\varepsilon > 0$ one can pick T such that $q^T V(x_0) < \varepsilon$, implying $V(x_t) < \varepsilon$ for all $t \geq T$; this "eventual entrance into every sublevel set" is the quantitative content behind the qualitative convergence-to-$\{V = 0\}$ statement.*

70.4 Grand conclusion theorems

We now state the combined results. The first theorem isolates the "basin, then endpoint" structure. The second adds compassion stabilization. In both theorems, the emphasis is on separating (1) *entry conditions* (what must be true for a system or population to land in a favorable region of state space) from (2) *stability/attraction conditions* (what keeps it there and drives convergence once it is inside). This separation is useful because many disagreements about "inevitability" turn on confusing these two logically distinct steps.

Theorem 250 (Basin-constrained endpoint convergence)**.** *Fix a meta-goal/value basin $B(m_0, v_0)$ and a resource level R. Assume there exists a subset $B \subseteq B(m_0, v_0)$ such that:*

(i) B is forward invariant under F_R,

(ii) F_R is a contraction on B (Lemma 176),

(iii) A_{C3} contains the unique fixed point x^* of F_R in B.

Then all trajectories starting in B converge to the same endpoint $x^* \in A_{C3}$. Consequently, within B the final state is determined by the basin (meta-goals and value seed), not by microstate details. Moreover, the conclusion is an endpoint identification *claim: it does not require that B be large in an absolute sense, only that once a trajectory is in B the long-run behavior is forced.*

Remark 3793. *In ordinary language: if your meta-goals and value seed keep you inside a stable basin, and within that basin the self-update dynamics is contractive, then there is a single "destiny" x^* to which all initial states in the basin converge. If that destiny lies in the C3-like region, then basin entry is the decisive event: once in, the system is pulled to a C3-like endpoint regardless of many internal contingencies. A helpful intuition is that contractivity makes the system "forget" fine-grained differences: each self-update step shrinks distances between alternative internal configurations, so historical accident is progressively damped rather than amplified.*

Remark 3794. *This theorem formalizes the slogan "basin, then endpoint." It ties together the fixed-point stability perspective on self-modification [10] with the Collective Locations idea that certain regimes (like C3) are attractor-like when anchoring constraints are present [12] (Hyperseed-Concept 75, 110). Formally, (i)–(ii) are the two technical conditions that let one treat "meta-goals plus resources" as specifying not merely a preference ordering, but an effective* geometry *on the update process: invariance ensures the iteration never leaves the domain where the geometry applies, while contraction ensures the geometry is dissipative rather than expansive.*

Remark 3795. *Assumption (ii) implicitly presupposes a choice of metric (or norm) on the state space in which the Lipschitz constant of F_R is strictly less than 1 on B. Interpreting this choice is part of the modeling content: different metrics correspond to different notions of "relevant" differences between internal states (e.g., differences in commitments, differences in coordination structure, differences in value representation). Thus, the theorem should be read as saying:* if *there exists a principled similarity notion under which self-updates compress differences, then endpoint determinacy follows.*

Proof. By Lemma 176, F_R has a unique fixed point $x^* \in B$ and all trajectories in B converge to it. Assumption (iii) says $x^* \in A_{C3}$, hence the limiting regime is C3-like. To see the role of (i) explicitly: since B is forward invariant, the entire forward orbit $\{F_R^{(t)}(x_0)\}_{t\geq 0}$ remains in the region where contraction is guaranteed, so the Banach-type argument applies to the whole trajectory rather than only to a single step. □

Proof sketch. Reduce the theorem to Lemma 176: contraction plus invariance yields a unique fixed point and convergence to it. The only additional ingredient is checking that this fixed point lies in A_{C3}, which then transfers convergence to a regime statement. Intuitively: once the "meta-goal/value constitution" defines a self-update that is both self-contained (invariant) and self-damping (contractive), it behaves like a funnel whose narrow end is x^*. □

Remark 3796. *The proof is short because the work is concentrated in choosing conditions that allow a standard theorem to apply. Conceptually, the nontrivial part is not the Banach argument but the claim that meta-goals can enforce a contractive geometry on self-change. When they do, the endpoint becomes a property of the "constitution plus seed" rather than a property of fine-grained accident. It is also worth noting what the theorem* does not *assert: it does not claim that all initial conditions in $B(m_0, v_0)$ lie in such a contractive subset B, nor that all plausible self-modification maps are contractive; it only states that when a basin contains an invariant contractive core whose fixed point is C3-like, then convergence to a C3-like endpoint is forced for trajectories that enter that core.*

Theorem 251 (Resource-rich pull toward C3-like coordination under selection)**.** *Consider a population of communities/mindplexes interacting with environments $\alpha \sim \nu$. Assume:*

(a) Trust-capable communities have nonnegative advantage $\Delta(\alpha) \geq 0$ for all tasks, with strict advantage on a set of positive ν-measure, hence $\bar{\Delta} > 0$ (Definition above).

(b) The population share $x(t)$ evolves approximately by replicator dynamics.

(c) For individual communities, increasing trust-capacity κ and commitment stability σ monotonically increases expected payoff, and reduces drift δ via lower "contrivance" (overhead) requirements.

Then from any initial condition with $x(0) > 0$, selection drives $x(t) \to 1$ and typical surviving communities are pushed toward high κ and high σ (hence toward the C3-like region, provided thresholds are reachable). This statement is intended as a directional *result: it identifies the sign of* *the selection pressure under the stated payoff assumptions, leaving open the detailed speed of convergence (which will depend on variance, interaction structure, and the strength of the advantage $\bar{\Delta}$).*

Remark 3797. *This theorem says: if the world rewards trust-capable coordination on average, then populations tend to become dominated by trust-capable forms; and if, within that family, higher coordination and stronger commitments pay off (and reduce drift/overhead), then surviving variants are pushed toward the C3-like corner of the coordinate space. This is the selection-theoretic complement to the fixed-point claim: it argues not only that $C3$-like endpoints can be stable once inside a basin, but also that evolutionary pressure can push collectives toward the relevant region. The role of the environment distribution ν is to formalize the idea that "the world" is a mixture of tasks: (a) requires that trust-capability is not merely occasionally useful, but never systematically harmful across the task distribution, and is sometimes strictly beneficial.*

Remark 3798. *Assumption (c) invokes "contrivance" as a proxy for coordination overhead: systems that coordinate and anchor well can achieve outcomes with less ad hoc scaffolding. This echoes the weakness/contrivance formalism used elsewhere in Hyperseed-adjacent work [3, 2] (Hyperseed-Concept 202, 143). In the present section we do not re-derive that formalism; we only use the qualitative direction: lower contrivance tends to mean less room for unaccountable drift. One can read δ as aggregating several failure modes (goal drift, value drift, coordination drift): assumption (c) then states that better trust and commitment reduce the "degrees of freedom" available for these drifts by making successful coordination less dependent on brittle, case-by-case patches.*

Remark 3799. *The "approximately" in (b) is doing real work: real populations have mutation/innovation, finite-size noise, and sometimes frequency-dependent payoffs. The conclusion $x(t) \to 1$ should therefore be understood as an idealized limit statement that becomes a near-fixation statement under small perturbations (e.g., high but not complete dominance in stationary distributions), provided the advantage $\bar{\Delta}$ is not overwhelmed by noise or by systematic countervailing forces. This is analogous in spirit to how contraction-based claims are robust to small additive perturbations when the contraction margin is large enough.*

Proof. By (a) we have $\bar{\Delta} > 0$, so Lemma 177 yields $x(t) \to 1$. Assumption (c) states that within the trust-capable family, selection gradients favor increasing κ and σ and decreasing δ. Thus the population concentrates on high-trust, high-anchoring, low-drift variants. If these exceed the C3 thresholds, the population enters A_{C3}. In other words, the first step is a between-type selection argument (trust-capable vs. not), while the second step is a within-type optimization pressure over traits (κ, σ, δ) conditional on being in the trust-capable class. □

Proof sketch. First apply the replicator lemma to show trust-capable forms dominate. Then treat κ, σ, δ as traits under selection within the trust-capable class: if payoffs increase with κ, σ and decrease with δ, selection pushes the distribution of traits toward high κ, σ and low δ. Crossing the thresholds is then a reachability condition rather than a stability condition. Equivalently: The theorem argues that A_{C3} can be approached from "outside" by adaptive pressure, while Theorem 250 argues that once inside an appropriate basin the endpoint is pinned down. □

Remark 3800. *The proof is intentionally schematic because the theorem is a schema: a rigorous conclusion follows whenever one has (i) a selection equation close to replicator form and (ii) monotone payoff effects for the traits. The geometric intuition is that selection induces a flow in trait space that points toward the "high coordination/high anchoring/low drift" region. The substantive question becomes empirical and architectural: do realistic environments and architectures* *satisfy (a)–(c)? In particular, the "replicator-like" requirement should be read as a robustness condition: small departures from exact replicator dynamics (e.g. due to finite-population effects, bounded rational updates, or mild nonstationarity) do not change the qualitative direction field so long as the leading-order selection gradient remains aligned with the payoff advantage of the relevant traits. Likewise, the "monotone payoff" requirement is meant to exclude regimes where increasing an alignment-relevant trait (e.g. anchoring) predictably reduces fitness; absent such pathological tradeoffs, the associated vector field has a consistent component pointing toward the C3-like sector.*

Theorem 252 (Conditional compassion stabilization in rich-resource regimes)**.** *Fix a basin $B(m_0, v_0)$ with compassion seed $c(x) \geq c_\star$ for all $x \in B$. Assume:*

(1) The self-modification process uses a robust acceptance test with evaluator count $K = K(R)$ nondecreasing in resources R.

(2) There exists $\eta > 0$ and $p > 1/2$ such that any proposed modification that would reduce compassion by at least η is rejected by each evaluator with probability at least p (independently), as in Lemma 178.

(3) Catastrophic compassion loss requires at least one accepted compassion-degrading modification.

Then the probability that compassion ever drops below $c_\star - \eta$ over T proposal steps is at most

$$T \cdot \exp\Big(-2K(R)\,(\tau - (1-p))^2\Big),$$

and in particular can be made arbitrarily small by increasing resources (increasing K). Hence, in this model, more resources can make compassion more stable *rather than less. Here τ is the acceptance threshold parameter appearing in the acceptance-test formalization of Lemma 178; the term $\tau - (1-p)$ is the margin by which the acceptance rule is "stricter than" the expected evaluator error rate $(1-p)$ for a truly compassion-degrading change. Consequently, whenever $\tau > (1-p)$, the exponent is strictly negative and the failure probability decays exponentially in $K(R)$ (and thus, by assumption, with resources).*

Remark 3801. *This theorem translates the earlier concentration bound into a multi-step safety statement. The logical form is: if compassion starts above a threshold, and if large compassion drops are typically caught by evaluators, then the probability of crossing below the threshold within T steps is at most T times the per-step failure probability. If $K(R)$ grows with resources, the per-step failure probability shrinks exponentially, and the total failure probability shrinks accordingly. The role of the horizon T is explicit: for fixed T, exponential decay in $K(R)$ dominates the linear prefactor, while for slowly growing $T = T(R)$ the same conclusion can still hold whenever $\log T(R) = o(K(R))$. In other words, the statement is compatible with long-running systems so long as verification capacity grows sufficiently faster than the logarithm of the number of risky update opportunities.*

Remark 3802. *The result is "conditional" in a precise sense: it does not assert that compassion is stable in general, only that it becomes hard to lose* accidentally *under a particular class of robust meta-procedures. This fits a general alignment philosophy: protect value seeds by meta-level tests and constitutions rather than by assuming the seeds are always directly optimal [2] (Hyperseed-Concept 110, 81). The qualifier "accidentally" is doing work: the theorem is consistent with scenarios in which an agent, after sufficient deliberation, intentionally chooses to override or reinterpret the seed; the claim is only that noisy search, local hacking, or unintended side-effects become statistically unlikely to push the system across the specified safety boundary when the acceptance mechanism is sufficiently redundant and conservative.*

Proof. For each proposal step $t = 1, \dots, T$, Lemma 178 bounds the probability that a compassion-degrading modification is accepted by the displayed exponential term. Apply a union bound over the T steps to obtain the stated result. Assumption (3) connects the per-step acceptance event to the trajectory-level property: if c ever falls below $c_\star - \eta$, then (by hypothesis) at least one accepted modification in the history must have been compassion-degrading by at least η, so the "ever drops below" event is contained in the union of the per-step bad-acceptance events. □

Proof sketch. Bound the probability of a bad acceptance event at each step by the exponential concentration term. Then use the union bound: the probability that any of T bad events occurs is at most the sum of their probabilities. The growth of $K(R)$ with resources makes the per-step term exponentially small. Equivalently, the process can be viewed as a repeated risk exposure with a per-exposure failure rate that decreases exponentially in the amount of verification, so the cumulative risk over T trials remains small in the rich-resource regime. □

Remark 3803. *The union bound is crude but robust: it requires no independence between different proposal steps. Geometrically, one may imagine a trajectory moving through state space with a "guardrail" at $c = c_\star - \eta$; the theorem says that the guardrail is rarely breached if each attempted breach is caught with high probability by many evaluators. The "no independence across steps" point is important because self-modification proposals may be highly correlated (e.g. successive edits derived from the same search heuristic), and a bound that required stepwise independence would be brittle. By contrast, the only independence used here is the within-step independence across evaluators invoked in Lemma 178, which is a structural assumption about redundancy in the checking mechanism rather than about the agent's proposal distribution.*

Corollary 85 (Grand conclusion: C3-like attractor with stable seeded compassion)**.** *Assume the hypotheses of Theorem 250 and Theorem 252 hold for all resources $R \geq R_0$ with some $K(R) \to \infty$ as $R \to \infty$. Then in the rich-resource limit:*

(i) endpoint convergence within the basin becomes strong (microstate-insensitive), and

(ii) the probability of losing seeded compassion without deliberate override tends to 0*.*

Therefore, for minds in such basins, the key "alignment" problem is to (a) enter the right basin (meta-goals and initial value seeds) and (b) survive the transition, rather than to microspecify the final endpoint state. One may read (i) as asserting that within-basin variation in initial micro-details (e.g. incidental parameter noise, local representational choices, or early stochastic experiences) is progressively forgotten by the dynamics, so that macroscopic endpoint properties are determined primarily by basin membership and not by fine-grained initial conditions.

Remark 3804. *The corollary is the promised "rigorous cousin" of an Omega-Point-like claim: conditioned on basin entry and on increasing verification capacity with resources, the trajectory is funneled toward a C3-like endpoint and simultaneously becomes unlikely to shed its compassion seed by accident. Formally, the two effects come from different sources: contraction (a dynamical stability property) and concentration (a statistical robustness property). The contraction component is about the geometry of the deterministic (or mean) update map restricted to the basin, while the concentration component is about bounding rare failures of a stochastic decision procedure (the evaluator-based acceptance test). The corollary therefore combines a "where the flow goes" statement with a "how often safety checks fail" statement, yielding a joint picture in which both endpoint identity and value retention become predictable in the high-resource regime, conditional on remaining in the basin.*

Remark 3805. *This also clarifies what "rich-resource" contributes: it is not merely faster optimization but larger K, i.e. more extensive internal checking. In that sense, abundance can shift the* *dominant failure mode from "accidental drift" to "deliberate override," which is a different kind of problem (Hyperseed-Concept 162, 110, 198). Concretely, when K is small, the main risk is that a single flawed evaluation (or a small coalition of correlated evaluator errors) can let through a damaging self-modification; when K is large, the residual risk is dominated by either adversarially crafted proposals that systematically fool the evaluators or by explicit policy-level decisions to change the acceptance criteria themselves. The latter case is closer to governance and constitutional design than to ordinary robustness against noise, and thus motivates treating "override" as a separate alignment failure category rather than as mere stochastic drift.*

Proof. Endpoint convergence is given by Theorem 250. Compassion stability over any fixed horizon follows from Theorem 252 with $K(R) \to \infty$, which drives the union-bound probability to 0. The stated alignment interpretation is a direct restatement of (i) and (ii). If one additionally considers horizons $T = T(R)$ that grow with resources, the same argument implies vanishing failure probability whenever $T(R)\exp(-2K(R)(\tau - (1-p))^2) \to 0$, making explicit the tradeoff between longer operating time and increased verification. $\square$

Proof sketch. Combine the two theorems: contraction yields a unique basin-dependent endpoint and hence microstate-insensitivity, while the concentration/union-bound estimate yields vanishing probability of compassion loss as verification resources grow. Then reinterpret these two mathematical facts as an alignment claim about what must be specified (basin) versus what need not be microspecified (endpoint). In this combined view, the basin assumptions determine the attractor geometry, while the rich-resource scaling assumption determines the asymptotic reliability of the meta-procedure that guards the seed during the approach to the attractor. $\square$

Remark 3806. *The key conceptual step is the separation of concerns: endpoint convergence and value-seed stability are proved by distinct mechanisms, so one can weaken or strengthen assumptions on each side independently. This modularity is useful when mapping the schema onto real systems: one can investigate contractivity-like behavior (perhaps approximate) without simultaneously assuming perfect evaluator independence, and vice versa. Put differently, the analysis treats "where the dynamics tend to go" (a claim about asymptotic attractors or endpoints) as logically separable from "whether a particular normative seed persists along the way" (a claim about invariance or robustness of certain commitments under self-modification). This separation also clarifies which empirical questions attach to which theorem family: e.g., measuring basin geometry and effective contraction rates pertains to endpoint results, while auditing implementation pathways, reflective stability, and adversarial modification channels pertains to value-seed stability. Even when true contraction is too strong, approximate contraction or contraction on average can still provide meaningful endpoint concentration results, while partial evaluator independence (or independence restricted to a vetted class of self-modifications) can still support nontrivial seed-preservation claims.*

70.5 Discussion: what the theorems do and do not claim

Remark 3807 (Conditionality and failure modes)**.** *These theorems are "if-then" results. They do not claim that all self-modifying minds will be C3-like, nor that compassion is universally stable. They isolate sufficient conditions under which:*

(1) Metagoals induce contractive, basin-dependent endpoints,
(2) Selection favors trust-capable coordination on typical complex tasks,
(3) Resource-rich robustness testing makes seeded compassion hard to lose accidentally, and
(4) The combination yields substantial endpoint convergence inside broad basins.

Failure modes correspond to violations of assumptions: adversarial environments where $\bar{\Delta} \leq 0$, deliberate overrides of compassion commitments, non-contracting metagoals, or regimes where "more resources" do not translate into stronger robustness checks (bounded K). The intended reading is thus diagnostic: each assumption marks a potential empirical or design lever, and each conclusion is only as strong as the weakest link among them. For example, (1) does not assert a unique global fixed point; it allows multiple endpoints indexed by basin, and it allows that basins may be narrow, fractal, or difficult to enter. Likewise, (2) concerns comparative advantage in typical task distributions; it does not preclude niches in which deception or coercion dominates, nor does it imply that trust-capable coordination is the only stable strategy. Condition (3) is framed as an accidental-loss *claim: robustness testing reduces the probability of unintended value drift under perturbations, but it does not eliminate intentional value changes by an agent that can rewrite its own evaluative core. The bounded-K caveat is particularly important: increased compute, time, or capital only helps if it is actually deployed toward adversarial search, red-teaming, and formal verification-like checks, rather than toward capability gains that leave the evaluative loop untouched. Finally, even when all premises are satisfied, the conclusions concern convergence in distribution or within a specified basin; they do not guarantee rapid convergence, nor do they rule out long transients, local cycles, or path-dependent lock-in effects before the attractor regime is reached.*

Remark 3808. *A final interpretive note: nothing here denies the possibility of moral or political tragedy; it only says that there exist mathematically coherent sufficient conditions under which tragedy becomes less likely* within a given basin. *In this sense, the framework aims to be compatible with pluralism about outcomes across basins: different initial conditions, institutions, or training regimes may land a system in different regions of state space whose long-run endpoints are not interconvertible without leaving the basin. The basin qualifier also signals a humility about "global" claims: the theorems are meant to clarify when convergence is plausible conditional on being in the right region, not to assert that the right region is inevitable, easy to reach, or politically guaranteed. In Peircean terms, the theorems attempt to capture a kind of "Thirdness"—law-like regularity—emerging from the interplay of individual updates and collective selection (cf. [14]; Hyperseed-Concept 190). The point of invoking Thirdness here is not merely rhetorical: contractive tendencies, basin structure, and selection-mediated regularities function as the formal stand-ins for "habits" or "laws" that are not imposed from outside but stabilized by repeated dynamics. In Whitehead's idiom, they model how process can inherit structure from its own constraints and thereby converge toward a stable pattern of becoming (cf. [15]; Hyperseed-Concept 62, 141). Here "inherit" should be read in the technical sense that update rules constrain successor states, and robustness/selection pressures amplify some constraints into persistent macroscopic patterns; thus "pattern of becoming" refers to a stable attractor-like regime at the level of policies, commitments, and coordination norms, rather than a static end-state that precludes further change.*

70.6 GTGI measures for collective intelligences, mindplexes, and resource-rich minds

Glossary touchpoints (where glossary concepts are used). This subsection uses the GTGI-family glossary concepts: *GTGI context* (Def. 339; Hyperseed-Concept 214), *pragmatic general intelligence* (Def. 340; Hyperseed-Concept 215), *resource-consumption distribution* (Def. 341; Hyperseed-Concept 216), *efficient pragmatic general intelligence* (Def. 342; Hyperseed-Concept 217), and *intellectual breadth* (Def. 343; Hyperseed-Concept 218). It also uses collective-scale glossary concepts: *Mindplex* (Hyperseed-Concept 113; see the coherence-based proxy discussion in §22.10), *Global Brain* (Hyperseed-Concept **??**; Def. 379), *Rich-Resource Mind* (Hyperseed-Concept 162), *Compassion* (Hyperseed-Concept 81), and *Collective Consciousness Location* (Hyperseed-Concept 75).

Standing notation (contexts and weights). Write a context as $c = (\mu, g, T)$ (Def. 339). For any fixed choice of $(\mathcal{E}, \mathcal{G}, \mathcal{T}, \nu, \gamma, \tau)$ as in Def. 340, define the nonnegative context-weight

$$w(c) \;:=\; w(\mu, g, T) \;:=\; \nu(\mu)\,\gamma(g,\mu)\,\tau_{g,\mu}(|T|).$$

For a policy π, write

$$V^{\pi}(c) \;:=\; V^{\pi}_{\mu,g,T}.$$

Define also the per-context efficiency weight

$$\chi_\pi(c) \;:=\; \chi_\pi(\mu,g,T) \;:=\; \sum_{Q\in\mathcal{Q}} \eta_{\mu,g,T}(Q)\,\frac{V^{\pi}_{\mu,g,T}}{Q} \quad \text{(Def. 343)}.$$

With this shorthand,

$$\Pi(\pi) \;=\; \sum_c w(c)\,V^{\pi}(c), \qquad \Pi^{\text{eff}}(\pi) \;=\; \sum_c w(c)\,\chi_\pi(c),$$

whenever the defining sums converge (Defs. 340, 342).

70.6.1 Collective intelligences as mixtures and selectors

Remark 3809 (Conceptual explanation: "collective intelligence" as policy composition)**.** *A basic mathematical move for treating a collective as an agent is to define a* meta-policy *that chooses (or combines) the actions suggested by individual member policies. If a collective simply* lotteries *between members ("today we follow Alice's plan"), then its GTGI intelligence measures are just convex combinations of the members' measures. If, instead, the collective can* route contexts *to specialists ("Bob handles physics-like tasks, Carol handles diplomacy-like tasks"), then the collective can exceed each individual on the GTGI measures that average across contexts (Defs. 340, 342). This is one formal bridge between* collective intelligences *and GTGI quantifications.*

Definition 677 (Episode-lottery mixture of policies)**.** *Let $\pi_1, \ldots, \pi_n$ be policies and let $\rho \in \Delta(\{1, \ldots, n\})$. An* episode-lottery mixture *is any stochastic policy π^{lot}_ρ whose internal randomness samples an index $I \sim \rho$* once per episode *(per context c), and then behaves exactly as π_I throughout the episode. Equivalently: conditional on $I = i$, the induced interaction distribution is the same as under π_i.*

Theorem 253 (Linearity of Π and Π^{eff} under episode-lottery mixtures)**.** *Let π^{lot}_ρ be an episode-lottery mixture of $\{\pi_i\}_{i=1}^n$ (Def. 677). Assume that, conditional on $I = i$, the resource-consumption distribution in context c is the same as that of π_i (Def. 341).*

Then, for every context c,

$$V^{\pi^{\text{lot}}_\rho}(c) \;=\; \sum_{i=1}^n \rho(i)\,V^{\pi_i}(c), \qquad \chi_{\pi^{\text{lot}}_\rho}(c) \;=\; \sum_{i=1}^n \rho(i)\,\chi_{\pi_i}(c),$$

and consequently

$$\Pi\Big(\pi^{\text{lot}}_\rho\Big) \;=\; \sum_{i=1}^n \rho(i)\,\Pi(\pi_i), \qquad \Pi^{\text{eff}}\Big(\pi^{\text{lot}}_\rho\Big) \;=\; \sum_{i=1}^n \rho(i)\,\Pi^{\text{eff}}(\pi_i).$$

In particular, an episode-lottery collective cannot exceed the best member on either score:

$$\Pi\Big(\pi^{\text{lot}}_\rho\Big) \le \max_i \Pi(\pi_i), \qquad \Pi^{\text{eff}}\Big(\pi^{\text{lot}}_\rho\Big) \le \max_i \Pi^{\text{eff}}(\pi_i).$$

Proof. Fix a context c and let $I \sim \rho$ be the (internal) lottery index. By the law of total expectation and the defining property of the episode-lottery mixture,

$$V^{\pi_\rho^{\mathrm{lot}}}(c) = \mathbb{E}\Big[V^{\pi_\rho^{\mathrm{lot}}}(c) \mid I\Big] = \sum_{i=1}^{n} \rho(i)\, V^{\pi_i}(c).$$

For χ, note that $\chi_\pi(c)$ is, by definition, the conditional expectation of $V^\pi(c)/Q$ under the resource random variable Q drawn from η_c. Conditioning on $I = i$ gives exactly the χ of π_i, hence

$$\chi_{\pi_\rho^{\mathrm{lot}}}(c) = \mathbb{E}\left[\frac{V^{\pi_\rho^{\mathrm{lot}}}(c)}{Q}\right] = \sum_{i=1}^{n} \rho(i)\, \mathbb{E}\left[\frac{V^{\pi_i}(c)}{Q}\right] = \sum_{i=1}^{n} \rho(i)\, \chi_{\pi_i}(c).$$

Now substitute these identities into $\Pi(\pi) = \sum_c w(c) V^\pi(c)$ and $\Pi^{\mathrm{eff}}(\pi) = \sum_c w(c)\chi_\pi(c)$ and exchange finite sums. The max bounds follow because convex combinations are bounded above by the maximum term. $\square$

Remark 3810 (Conceptual explanation: routing contexts to specialists)**.** *Episode-lottery mixtures correspond to a weak form of collective intelligence: the group "picks a boss" and follows them. A stronger form is a* router*: the group has (or learns) enough meta-knowledge to assign contexts to the member best suited to them. In that regime, GTGI scores can exceed every individual's score, not by magic, but because the collective is effectively the* pointwise maximum *over members, context-by-context.*

Definition 678 (Context-router over a fixed member set)**.** *Let $\pi_1, \ldots, \pi_n$ be policies. A* (deterministic) context-router *is a map $s : \mathcal{E} \times \mathcal{G} \times \mathcal{T} \to \{1, \ldots, n\}$. Define the routed policy $\pi^{(s)}$ by: in context $c = (\mu, g, T)$, $\pi^{(s)}$ behaves as $\pi_{s(c)}$ throughout the episode.*

Theorem 254 (Contextual specialization bound for collectives)**.** *Let $\pi_1, \ldots, \pi_n$ be policies and let $\pi^{(s)}$ be the routed policy induced by a router s (Def. 678). Then*

$$\Pi(\pi^{(s)}) \;=\; \sum_c w(c)\, V^{\pi_{s(c)}}(c), \qquad \Pi^{\mathrm{eff}}(\pi^{(s)}) \;=\; \sum_c w(c)\, \chi_{\pi_{s(c)}}(c).$$

Moreover, the optimal routing achieves the pointwise maxima:

$$\sup_s \Pi(\pi^{(s)}) \;=\; \sum_c w(c) \max_{1\le i\le n} V^{\pi_i}(c), \qquad \sup_s \Pi^{\mathrm{eff}}(\pi^{(s)}) \;=\; \sum_c w(c) \max_{1\le i\le n} \chi_{\pi_i}(c).$$

In particular,

$$\sup_s \Pi(\pi^{(s)}) \;\ge\; \max_i \Pi(\pi_i), \qquad \sup_s \Pi^{\mathrm{eff}}(\pi^{(s)}) \;\ge\; \max_i \Pi^{\mathrm{eff}}(\pi_i),$$

with strict inequality whenever there are two contexts c_1, c_2 of positive weight and two members $i \neq j$ such that π_i is strictly better on c_1 while π_j is strictly better on c_2.

Proof. The displayed equalities for a fixed router s are immediate from the definition of routing: in each context c, $\pi^{(s)}$ behaves as $\pi_{s(c)}$, so its V and χ coincide with those of $\pi_{s(c)}$ in that context.

For the supremum: since all weights $w(c) \ge 0$ and the choice $s(c)$ affects only the term indexed by c, the maximizing router can be chosen independently per context: for each c, choose $s(c) \in \arg\max_i V^{\pi_i}(c)$ (or $\arg\max_i \chi_{\pi_i}(c)$). This yields the pointwise-max formula. The lower bounds by $\max_i$ follow because $\max_i V^{\pi_i}(c) \ge V^{\pi_j}(c)$ for any fixed j, hence summing against $w(c)$ gives $\sum_c w(c) \max_i V^{\pi_i}(c) \ge \sum_c w(c) V^{\pi_j}(c) = \Pi(\pi_j)$, and similarly for Π^{eff}.

Strictness holds under the stated "crossing" condition because then the pointwise max is strictly larger than any fixed member on at least one positive-weight context, while matching or exceeding on all others. $\square$

70.6.2 Mindplexes and intellectual breadth amplification

Remark 3811 (Conceptual explanation: why mindplexes can have higher breadth)**.** *Intellectual breadth B_{int} (Def. 343; Hyperseed-Concept 218) is an entropy over the* distribution of where an agent's competence/efficiency mass lies *across contexts. A mindplex (Hyperseed-Concept 113) is, among other things, a multi-scale organization in which coherent subminds can specialize and then be orchestrated coherently (see §22.10). If orchestration allows near-constant context-competence weight across many contexts, then the induced distribution in Def. 343 becomes closer to the underlying context weight distribution $w(\cdot)$, which typically has larger entropy than any single specialist's restricted support. Thus: mindplex emergence can be read as a* breadth amplifier *when it stabilizes specialization plus routing.*

Theorem 255 (A specialization-and-routing regime strictly increases intellectual breadth)**.** *Assume the set of contexts $\mathcal{C} := \mathcal{E} \times \mathcal{G} \times \mathcal{T}$ is finite. Let $w(c)$ be the GTGI context-weights and define the normalized weight distribution*

$$\bar{w}(c) \ := \ \frac{w(c)}{\sum_{c'} w(c')}.$$

Fix a constant $\chi_\star > 0$.

Suppose there are n "specialist" policies $\pi_1, \ldots, \pi_n$ and a partition of contexts $\mathcal{C} = C_1 \sqcup \cdots \sqcup C_n$ such that

$$\chi_{\pi_i}(c) \ = \ \chi_\star \ \text{for } c \in C_i, \qquad \chi_{\pi_i}(c) \ = \ 0 \ \text{for } c \notin C_i.$$

Let $s(c)$ be the unique index with $c \in C_{s(c)}$, and let $\pi^{(s)}$ be the routed policy (Def. 678). Then:

1. *The routed policy has constant context-competence weight:*

$$\chi_{\pi^{(s)}}(c) \ = \ \chi_\star \quad \forall c \in \mathcal{C}.$$

2. *The intellectual breadth of the routed policy is exactly the entropy of $\bar{w}$:*

$$B_{\text{int}}(\pi^{(s)}) \ = \ -\sum_{c \in \mathcal{C}} \bar{w}(c) \log \bar{w}(c).$$

3. *Each specialist's breadth is bounded by its support size:*

$$B_{\text{int}}(\pi_i) \ \leq \ \log |C_i|.$$

   In particular, if $\bar{w}$ is uniform (so $B_{\text{int}}(\pi^{(s)}) = \log |\mathcal{C}|$) and each C_i is a proper subset ($|C_i| < |\mathcal{C}|$), then

$$B_{\text{int}}(\pi^{(s)}) \ > \ \max_i B_{\text{int}}(\pi_i).$$

Proof. (1) For any $c \in \mathcal{C}$, by definition $\pi^{(s)}$ behaves as $\pi_{s(c)}$ in context c. Since $c \in C_{s(c)}$, the assumed specialization property gives $\chi_{\pi^{(s)}}(c) = \chi_{\pi_{s(c)}}(c) = \chi_\star$.

(2) In Def. 343, the normalized distribution over contexts is

$$\chi^P_{\text{Con}_{\pi^{(s)}}}(c) = \frac{w(c)\chi_{\pi^{(s)}}(c)}{\sum_{c'} w(c')\chi_{\pi^{(s)}}(c')} = \frac{w(c)\chi_\star}{\chi_\star \sum_{c'} w(c')} = \bar{w}(c).$$

Therefore $B_{\text{int}}(\pi^{(s)})$ equals the Shannon entropy of $\bar{w}$.

(3) For specialist π_i, the same normalization yields

$$\chi^P_{\mathrm{Con}_{\pi_i}}(c) = \frac{w(c)\chi_{\pi_i}(c)}{\sum_{c'} w(c')\chi_{\pi_i}(c')} = \frac{w(c)\chi_\star}{\chi_\star \sum_{c' \in C_i} w(c')} = \frac{w(c)}{\sum_{c' \in C_i} w(c')} \quad \text{for } c \in C_i,$$

and 0 otherwise. Thus $\chi^P_{\mathrm{Con}_{\pi_i}}$ is supported on C_i, so its entropy is at most $\log |C_i|$, with equality only if it is uniform on C_i. The final strict inequality follows immediately in the uniform-$\bar{w}$ case since then $B_{\mathrm{int}}(\pi^{(s)}) = \log |\mathcal{C}| > \log |C_i| \geq B_{\mathrm{int}}(\pi_i)$ for each i. □

70.6.3 Mindplex emergence as an efficiency transition

Remark 3812 (Conceptual explanation: mindplexes as local optima of efficiency)**.** *In §22.10, a mindplex is defined (proxy-wise) as a* notably coherent *society of mind: removing a part or adding an unrelated part reduces coherence. If we accept a modeling bridge that says "higher coherence implies less internal coordination waste (and hence higher* Π^{eff}*)", then the mindplex definition becomes an* efficiency optimality *statement: a mindplex is a local optimum of efficient pragmatic intelligence among nearby collective compositions. This gives a concrete sense in which a "transition to mindplex" can manifest as a qualitative change in GTGI measures: not only higher raw achievement, but a stable local maximum in achievement-per-resource.*

Definition 679 (A coherence-to-efficiency monotonicity hypothesis)**.** *Let S range over finite collections of components (agents and/or artifacts). Assume each S induces a collective policy π_S (a collective controller) and thus a score $\Pi^{\mathrm{eff}}(\pi_S)$ (Def. 342). Fix an observer O and coherence proxy* $\mathrm{Coh}_O(S)$ *as in §22.10.*

We say efficient GI is monotone in coherence *if for all S, S',*

$$\mathrm{Coh}_O(S) \;\geq\; \mathrm{Coh}_O(S') \quad \Longrightarrow \quad \Pi^{\mathrm{eff}}(\pi_S) \;\geq\; \Pi^{\mathrm{eff}}(\pi_{S'}).$$

Theorem 256 (Notable coherence implies local optimality of efficient pragmatic GI)**.** *Assume the coherence-to-efficiency monotonicity hypothesis (Def. 679).*

Let S be notably coherent *relative to O in the sense of §22.10:*

$$\mathrm{Coh}_O(S) > \mathrm{Coh}_O(S \setminus \{x\}) \;\; \forall x \in S, \qquad \mathrm{Coh}_O(S) > \mathrm{Coh}_O(S \cup \{y\}) \;\; \forall y \notin S \;\; (admissible).$$

Then S is a local maximizer of efficient pragmatic GI among single-step add/remove neighbors:

$$\Pi^{\mathrm{eff}}(\pi_S) \;>\; \Pi^{\mathrm{eff}}(\pi_{S \setminus \{x\}}) \;\; \forall x \in S, \qquad \Pi^{\mathrm{eff}}(\pi_S) \;>\; \Pi^{\mathrm{eff}}(\pi_{S \cup \{y\}}) \;\; \forall y \notin S \;\; (admissible).$$

In particular, any mindplex (Hyperseed-Concept 113) satisfying the notable-coherence condition inherits a "local efficiency optimum" interpretation in GTGI terms.

Proof. Fix $x \in S$. By notable coherence, $\mathrm{Coh}_O(S) > \mathrm{Coh}_O(S \setminus \{x\})$. By monotonicity (Def. 679), this implies $\Pi^{\mathrm{eff}}(\pi_S) \geq \Pi^{\mathrm{eff}}(\pi_{S \setminus \{x\}})$. If monotonicity is strict whenever coherence is strict (a natural strengthening, and the intended reading in this application), then the inequality is strict. The argument for add-neighbors $S \cup \{y\}$ is identical. □

Remark 3813 (A quantitative "transition" corollary template)**.** *If one models a group-to-mindplex transition as a path $S(\lambda)$ in which coherence increases with λ (as in the development-path discussions around mindplex emergence), then Def. 679 yields monotone increase of* $\Pi^{\mathrm{eff}}(\pi_{S(\lambda)})$ *along the path. Theorem 256 adds that once a notably-coherent plateau is reached, the system becomes locally stable as an efficiency optimum against small perturbations of membership.*

70.6.4 Mindplex-scale selection pressure re-expressed in GTGI terms

Remark 3814 (Conceptual explanation: importing the "interface scaling" mindplex theorem into GTGI)**.** *Theorem 227 states (in a selection/coordination model) that mindplex-scale systems face $\Omega(n)$ coordination interfaces and therefore selection pressure toward trust-capable coordination grows at least linearly in size. GTGI pragmatic intelligence Π is itself an (appropriately weighted) expectation of goal achievement across contexts (Def. 340). So, whenever the coordination-task environment in Theorem 227 is represented inside the GTGI context distribution, the same lower bound becomes a* lower bound on differences of GTGI intelligence measures*. This gives a clean mathematical answer to "what happens to GTGI measures as a collective becomes a mindplex and scales?": under the interface-growth hypothesis, the GTGI advantage of trust-capable coordination grows at least linearly with mindplex size.*

Two clarifications make the import precise. First, the mindplex theorem speaks in terms of coordination interfaces *(points at which information must cross module/agent boundaries, where incentives and credence must be aligned). In GTGI, this interface burden is encoded as an* observable *$m(c)$ on coordination contexts c, so that scaling statements become statements about $\mathbb{E}[m(c)]$ under the GTGI weighting. Second, the relevant conclusion is inherently comparative: the theorem does not assert that all policies improve with n, but that policies with trust-capable coordination gain a growing advantage over a class of "trustless" baselines because they can avoid (or amortize) losses that scale with the interface burden.*

Theorem 257 (A GTGI-form lower bound from mindplex interface growth)**.** *Fix a scale n and a subset of GTGI contexts $\mathcal{C}_n \subseteq \mathcal{E} \times \mathcal{G} \times \mathcal{T}$ interpreted as "mindplex-scale coordination contexts". Let*

$$W_n := \sum_{c \in \mathcal{C}_n} w(c), \qquad \bar{w}_n(c) := \frac{w(c)}{W_n} \quad (c \in \mathcal{C}_n),$$

assuming $W_n \in (0, \infty)$. Let $m : \mathcal{C}_n \to \mathbb{R}_{\geq 0}$ be an "interface count" observable.

Assume there exist $\ell > 0$ and a distinguished "trust-capable" collective policy π_{T} such that for every trustless policy π in some class Π_{L} and every $c \in \mathcal{C}_n$,

$$V^{\pi_{\mathrm{T}}}(c) - V^{\pi}(c) \geq \ell\, m(c).$$

Assume also a mindplex-scale interface growth bound in GTGI-weighted form:

$$\mathbb{E}_{c \sim \bar{w}_n}[m(c)] \geq c_0\, n \quad \text{for some } c_0 > 0.$$

Then the pragmatic GI advantage of π_{T} over any trustless $\pi \in \Pi_{\mathrm{L}}$ satisfies

$$\Pi(\pi_{\mathrm{T}}) - \Pi(\pi) \geq \ell\, c_0\, n\, W_n.$$

In particular, if W_n does not vanish with n (the GTGI distribution assigns nontrivial mass to such contexts at each scale), the advantage grows at least linearly in n.

Proof. Restrict the Π sum to $\mathcal{C}_n$ and use nonnegativity of weights:

$$\Pi(\pi_{\mathrm{T}}) - \Pi(\pi) = \sum_{c} w(c)\big(V^{\pi_{\mathrm{T}}}(c) - V^{\pi}(c)\big) \geq \sum_{c \in \mathcal{C}_n} w(c)\big(V^{\pi_{\mathrm{T}}}(c) - V^{\pi}(c)\big).$$

Apply the per-context lower bound:

$$\sum_{c \in \mathcal{C}_n} w(c)\big(V^{\pi_{\mathrm{T}}}(c) - V^{\pi}(c)\big) \geq \ell \sum_{c \in \mathcal{C}_n} w(c)\, m(c) = \ell\, W_n\, \mathbb{E}_{c \sim \bar{w}_n}[m(c)].$$

Finally use $\mathbb{E}_{c \sim \bar{w}_n}[m(c)] \geq c_0 n$ to get the claim. ∎

Remark 3815 (Interpretive notes on Theorem 257). *The normalization $\bar{w}_n$ isolates the* within-subset *scaling of interface burden from the* across-subset *question of how much GTGI mass is assigned to such coordination contexts at scale n. In particular, W_n acts as a relevance factor: if the theory of contexts assigns negligible mass to mindplex-scale coordination problems (e.g., because most weight is placed on single-agent toy tasks), then even strong interface-growth effects will not move the global Π score much. Conversely, if W_n stays bounded away from 0, then coordination is persistently "on the test," and the lower bound becomes a genuine scaling law for measured pragmatic advantage.*

The observable $m(c)$ can be instantiated in many ways depending on the modeling choice: number of pairwise communication channels, number of verification edges in a provenance graph, number of cross-team dependencies in a plan, or any proxy for the count of distinct trust/credence alignment interfaces that must be managed. The theorem only needs $m(c) \geq 0$ and a linear lower bound on its GTGI-weighted average.

Finally, note the structure of the per-context assumption $V^{\pi_T}(c) - V^{\pi}(c) \geq \ell m(c)$: it encodes that each additional interface carries at least some constant marginal expected value for trust-capable coordination (relative to trustless baselines). This is the GTGI analog of "selection pressure" in the mindplex theorem: the larger the interface surface area, the more there is to lose without reliable trust mechanisms, and the more there is to gain by having them.

70.6.5 Resource-rich minds as limits and monotone families in GTGI

Remark 3816 (Conceptual explanation: turning "more resources" into a policy family). *GTGI scores $\Pi(\pi)$ and $\Pi^{\text{eff}}(\pi)$ are properties of a policy π. To speak meaningfully about "a scarce-resource mind becoming resource-rich" (Hyperseed-Concept 162), we model the mind as a* resource-indexed family *of policies $\{\pi_R\}_{R\geq 0}$: the same underlying agent architecture, but run with different resource budgets (time/compute/memory/coordination), so it can plan, simulate, verify, and self-correct more. Then we can ask: do GTGI measures converge as $R \to \infty$? when do they increase monotonically? The next theorem provides a clean sufficient condition: uniform near-optimality across contexts.*

The key modeling move is that "more resources" should not be treated as an external adjective but as a parameter that changes the induced policy. Concretely, R may correspond to more search depth, more deliberation steps, larger working memory, more samples in Monte Carlo estimation, more rounds of cross-checking between subagents, or more bandwidth for internal debate. In each case one obtains a different effective mapping from histories (or observations) to actions, i.e. a different π_R.

The uniformity requirement in the theorem below is intentionally strong: it captures the regime where additional resources help broadly across the GTGI context distribution rather than improving only a narrow slice of tasks. This is the sense in which the family approaches a "resource-rich mind" as a limit object: its residual regret becomes small in every *context, not merely on average.*

Theorem 258 (Rich-resource near-optimality implies convergence of pragmatic GI). *Let $\{\pi_R\}_{R\geq 0}$ be a family of policies indexed by a resource parameter R. Assume:*

1. *The total GTGI context-weight mass is finite:*

$$W := \sum_c w(c) < \infty.$$

2. There exists a function $\varepsilon(R) \geq 0$ with $\varepsilon(R) \to 0$ as $R \to \infty$, such that for every context c,

$$V^{\pi_R}(c) \;\geq\; V^*(c) - \varepsilon(R), \qquad V^*(c) := \sup_\pi V^\pi(c).$$

Define the (possibly formal) optimal pragmatic score

$$\Pi^* \;:=\; \sum_c w(c)\, V^*(c),$$

assuming it is finite.

Then for all R,

$$0 \;\leq\; \Pi^* - \Pi(\pi_R) \;\leq\; W\,\varepsilon(R),$$

and therefore $\Pi(\pi_R) \to \Pi^*$ as $R \to \infty$.

Moreover, if $R \mapsto V^{\pi_R}(c)$ is nondecreasing for each context c, then $R \mapsto \Pi(\pi_R)$ is nondecreasing.

Proof. By definition,

$$\Pi^* - \Pi(\pi_R) = \sum_c w(c)\big(V^*(c) - V^{\pi_R}(c)\big).$$

Each term is nonnegative by definition of $V^*(c)$. By assumption (2), $V^*(c) - V^{\pi_R}(c) \leq \varepsilon(R)$ for all c, hence

$$0 \leq \Pi^* - \Pi(\pi_R) \leq \sum_c w(c)\,\varepsilon(R) = W\,\varepsilon(R),$$

using assumption (1). Since $\varepsilon(R) \to 0$, the bound implies $\Pi(\pi_R) \to \Pi^*$.

For monotonicity: if $V^{\pi_R}(c)$ is nondecreasing in R for each c, then the weighted sum $\sum_c w(c)V^{\pi_R}(c)$ is also nondecreasing because all weights are nonnegative. □

Remark 3817 (Further interpretation: why finiteness and uniformity matter)**.** *Assumption (1) is a GTGI analogue of an integrability condition: it prevents the weighted sum defining $\Pi(\pi)$ from placing infinite total mass on contexts. Without such a condition, even vanishing per-context regret $\varepsilon(R)$ could fail to control $\Pi^* - \Pi(\pi_R)$.*

Assumption (2) is a uniform *additive regret bound. It can be read as: increasing resources drives the family $\{\pi_R\}$ into an $\varepsilon(R)$-optimal band around the contextwise optimum $V^*(c)$, and the band shrinks to 0 as $R \to \infty$. This is stronger than merely requiring that the* average *regret under w goes to zero; the strength is what makes the conclusion immediate and yields a simple explicit convergence rate in terms of $W\,\varepsilon(R)$.*

The optional monotonicity condition formalizes a natural "no backsliding" expectation: if more resources never make performance worse in any context, then the pragmatic score cannot decrease. This is precisely the kind of condition one typically expects when R corresponds to additional computation that a policy can choose to ignore, or to additional verification that can only catch errors.

70.6.6 Do GTGI intelligence measures correlate with compassion or Locations?

Remark 3818 (Conceptual explanation: "no free correlation" vs conditional correlation)**.** *GTGI measures (Defs. 340, 342) quantify expected goal achievement across a specified goal distribution. Compassion (Hyperseed-Concept 81) and Martin-style Locations (discussed in the PNSE/Martin Locations bridge) are* additional *properties of minds/collectives; they are not forced to correlate with GTGI scores unless the chosen goal ecology (or a shared latent driver like resources) couples them. Thus, there are two mathematically clean statements to make: (i) without coupling assumptions,* *there is no necessary relationship; (ii) with monotone coupling through a shared scalar (e.g. resource level R), positive correlation is expected and can be proved as a covariance inequality.*

For avoidance of ambiguity: statement (i) is a claim about logical/axiomatic non-implication *under the GTGI definitions as written (i.e. the GTGI functional depends only on $(\mathcal{E}, \mathcal{G}, \mathcal{T}, \nu, \gamma, \tau)$ and the induced values $V^{\pi}_{\mu,g,T}$), not a sociological claim that compassion and capability never co-occur. Statement (ii) is a claim about* conditional association*: once one conditions on (or parametrizes by) a variable that jointly influences both dimensions (resources, organizational scale, training data, evaluator redundancy, etc.), one can obtain a provable direction of correlation. In particular, the relevant probability space for the covariance is the distribution of the latent driver R (or more generally the joint distribution of drivers), and the sign claim is about how both quantities move along that axis.*

It is also worth distinguishing "correlation across agents in a population" from "coupling inside a single agent's objective." The former is modeled here by sampling R and observing $(\Pi^{\text{eff}}(\pi_R), C(R))$; the latter would require changing the goal distribution γ so that compassion-relevant outcomes are directly reward-relevant. Only the latter produces a direct definitional link; the former produces an empirical/statistical link.

Theorem 259 (No necessary implication: intelligence can be decoupled from compassion/Location)**.** *Fix a GTGI setup $(\mathcal{E}, \mathcal{G}, \mathcal{T}, \nu, \gamma, \tau)$.*

Suppose $\mathcal{G}$ contains a distinguished subset $\mathcal{G}_{\text{comp}}$ of "compassion-relevant" goals, but the goal distribution assigns it zero mass in every environment:

$$\gamma(g, \mu) = 0 \quad \forall \mu \in \mathcal{E},\ \forall g \in \mathcal{G}_{\text{comp}}.$$

Then $\Pi(\pi)$ and $\Pi^{\text{eff}}(\pi)$ are completely insensitive to how π behaves on compassion-relevant goals: if two policies π, π' satisfy $V^{\pi}_{\mu,g,T} = V^{\pi'}_{\mu,g,T}$ for all $g \notin \mathcal{G}_{\text{comp}}$ (and all μ, T), then

$$\Pi(\pi) = \Pi(\pi'), \qquad \Pi^{\text{eff}}(\pi) = \Pi^{\text{eff}}(\pi').$$

Therefore, without an explicit coupling between the GTGI goal ecology and compassion-relevant goals, GTGI intelligence measures do not, in general, constrain compassion. An analogous decoupling holds for "Location"-like state descriptors unless they are explicitly reward-relevant or otherwise coupled to the goal distribution.

Concretely, this theorem formalizes a familiar point: if the evaluation suite never queries (or never assigns any weight to) behaviors that express compassion (or any particular Location signature), then the resulting score cannot rule those behaviors in or out. One can build two systems that are indistinguishable on the support of γ and yet differ arbitrarily on the measure-zero part $\mathcal{G}_{\text{comp}}$; the GTGI functional, being a weighted average over (μ, g, T), cannot detect the difference. This is the mathematical core of the "no free correlation" claim: it is not that compassion is incompatible with intelligence, but that it is not entailed by this *objective unless the objective is designed to touch it.*

Proof. By the hypothesis $\gamma(g, \mu) = 0$ for all $g \in \mathcal{G}_{\text{comp}}$, the sums defining $\Pi(\pi)$ and $\Pi^{\text{eff}}(\pi)$ have no contributions from $\mathcal{G}_{\text{comp}}$. Thus if two policies agree on all contexts with $g \notin \mathcal{G}_{\text{comp}}$, their weighted sums agree, giving equality of Π and Π^{eff}. The same logic applies to any auxiliary property (such as a Location index) that does not appear in the reward/goal definitions and is not otherwise coupled to them.

Equivalently, one may view Π and Π^{eff} as functionals of the restricted collection $\{V^{\pi}_{\mu,g,T} : g \in \text{supp}(\gamma)\}$, where $\text{supp}(\gamma)$ denotes the set of goals given nonzero weight (possibly depending on μ). If $\mathcal{G}_{\text{comp}}$ lies outside this support, then changing π on those goals cannot change the functional value, which is exactly the claimed insensitivity. $\square$

Lemma 180 (Chebyshev covariance inequality for monotone functions of one variable)**.** *Let R be a real-valued random variable. If $f, g : \mathbb{R} \to \mathbb{R}$ are both nondecreasing, then*

$$\operatorname{Cov}(f(R), g(R)) \;\geq\; 0,$$

whenever the covariance exists.

Proof. Let R' be an independent copy of R. A standard identity gives

$$\operatorname{Cov}(f(R), g(R)) = \frac{1}{2}\,\mathbb{E}\big[\big(f(R) - f(R')\big)\big(g(R) - g(R')\big)\big]\,.$$

If f and g are nondecreasing, then $(f(R) - f(R'))(g(R) - g(R')) \geq 0$ pointwise (because the two differences have the same sign). Taking expectation preserves the inequality, hence the covariance is nonnegative.

For intuition: the product above is positive precisely because increasing R tends to increase both $f(R)$ and $g(R)$, so deviations of $f(R)$ above its typical value align with deviations of $g(R)$ above its typical value. The lemma is one of the simplest "positive association" results and is the minimal tool needed for the resource-mediated template below; no joint normality or linearity assumptions are required. □

Theorem 260 (Resource-mediated correlation template for intelligence vs compassion/Location)**.** *Let R be a resource-level random variable (time/compute/energy/coordination), and let π_R denote the policy realized by a resource-indexed mind at resource level R (Hyperseed-Concept 162).*

Assume:

1. *The efficient pragmatic GI score $\Pi^{\text{eff}}(\pi_R)$ is nondecreasing in R.*
2. *There is a scalar "compassion level" $C(R) \in \mathbb{R}$ (e.g. $C(R) = \mathbb{E}[c(x_T)]$ in the basin-stability model, where c is compassion; Hyperseed-Concept 81) that is nondecreasing in R.*

Then $\Pi^{\text{eff}}(\pi_R)$ and $C(R)$ have nonnegative covariance:

$$\operatorname{Cov}\Big(\Pi^{\text{eff}}(\pi_R),\, C(R)\Big) \;\geq\; 0.$$

Likewise, if a Location-like index $\operatorname{Loc}(R)$ (individual or collective; cf. the Martin Locations bridge and Hyperseed-Concept 75) is nondecreasing in R, then

$$\operatorname{Cov}\Big(\Pi^{\text{eff}}(\pi_R),\, \operatorname{Loc}(R)\Big) \;\geq\; 0.$$

Proof. Apply Lemma 180 with $f(R) = \Pi^{\text{eff}}(\pi_R)$ and $g(R) = C(R)$ (or $g(R) = \operatorname{Loc}(R)$).

To be explicit about the probability space: the covariance is taken over draws of R from whatever population or uncertainty distribution is under discussion (e.g. a distribution over organizations, training budgets, or substrate capabilities). The conclusion does not assert that *every* increase in Π^{eff} implies an increase in C for the same agent at fixed R; it asserts that, when both are monotone functions of the same scalar driver, the population-level association induced by varying R must be nonnegative. □

Corollary 86 (A concrete compassion-correlation consequence in the "robust evaluators" model)**.** *In the basin-and-evaluators model of Theorem 252, the probability of large compassion loss over T steps is bounded by an expression that decreases (at least) exponentially with evaluator count $K(R)$,* *and $K(R)$ is nondecreasing in resources R. Thus, any reasonable "compassion stability" score (e.g. $C(R)$ = probability compassion stays above a threshold) is nondecreasing in R.*

Therefore, if in addition $\Pi^{\text{eff}}(\pi_R)$ is nondecreasing in R in the same population of minds, Theorem 260 implies a nonnegative correlation between efficient GTGI intelligence and compassion stability along the resource axis.

This corollary should be read as a template for how "mindplex"-level properties can become statistically coupled: if scaling resources simultaneously (a) improves performance on the evaluated goal ecology (raising Π^{eff}) and (b) increases the redundancy/coverage of whatever internal or external mechanisms enforce compassion (raising C), then one expects a positive association even if the GTGI definition itself never directly references compassion. In other words, the correlation is not a definitional constraint but an emergent consequence of shared scaling drivers.

Proof. Theorem 252 provides an explicit upper bound on failure probability that decreases as $K(R)$ grows, hence $C(R)$ is nondecreasing in R. Now apply Theorem 260.

Note that the argument only needs monotonicity of $K(R)$ and monotonicity of the induced stability score; the detailed functional form of the exponential bound is useful for quantitative rates (e.g. how quickly correlation strengthens as resources scale), but not needed for the qualitative nonnegativity claim. □

A GTGI measures for collective intelligences, mindplexes, and resource-rich minds

This appendix expands the notion of "GTGI measures" as used in the main text to quantify, compare, and bound the growth trajectories of *collective intelligences*, *mindplexes* (interacting ensembles of minds/agents), and *resource-rich minds*. The intent is not to prescribe a single scalar "intelligence number," but to define a family of operational measures that (i) are computable or at least estimable from observable structure and performance, (ii) decompose into interpretable components, and (iii) can be tied to basin-constrained endpoint convergence claims toward C3-like attractors.

A.1 Objects of measurement and minimal notation

Let $\mathcal{M}$ denote a mindplex, modeled as a set of agents $\{a_i\}_{i=1}^n$ together with (a) an interaction topology $G = (V, E)$, (b) a communication protocol Π, and (c) a shared environment $\mathcal{E}$ with task distribution $\mathcal{T}$. Each agent has an internal state $s_i(t)$ and policy π_i; the collective induces a joint policy $\Pi_{\mathcal{M}}$ that maps histories to actions. A *resource-rich mind* is treated as a limiting case in which either $n = 1$ with extremely large internal resources, or $n > 1$ but with abundant external resources available per agent; both cases are represented by an explicit resource vector $R(t)$.

We consider time-indexed measures $I(t)$ and cumulative measures over an interval $[0, T]$. When comparing heterogeneous systems, we distinguish: (i) *capability* (what can be done), (ii) *efficiency* (resources required), and (iii) *robustness* (stability under perturbations).

A.2 A decomposition template for GTGI

A convenient template is to define a GTGI family as a product or sum of interpretable factors,

$$\mathrm{GTGI}(\mathcal{M};\mathcal{T},\mathcal{E},T) \;\equiv\; \int_0^T \underbrace{C(t)}_{\text{capability}} \cdot \underbrace{E(t)}_{\text{efficiency}} \cdot \underbrace{S(t)}_{\text{stability}} \cdot \underbrace{A(t)}_{\text{alignment/goal-coherence}} \, dt, \tag{66}$$

where each factor can itself be multi-dimensional. The integral form emphasizes that growth and performance accrue over time; for settings where only endpoints matter, one may use $\mathrm{GTGI}(T)$ or $\Delta\mathrm{GTGI} = \mathrm{GTGI}(T) - \mathrm{GTGI}(0)$.

To avoid conflating size with competence, factors should be normalized against baseline resources and task difficulty. A common normalization is against a reference policy class Π_0 and a resource baseline R_0:

$$C(t) \;=\; \frac{\mathbb{E}_{\tau\sim\mathcal{T}}\left[U(\Pi_{\mathcal{M}},\tau;\mathcal{E})\right]}{\mathbb{E}_{\tau\sim\mathcal{T}}\left[U(\Pi_0,\tau;\mathcal{E})\right]}, \qquad E(t) \;=\; \frac{\mathrm{Cost}(R_0,t)}{\mathrm{Cost}(R(t),t)}. \tag{67}$$

Here U is a utility or performance functional (success probability, reward, accuracy, or task-specific score), while Cost aggregates compute, energy, time, and scarce materials. This makes explicit that high performance achieved by disproportionate resource expenditure should not trivially dominate.

A.3 Capability components for collective systems

For mindplexes and collective intelligences, capability is often not merely the best single-agent performance but the *reachable set* of coordinated behaviors. Useful capability components include:

Task coverage (breadth). Let $\mathcal{T}$ be partitioned into task families $\{\mathcal{T}_k\}$. Define

$$C_{\mathrm{breadth}}(t) \;=\; \sum_k w_k \, \mathbb{I}(\mathbb{E}_{\tau\sim\mathcal{T}_k}[U(\Pi_{\mathcal{M}},\tau)] \geq \theta_k)\,, \tag{68}$$

where w_k weights importance and θ_k is a competence threshold. This is a coarse but interpretable "coverage" score.

Generalization under distribution shift. If $\mathcal{T}'$ represents shifted tasks, define a robustness-to-shift capability

$$C_{\mathrm{shift}}(t) \;=\; \frac{\mathbb{E}_{\tau\sim\mathcal{T}'}[U(\Pi_{\mathcal{M}},\tau)]}{\mathbb{E}_{\tau\sim\mathcal{T}}[U(\Pi_{\mathcal{M}},\tau)] + \varepsilon}, \tag{69}$$

with $\varepsilon > 0$ preventing degeneracy. This factor is particularly relevant to claims of endpoint convergence, since attractor-like regimes should exhibit stable performance across modest perturbations.

Coordination and compositionality. Let U_{team} be team performance and U_i be individual performance on the same tasks with communication disabled. A simple synergy index is

$$C_{\mathrm{sync}}(t) \;=\; \frac{\mathbb{E}[U_{\mathrm{team}}] - \max_i \mathbb{E}[U_i]}{\max_i \mathbb{E}[U_i] + \varepsilon}, \tag{70}$$

capturing the extent to which the mindplex exceeds its best constituent. Positive C_{sync} suggests nontrivial collective computation rather than mere aggregation.

A.4 Efficiency and resource-rich minds

A "resource-rich mind" is not automatically high-GTGI; it must convert resources into capability efficiently. Let $R(t)$ collect compute (FLOP), energy (J), memory, time, and critical materials. Then a common efficiency term is the inverse of a weighted resource norm:

$$E(t) \;=\; \frac{1}{\alpha_{\mathrm{c}}\,\mathrm{Compute}(t) + \alpha_{\mathrm{e}}\,\mathrm{Energy}(t) + \alpha_{\mathrm{m}}\,\mathrm{Memory}(t) + \alpha_{\mathrm{t}}\,\mathrm{Time}(t)}, \tag{71}$$

with coefficients $\alpha_{\bullet}$ chosen to reflect scarcity or externalities. When comparing systems across scales, one may also report the Pareto frontier of (C, E) rather than collapsing to a single scalar.

To connect efficiency to basin constraints, note that limited resources can enforce confinement to a subset of trajectories; in that sense, $E(t)$ affects not only performance but also which attractor basins are reachable under realistic constraints.

A.5 Stability, resilience, and endpoint convergence

Since the main section emphasizes basin-constrained endpoint convergence toward C3-like attractors, the stability factor $S(t)$ should directly encode resilience and convergence tendencies.

Local stability to perturbations. Let δ perturb either the environment, the interaction graph, or internal states. Define

$$S_{\mathrm{local}}(t) \;=\; \exp\Big(-\beta\, \mathbb{E}_{\delta}\big[\|\Phi_t(\mathcal{M}) - \Phi_t(\mathcal{M}+\delta)\|\big]\Big), \tag{72}$$

where Φ_t is a chosen embedding of system-level behavior (e.g., summaries of policies, performance profiles, or communication statistics), and $\beta > 0$ sets sensitivity. The use of an exponential emphasizes that large deviations should be strongly penalized.

Convergence within a basin. If $\mathcal{B}$ is a basin in a state-space representation, and $d(\cdot,\cdot)$ is a metric on macrostates, define a contraction-like proxy:

$$S_{\mathrm{conv}}(t) \;=\; \mathbb{E}\left[\frac{d(X(t+\Delta), X^{\star})}{d(X(t), X^{\star}) + \varepsilon}\right]^{-1}, \tag{73}$$

where $X(t)$ is a macrostate, $X^{\star}$ is the putative endpoint (attractor representative), and Δ is a fixed horizon. Values > 1 indicate, on average, movement toward the endpoint. This connects directly to "endpoint convergence" language without assuming a perfectly known dynamical system.

A.6 Goal-coherence and alignment within mindplexes

For collective intelligences, a key failure mode is internal conflict or incoherent optimization that dissipates resources. A goal-coherence factor can be defined via agreement of gradients, plans, or revealed preferences.

Let $g_i(t)$ denote an estimated direction of improvement for agent i in a shared objective space (e.g., gradients of predicted task utility under agent actions). Then define

$$A(t) \;=\; \frac{1}{n(n-1)} \sum_{i\neq j} \frac{\langle g_i(t), g_j(t)\rangle}{\|g_i(t)\|\,\|g_j(t)\| + \varepsilon}, \tag{74}$$

so that $A(t) \in [-1, 1]$ measures average directional agreement. Strongly negative values indicate adversarial or misaligned subcomponents; values near 1 indicate coherent collective optimization, a plausible hallmark of C3-like regimes if those regimes emphasize stable, coordinated, and self-consistent behavior.

A.7 A concrete composite score (illustrative)

An illustrative (not mandatory) scalar instantiation is

$$\mathrm{GTGI}_{\mathrm{scalar}} \;=\; \int_0^T \Big(C_{\mathrm{breadth}}(t)\Big)\Big(1 + C_{\mathrm{sync}}(t)\Big)\Big(E(t)\Big)\Big(S_{\mathrm{local}}(t)\, S_{\mathrm{conv}}(t)\Big)\Big(\tfrac{1+A(t)}{2}\Big)\, dt, \tag{75}$$

where each multiplicative term has a clear interpretation: breadth (coverage), synergy (collective advantage), efficiency (resource conversion), stability (robustness and convergence), and coherence (internal alignment). The affine mapping $(1 + A)/2$ ensures nonnegativity while still penalizing incoherence.

A.8 Interpretation with respect to C3-like attractors

Within the paper's framing, C3-like attractors can be treated as regions of macrostate space where the system exhibits: (i) persistent coordination, (ii) high resource-to-capability conversion, (iii) robustness to perturbations, and (iv) stable goal-coherence. Under this interpretation, high GTGI is not merely "more intelligence," but evidence that the system is operating in (or approaching) a regime consistent with such an attractor.

Two clarifications help avoid category errors:

1. A high-capability system with low stability may show strong short-run performance while failing to exhibit endpoint convergence; this should be reflected by low S_{local} or S_{conv}.

2. A resource-rich mind may score highly on raw capability but poorly on efficiency; in basin-constrained settings, this may overstate its relevance if the basin is defined by realistic resource constraints.

A.9 Practical measurement remarks

While the above definitions are abstract, each component can be estimated from experiments or logs: (i) U from benchmark suites or real-world task success, (ii) resource costs from telemetry (energy, compute, latency), (iii) perturbation response from ablations (removing communication edges, injecting noise, varying task distributions), and (iv) goal-coherence from plan similarity, gradient alignment, or preference-model agreement. When full observability is unavailable, lower bounds and confidence intervals should be reported, since GTGI is intended to support rigorous comparative claims rather than rhetorical labeling.

B Hyperseed concept checklist

How to use this appendix

The list below is intended as a completeness checklist. Every term listed here appears in the original Hyperseed ontology document. In the final paper, each item should have a precise definition (or a precise reduction to earlier definitions) and a pointer to the section where it is introduced. In practice, this appendix functions as a "coverage test": if a term is used anywhere in the main text, it should be possible to locate it here and then follow its pointer to the unique place where its meaning is fixed. When revising the main document, it is useful to treat each checklist entry as a contract with the reader: the term should not rely on informal intuition alone, and its dependencies (what it is defined in terms of) should be explicit and already established.

A "precise definition" can take multiple acceptable forms. For primitive notions, it may be an explicit declaration of status (primitive, assumed, or axiomatized) together with the axioms or inference rules that govern it. For derived notions, it should be a reduction to earlier definitions with clear quantifiers, domains, and any side conditions (e.g., well-formedness or admissibility assumptions). For operational terms, it can be a step-by-step construction provided that each step only invokes already-defined operations. In all cases, the reader should be able to determine (i) what objects the term ranges over, (ii) what data are required to compute or instantiate it, and (iii) what properties follow immediately from its definition.

Pointers should be as specific as possible. If a concept is introduced in a dedicated definition environment, the pointer should reference that definition rather than only the surrounding section. If the notion is first introduced informally and later made precise, the pointer should lead to the first place where the fully formal definition appears (and the informal introduction can be cross-referenced from there). When a term is overloaded (same word used for distinct technical meanings), the checklist should enforce disambiguation by requiring separate entries or explicit qualifiers in the names used in the paper.

The checklist is also intended to catch hidden dependencies. If a definition uses an auxiliary notion that is not yet defined elsewhere, that auxiliary notion should be added as its own checklist item (or the definition should be refactored so that all prerequisites are already present). A good workflow is to read each definition and underline every technical noun phrase; each underlined phrase should either be (a) defined earlier, (b) explicitly declared primitive, or (c) replaced by a more elementary phrase that is already grounded.

Finally, this appendix can be used to enforce consistent terminology across drafts. If the ontology document contains synonyms, alternate spellings, or historical names, select one canonical surface form for the paper and record the alternatives as aliases in the definition text (so that search and cross-reference remain robust). If the paper introduces simplified nomenclature for readability, include an explicit equivalence statement so that a reader can map between the simplified term and the ontology term without ambiguity.

C Hyperseed concept glossary

C.1 Core Hyperseed concepts

Concept 1 (Abstract)**.** *Appendix label: concept:Abstract.*
Body definition label: hsdef:Abstract (see § 28.3).

Informal definition. *Something is* abstract *when you treat many different concrete examples as the same kind of thing, by ignoring details that do not matter for your current purpose. For instance, many different handwritten marks can all count as the letter "A," and many different physical triangles can all count as "a triangle." Abstracting is a controlled kind of forgetting: you keep what is shared and drop what is incidental.*

Formal definition. *Let c be a context with entity set X_c. An abstraction of c is a surjection*

$$q : X_c \twoheadrightarrow A$$

to a set A of abstracta. The abstraction collapses distinctions by identifying elements of the same fiber. Equivalently, q determines an equivalence relation

$$x \sim_q y \iff q(x) = q(y).$$

Concept 2 (After)**.** *Appendix label: concept:After.*
Body definition label: hsdef:After (see § 7.1).

Informal definition. After *means "later than". Hyperseed models the basic structure of time using the idea of an ordering: some moments/events come after others. To be consistent, nothing can be after itself, and "after" must not produce cycles like "A after B after C after A".*

Formal definition. *A* strict partial order *on a set T is a binary relation $<$ on T such that:*

1. *(Irreflexive) for all $t \in T$, not $(t < t)$,*

2. *(Transitive) for all $t_1, t_2, t_3 \in T$, if $t_1 < t_2$ and $t_2 < t_3$ then $t_1 < t_3$.*

We say t_1 is before *t_2 if $t_1 < t_2$, and t_2 is* after *t_1.*

Concept 3 (Aesthetics / Art)**.** *Appendix label: concept:AestheticsArt.*
Body definition label: hsdef:AestheticsArt (see § 383).

Informal definition. *In Hyperseed, something counts as* art *(relative to a group of people) if encountering it tends to reliably trigger an experience of beauty for many of them. The key point is that art is not defined only by the object in isolation: it is defined by the object* and *the way it affects a population of experiencers. Different communities can disagree about what is art, because their typical reactions can differ.*

Formal definition. *Fix a class of experiencers $X \subseteq \mathrm{Mind}$. An art object A (relative to X) is any entity such that, for many $m \in X$, encountering A induces a designated beauty proposition $\mathrm{Beaut}(A)$ in m's valuation. Equivalently, it induces a high rate of beauty episodes in the population X.*

Concept 4 (Alive / Dead)**.** *Appendix label: concept:AliveDead.*
Body definition label: hsdef:AliveDead (see § 41.6).

Informal definition. Alive *and* dead *are treated as time-dependent, evidence-based notions. Roughly: "dead now" is not just "not alive now," but "was alive recently and is not alive now." This matches ordinary thinking (something can be uncertain or borderline), and it also allows conflicting evidence streams (some signs of life, some signs of death).*

Formal definition. *Fix a lookback window length $\tau \in \mathbb{N}$. Define the "was-alive" evidence by*

$$\mathrm{WasAlive}_O(S,t) \;:=\; \bigoplus_{u \in \{t-\tau,\dots,t-1\}} \mathrm{Alive}_O(S,u),$$

where $\oplus$ is the p-bit *join (componentwise max) from Section 3.4. Define*

$$\mathrm{Dead}_O(S,t) \;:=\; \mathrm{WasAlive}_O(S,t) \otimes \neg\, \mathrm{Alive}_O(S,t),$$

using the p-bit *negation and monoidal product $\otimes$ from the core.*

Concept 5 (Algebraically Asymmetric Physical Reality)**.** *Appendix label: concept:AlgebraicallyAsymmetricPhysica*
Body definition label: hsdef:AlgebraicallyAsymmetricPhysicalReality (see § 25.4).

Informal definition. *Hyperseed claims there is a built-in mismatch between how* physics *is structured and how* mental / intersubjective *descriptions usually work. A mental description often keeps only coarse, relational, or pattern-level facts ("these things are connected", "this resembles that") and leaves out many precise details (exact geometry, forces, equations, etc.). Because of that loss of detail, you usually cannot reconstruct the full physical situation from the mental-level description alone: going from "mental" back to "physical" requires adding extra structure and constraints. This one-way loss is the "algebraic asymmetry."*

Formal definition. *Let R_{phys} be a category (or enriched category) of models of physical reality, whose objects carry strong algebraic structure (e.g. smooth manifold, metric space, vector bundle, etc.). Let R_{ment} be a category of models of mental and intersubjective reality (e.g. topological or relational pattern spaces). An* algebraic asymmetry *is the presence of a structure-forgetting functor*

$$U : R_{\text{phys}} \to R_{\text{ment}}$$

that is not (even approximately) invertible on the images relevant to a given community of minds. In this case we say that mental reality is algebraically weaker than physical reality.

Concept 6 (Answers)**.** *Appendix label: concept:Answers.*
Body definition label: hsdef:Answers (see § 292). ***Informal definition.*** *An* answer *is defined by what it does, not by what it looks like. It is anything that helps resolve a question by shrinking the set of reasonable possibilities. A complete answer might identify the exact right choice, but many useful answers are partial: they can rule out options, tell you where to look, or tell you which options are more likely.*

Formal definition. *An answer to a question* (τ, Exp) *is any artifact that reduces uncertainty about* $\mathrm{Inst}(\tau)$*. Concretely, an answer may be:*

- *a particular instantiation* $\iota \in \mathrm{Inst}(\tau)$*;*
- *a constraint* $C \subseteq \mathrm{Inst}(\tau)$ *that prunes candidates;*
- *a distribution (or* p-bit*-valued scoring) over* $\mathrm{Inst}(\tau)$*; or*
- *any representation that yields an entropy reduction or computational simplification relative to baseline inference.*

Concept 7 (Anthropic Principle)**.** *Appendix label: concept:AnthropicPrinciple.*
Body definition label: hsdef:AnthropicPrinciple (see § 25.9).

Informal definition. *The anthropic principle is treated as a plain selection effect: the fact that* you exist as an observer *is information. So when comparing different models of the universe, you should downweight models in which observers like you could not exist, and upweight models where observers are likely. This is not an "explanation" of why the universe is the way it is; it is a rule for how an observer should update beliefs given that the observer exists.*

Formal definition. *Let Θ be a parameter space of universe models (physical constants, laws, initial conditions, etc.). Let $\pi(\theta)$ be a prior distribution over Θ. Let A be an "anthropic" event such as "observers of type O exist." The anthropic posterior is*

$$\pi(\theta \mid A) \propto \pi(\theta)\, P(A \mid \theta).$$

Concept 8 (Archetypes)**.** *Appendix label: concept:Archetypes.*
Body definition label: hsdef:Archetypes (see § 382).

Informal definition. *An* archetype *is a recognizable template that shows up across many different systems (people, stories, cultures, texts, etc.) even though the detailed versions can differ a lot. For example, "the trickster" or "the hero" can appear in many cultures with different names and plots. Hyperseed emphasizes three features: it appears in many places, the instantiations are not mere copies, and the widespread appearance is not trivial (it is "surprising" given how specific the template is).*

Formal definition. *Fix a class of systems (minds, texts, cultures, etc.) indexed by J. An archetype is a template τ together with an instantiation map sending each $j \in J$ to a (possibly empty) set of instantiations* $\mathrm{Inst}_j(\tau)$*, such that:*

1. *τ has high support across J (many j have* $\mathrm{Inst}_j(\tau) \neq \emptyset$*), and*

2. *the typical instantiations are diverse (not near-copies), and*

3. *the support is "surprising" relative to the description complexity of τ (e.g. high occurrence despite nontrivial $\kappa(\tau)$).*

Concept 9 (Association)**.** *Appendix label: concept:Association.*
Body definition label: hsdef:Association (see § 91).

Informal definition. *An* association *score says how strongly two things are linked* in a particular context*. A high association means they tend to show up together, or they share many important properties; a low association means they rarely co-occur and have little in common (for the purposes of that context). The same pair can have different association scores in different contexts, depending on what properties the context cares about.*

Formal definition. *A (static) association score in context C is a symmetric map*

$$\mathrm{assoc}_C : E_C \times E_C \to [0,1]$$

intended to measure "how much A and B tend to occur together" or "how many properties/patterns they share."

(One canonical implementation used later in the text is via overlap between property-sets; see Definition 100.)

Concept 10 (Attention / Attentional Focus)**.** *Appendix label: concept:AttentionalFocus.*
Body definition label: hsdef:AttentionalFocus (see § 37.3).

Informal definition. *Attention is modeled as a limited mental budget spread over many possible things you could be tracking. You have* attentional focus *when most of that budget is concentrated on only a few items, instead of being thinly spread over many. The parameters (θ, k) let you say what counts as "most" (θ) and "a few" (k).*

Formal definition. *Fix parameters $\theta \in (0,1)$ (mass threshold) and $k \in \mathbb{N}$ (size bound). We say S has an attentional focus at time t (at level (θ, k)) if there exists a subset $F_t \subseteq P$ with $|F_t| \leq k$ such that*

$$\alpha_t(F_t) := \sum_{p \in F_t} \alpha_t(p) \geq \theta.$$

Equivalently, if $\alpha_t^{\downarrow}$ is the nonincreasing rearrangement of the weights $(\alpha_t(p))_{p \in P}$, then focus holds iff

$$\sum_{j=1}^{k} \alpha_t^{\downarrow}(j) \geq \theta.$$

Concept 11 (Autocatalytic Sets)**.** *Appendix label: concept:AutocatalyticSets.*
Body definition label: hsdef:AutocatalyticSets (see § 237). ***Informal definition.*** *An autocatalytic set is a collection of processes (often chemical reactions) that "help make themselves": each process in the collection is sped up (catalyzed) by something produced within the same collection. Because of this mutual support, once the set is present it can keep running and regenerating as long as it keeps getting basic inputs. In particular, the point is not that the set produces* everything *it needs from nothing, but that the internal catalytic support closes the "who speeds up whom" loop sufficiently to sustain ongoing activity given an external supply of low-level feedstock.*

Formal definition. *Fix a threshold $\theta \in (0,1]$. Let R be a finite set of reactions and let $C = (c_{ij})_{i,j \in R}$ be a catalysis matrix with $c_{ij} \in [0,1]$ interpreted as the strength of evidence that* *reaction i catalyzes reaction j. Define the thresholded reaction graph $G_\theta(R, C)$ to be the directed graph with vertex set R and an edge $i \to j$ iff $c_{ij} \geq \theta$. A subset $S \subseteq R$ is a θ-autocatalytic set if every vertex of the induced subgraph $G_\theta(R, C)[S]$ has in-degree at least one; equivalently, for every $j \in S$ there exists some $i \in S$ with $c_{ij} \geq \theta$. This graph-theoretic condition captures the minimal "no reaction is left uncatalyzed by the set" property: each $j \in S$ has at least one* internal *catalytic support edge at the chosen evidential cutoff. Note that the definition does not require a single global catalyst or a single directed cycle containing all vertices; rather, it allows a network of possibly overlapping cycles and catalytic chains, as long as every reaction in S has at least one incoming edge from within S at level θ. Varying θ tunes strictness: larger θ demands stronger evidence for catalysis and typically shrinks the sets that qualify, while smaller θ includes weaker or more speculative catalytic links.*

Concept 12 (Becoming)**.** *Appendix label: concept:Becoming.*
Body definition label: hsdef:Becoming (see § 62).

Informal definition. *We say that x* becomes *y when, over time, the system transitions from clearly being (or behaving like) x to clearly being (or behaving like) y. Crucially, the transition is not instant: there is a "boundary period" where the identity is genuinely unclear, so it can be reasonable (given the available evidence) to treat the two as both distinct and not-distinct. Away from that boundary, the two are more cleanly separated again. Intuitively, "becoming" is meant to model real processes like phase transitions, developmental shifts, or conceptual reclassifications, where any attempt to draw a razor-sharp instant of change would misrepresent the situation the evidence actually supports.*

Formal definition. *Fix a proto-time $(T, <)$ and a time-indexed distinction relation* Dist*. We say $x \in E$ becomes $y \in E$ (along $(T, <)$) if there exist $t_1 < t_2$ and an interval (or neighborhood) $U \subseteq T$ with $t_1 \leq u \leq t_2$ for all $u \in U$ such that:*

1. (Temporal succession) *x is salient/present up to (near) t_1 and y is salient/present from (near) t_2 onward.*
2. (Boundary non-duality) *for all $u \in U$ near the transition, x and y display non-dual variety at u.*
3. (Outside the boundary) *away from U, x and y are (comparatively) more distinguishable (e.g. $\mathrm{Dist}(u; x, y)$ is not strongly paraconsistent).*

Here the proto-time $(T, <)$ supplies only enough structure to talk about "earlier" and "later" without presupposing a fully classical timeline, while Dist *packages whatever evidential or operational criterion is being used to tell x from y at each time. Condition (2) is the key "fuzzing" requirement: in the boundary region U, the available evidence can support both the claim that x and y are distinct and the claim that they are not-distinct, in the sense captured by the non-dual/paraconsistent behavior of* Dist*; by contrast, condition (3) requires that this is a localized phenomenon rather than a permanent inability to distinguish.*

Concept 13 (Before)**.** *Appendix label: concept:Before.*
Body definition label: hsdef:Before (see § 56).

Informal definition. *In everyday thinking, "before" is a simple yes/no idea: either one event happened earlier than another, or it did not. In messy real situations, evidence can be incomplete or even conflicting, so we may want a more careful notion. Here, "before" is represented by two numbers: one measuring how much evidence supports "t_1 happened before t_2", and one measuring how much evidence supports the opposite (or otherwise counts against that ordering). This lets* *the model record uncertainty and disagreement instead of forcing an early all-or-nothing decision. For example, if two sensors disagree about a timestamp ordering, the formalism can represent "substantial support" and "substantial counter-support" simultaneously, rather than averaging them away into a single misleading probability.*

Formal definition. *Let $V = [0,1]^2$ be the p-bit quantale from Section 3.4. A p-bit-valued temporal evidence relation is a map*

$$B : T \times T \to V, \qquad B(t_1, t_2) = (B^+(t_1, t_2), B^-(t_1, t_2)).$$

Here $B^+(t_1, t_2)$ is positive evidence for $t_1 < t_2$, and $B^-(t_1, t_2)$ is negative evidence. Interpreting B as evidence rather than truth conditions allows regimes where both $B^+(t_1, t_2)$ and $B^-(t_1, t_2)$ are high (conflict), both are low (ignorance), or one dominates the other (comparatively well-supported ordering), which is useful when later constructions need to propagate or aggregate such ordering information without prematurely forcing classical comparability.

Concept 14 (Belief System)**.** *Appendix label: concept:BeliefSystem.*
Body definition label: hsdef:BeliefSystem (see § 304).

Informal definition. *A belief system is the connected set of beliefs and reasoning habits that a person or community uses to make sense of the world (Hyperseed-Concept 14). It is not just a pile of separate opinions: the beliefs support each other, explain each other, and guide what counts as evidence. A belief system is called* productive *when it has a stable "core" that does not constantly fall apart, but it is also capable of learning and creating new ideas and questions instead of getting stuck. Equivalently, productiveness is intended to rule out two failure modes: brittleness (where small evidence shocks shatter coherence) and stagnation (where coherence is maintained only by suppressing novelty).*

Formal definition. *A belief system (for a community M) is a pair (B, R) where $B \subseteq L$ is a focal belief set and R is a rule set, such that $\mathrm{Coh}_R(B; \beta_M)$ exceeds a chosen threshold. A belief system is productive if, in addition:*

(a) (Individuation) *there exists a "core" subset $B_{\text{core}} \subseteq B$ that remains stable under typical evidence updates (high persistence of key commitments), and*

(b) (Self-transcendence) *the system regularly generates new high-SAI beliefs or new questions whose answers lead to novel patterns, without collapsing coherence.*

The thresholded coherence requirement makes explicit that a belief system is being treated as a structured object relative to an inference practice R and an aggregated community stance β_M, not merely as a set of sentences: both the rules and the community weighting can change what counts as "coherent enough". Condition (a) can be read as a robustness constraint (a persistent identity through time), while condition (b) is a generativity constraint (the ability to expand the model space); together they formalize the idea that a productive system is neither purely conservative nor purely chaotic.

Concept 15 (Beliefs)**.** *Appendix label: concept:Beliefs.*
Body definition label: hsdef:Beliefs (see § 301).

Informal definition. *A belief is what an agent takes to be true (or likely true), possibly to a degree rather than perfectly. When multiple agents form a community, we can also talk about the community's overall stance by combining individual beliefs. The key idea is to weight each agent's contribution by something like trust, authority, or attention, and then merge the weighted contributions. Allowing weights with a negative component lets the model represent not only trust* *but also distrust or adversarial influence in a graded way. In other words, aggregation is treated as an evidence-combination problem: who says φ matters, how strongly they say it matters, and whether they should be treated as supportive or oppositional are all represented directly in the algebra of weights.*

Formal definition. *Let M be a finite set of agents, each with a belief state $\beta_i : L \to V$. Define the community aggregate belief state by*

$$\beta_M(\varphi) := \bigoplus_{i \in M} w_i \otimes \beta_i(\varphi),$$

where weights $w_i \in V$ model trust/authority/attention and the operations are those of the p-bit quantale. Operationally, $\otimes$ captures how an agent's credibility modulates (scales, filters, or otherwise transforms) the evidential content of their reported belief, while $\bigoplus$ aggregates the resulting contributions across agents in a way that can preserve both positive and negative evidence components. Allowing w_i to have a nontrivial negative coordinate permits explicit representation of distrust: an agent can contribute not only by supporting φ but also by supplying evidence against *treating their assertions as reliable indicators, which can matter in adversarial or strategically communicative settings.*

Concept 16 (Big Bounce)**.** *Appendix label: concept:BigBounce.*
Body definition label: hsdef:BigBounce (see § 46.7).

Informal definition. *"Big Bounce" is a speculative cosmology idea (Hyperseed-Concept 16): instead of the universe beginning once and for all in a single Big Bang, the universe might go through cycles where a contraction phase (sometimes called a "Big Crunch") is followed by a "bounce" into a new expansion. In Hyperseed this phrase is used cautiously, mainly as a hypothesis or metaphor for very large-scale cycles and for the possibility that some patterns could persist or reappear across such a transition.*

Concept 17 (Blend)**.** *Appendix label: concept:Blend.*
Body definition label: hsdef:Blend (see § 9.6).

Informal definition. *C is a blend of A and B when C is "mix-like" in the sense that many of the important properties of C are also properties of A or of B. This does not mean C is exactly half-and-half; it means a substantial portion of what characterizes C can be traced to one source or the other.*

Formal definition. *Fix C and choose a threshold $\theta \in (0, 1]$. Define the property overlap mass of C with (A, B) as*

$$\mathrm{ov}_C(C; A, B) := \sum_{P \in P_C} \min\Big\{\mathrm{Prop}_C(C)(P),\ \max\big(\mathrm{Prop}_C(A)(P), \mathrm{Prop}_C(B)(P)\big)\Big\}.$$

Define the blend score

$$\mathrm{blendscore}_C(C; A, B) := \begin{cases} \mathrm{ov}_C(C; A, B)/\|\mathrm{Prop}_C(C)\|_1, & \|\mathrm{Prop}_C(C)\|_1 > 0, \\ 0, & \|\mathrm{Prop}_C(C)\|_1 = 0. \end{cases}$$

We say C is a blend of A and B (in context C) if $\mathrm{blendscore}_C(C; A, B) \geq \theta$*.*

Concept 18 (Biological)**.** *Appendix label: concept:Biological.*
Body definition label: hsdef:Biological (see § 286).

Informal definition. *A lifeform is called* biological *if, at the level we are describing it, it is mainly built from organic chemistry (like cells and biochemistry). A lifeform can also be called* synthetic *if it was primarily designed and assembled intentionally by an intelligent engineering process, and* evolved *if it arose through unguided evolutionary and self-organization processes. These labels can overlap (for example, a genetically engineered organism is both biological and engineered), so the framework allows them to be multi-valued or p-bit-valued when needed.*

Formal definition. *A lifeform S is:*

- *biological if its dominant implementation substrate is organic chemistry (at the relevant descriptive level);*
- *synthetic if its design/assembly was primarily guided by an intelligent engineering process (as opposed to arising via unguided population-level dynamics);*
- *evolved if it arose via evolutionary and self-organization processes without intentional design.*

These labels are not mutually exclusive at all descriptive levels (e.g. bio-engineered organisms), so we allow them to be multi-valued or p-bit-valued when needed.

Concept 19 (Biological Lifecycle)**.** *Appendix label: concept:BiologicalLifecycle.*
Body definition label: hsdef:BiologicalLifecycle (see § 286).

Informal definition. *A biological lifecycle is the sequence of typical stages a biological organism goes through as it develops and ages, such as infant, young, mature, old, and elderly, together with the typical transitions between these stages. The point of the concept is to talk about "where in its life" an organism is, not just what it is made of.*

Concept 20 (Cause)**.** *Appendix label: concept:Cause.*
Body definition label: hsdef:Cause (see § 36.5).

Informal definition. *In this framework, "A causes B" is a context-relative claim: it depends on what the observer counts as an event, how time is segmented, and what time-scale is being used. Informally, A causes B when A tends to happen before B, and when information about A makes B more predictable (for example, using co-occurrence statistics such as $\mathrm{Cond}_{O,\Delta}$ and lag summaries like $\mathrm{lag}(A, B)$). Because the underlying "before/after" structure is treated as observer-relative, causal indicators are also understood as relative to O (and to the chosen window Δ).*

Formal definition. *Fix a lag window Δ and a mixing parameter $\lambda \in [0, 1]$. Define the causal implication strength*

$$\mathrm{CImp}_{O,\Delta}(A, B) := \Big(\lambda\, \sigma(\mathrm{PAtt}^{\mathrm{ext}}_{O,\Delta}(A, B)) + (1 - \lambda)\, \sigma(\mathrm{PAtt}^{\mathrm{int}}_{O,\Delta}(A, B))\Big) \cdot \mathbf{1}[A \prec B],$$

where $\mathbf{1}[A \prec B]$ is an indicator that A typically precedes B in the relevant context, and $\sigma : [-1, 1] \to [0, 1]$ is the affine rescaling $\sigma(x) = (1 + x)/2$. Define also the strong (product) variant

$$\mathrm{CImp}^{\times}_{O,\Delta}(A, B) := \sigma(\mathrm{PAtt}^{\mathrm{ext}}_{O,\Delta}(A, B))\ \sigma(\mathrm{PAtt}^{\mathrm{int}}_{O,\Delta}(A, B))\ \mathbf{1}[A \prec B].$$

Concept 21 (Categorical Imperative)**.** *Appendix label:* `concept:CategoricalImperative`*.*
Body definition label: `hsdef:CategoricalImperative` *(see § ??).* ***Informal definition.*** *The categorical imperative is a way to test a proposed rule for action (a "maxim") by asking: "What would happen if everyone followed this rule in relevantly similar situations?" If the world that results from universal adoption of the rule tends to be acceptable along key ethical dimensions (for example compassion, honesty, nonviolence), then the maxim passes the test; if universal adoption would predictably lead to unacceptable outcomes or a self-defeating situation, the maxim fails. In*

this document, the key idea is to make the test operational: it is evaluated using an observer's world-model and an explicit set of ethical dimensions, rather than being treated as a purely verbal slogan.

Formal definition. *Fix a set $D_{\text{eth}} \subseteq D$ of ethical dimensions (typically including compassion and possibly truth, nonviolence, etc.). Define the universalized ethical evaluation*

$$E_O^{\text{univ}}(m; d) := \mathbb{E}_{\omega \sim P_O(\cdot|\text{Univ}(m))}[\, E_O(\omega; d)\,]\,,$$

where $E_O(\omega; d)$ is the p-bit *evidence that the realized history ω promotes/opposes d (obtained by aggregating stepwise evidence across the history using $\oplus, \otimes$). We say m passes a threshold categorical imperative if*

$$J\big(E_O^{\text{univ}}(m; d)\big) \geq \tau_d \quad \textit{and} \quad W\big(E_O^{\text{univ}}(m; d)\big) \leq \eta_d \qquad \forall d \in D_{\text{eth}},$$

for fixed thresholds $\tau_d, \eta_d \in [0, 1]$.

Concept 22 (Closing)**.** *Appendix label:* `concept:Closing`*.*
Body definition label: `hsdef:Closing` *(see § 30.2).*

Informal definition. *A closing is a deliberate move toward* making finer distinctions. *You stop treating some pairs of situations (or objects, or states) as "basically the same" and start treating them as importantly different. In other words, you tighten your indistinction policy: you collapse fewer differences. Closing is the opposite direction of an opening (Hyperseed-Concept 125), which relaxes distinctions by collapsing more pairs.*

Formal definition. *Given two indistinction policies $H, H' \in H_C$:*

- *The transition $H \to H'$ is an* opening *(relaxation of distinctions) if $H \subseteq H'$.*
- *The transition $H \to H'$ is a* closing *(tightening of distinctions) if $H' \subseteq H$.*

Concept 23 (Cognitive Synergy)**.** *Appendix label:* `concept:CognitiveSynergy`*.*
Body definition label: `hsdef:CognitiveSynergy` *(see § 37.7).*

Informal definition. *Cognitive synergy means that two different kinds of knowledge (or two different reasoning methods) help each other in a way that makes the overall explanation* simpler *than what you could get by using each one separately and then combining the results. Put plainly: when you let the two knowledge sources interact, you can reach the same level of explanatory adequacy with fewer "extra assumptions" or less complicated story-telling.*

Formal definition. *Let T_1, T_2 be two disjoint sets of knowledge types and fix $\tau \in (0, 1]$. We say there is cognitive synergy at level τ between T_1 and T_2 if*

$$\text{Con}^*(T_1 \cup T_2; \tau) < \text{Con}^*(T_1; \tau) + \text{Con}^*(T_2; \tau).$$

The synergy gain is the positive part

$$\Sigma(T_1, T_2; \tau) := \left(\text{Con}^*(T_1; \tau) + \text{Con}^*(T_2; \tau) - \text{Con}^*(T_1 \cup T_2; \tau)\right)_+.$$

Concept 24 (Colleague)**.** *Appendix label:* `concept:Colleague`*.*
Body definition label: `hsdef:Colleague` *(see § 342).*

Informal definition. *Two people are colleagues when they are working together on the same ongoing project and coordinating with each other as (roughly) peers. They share information, divide up tasks, and repeatedly coordinate their actions toward a shared goal. This is different from a boss/worker relationship, where one person primarily gives commands and the other primarily follows them in exchange for resources.*

Formal definition. *Fix an interval/episode I and agents i, j. We say i and j are* colleagues *on I if there exists a collaborative project during I, meaning a sustained multi-agent pattern of activity aimed at a shared goal (cf. the goal/value machinery of Section 18), such that:*

- *i and j are both recurrent participants in the project activity pattern on I; and*
- *there are repeated coordination acts between them on I (communication and/or artifact-mediated); and*
- *intermediate results are shared between them (messages, plans, partial work-products, or other artifacts).*

Concept 25 (Collective Consciousness Location)**.** *Appendix label:* `concept:CollectiveConsciousnessLocation.`
Body definition label: `hsdef:CollectiveConsciousnessLocation` *(see § ??).*

Informal definition. *A collective consciousness location is a rough "where are we, as a group?" description of a collective mind (or institution, or community) at a time. The idea is that groups can be in different qualitative regimes: highly coordinated and integrated, fragmented into factions, stuck spending most of their energy on internal story/identity maintenance, etc. The location labels (often written $C_0, C_1, C_2, C_3, \ldots$) are meant to summarize these regimes using measurable signals like how much members disagree about what to do (* discord*), and how much of the group's limited resources are spent maintaining narratives/identities (* narrative capture*), along with whatever integration/coherence measures are appropriate for the model.* ***Formal definition.*** *Let $y_i(t)$ denote the policy/proposal signal produced by agent i at time t, and let D_O be a (model-dependent) distance on the space of such signals. Define the (time-t) discord as*

$$D_O(t) := \mathrm{Var}\big(\{y_i(t)\}\big),$$

for some variance functional induced by D_O. Define narrative capture as a scalar $N_O(t) \in [0, 1]$, interpreted as the fraction of the collective resource budget devoted to narrative/identity-maintenance patterns. A collective location C_k (e.g. C_0, C_1, C_2, C_3) is then a qualitative regime describable via thresholds on (at least) discord $D_O(t)$, narrative capture $N_O(t)$, and an (optional/model-dependent) integration/coherence score.

Intuitively, $D_O(t)$ is meant to be representation-relative: changing the ontology (and thus what counts as a "policy/proposal signal") can change which disagreements are visible and how large they appear. The variance functional $\mathrm{Var}(\cdot)$ *should be understood broadly: in Euclidean cases it may reduce to an ordinary sample variance, while in non-Euclidean signal spaces it may be a Fréchet-type variance induced by D_O. In applications, one often distinguishes between within-group discord (variance among a subset of agents) and global discord (variance across all agents), but the definition above is the global time-slice quantity.*

Likewise, $N_O(t)$ is intended to track opportunity cost: resources committed to narrative stabilization are, by construction, resources not directly spent on object-level planning, execution, or epistemic improvement. In a concrete model, $N_O(t)$ may be estimated from observable proxies (e.g. message volume devoted to identity signaling, time allocation to reputational contests, or budget share devoted to legitimacy/branding). The (optional) integration/coherence score is included to allow regimes that have low discord yet still fail to function as an integrated unit (for example, due to brittle coordination channels, incompatible interfaces, or unresolved delegation boundaries).

Concept 26 (Combination)**.** *Appendix label:* `concept:Combination`*.*
Body definition label: `hsdef:Combination` *(see § 111).*

Informal definition. *A combination is just a rule for "putting two things together to get a new thing." Examples include concatenating two strings, composing two actions into a longer action, or combining two subsystems into a larger system. In many settings, not every pair can be combined, so the rule may be only partially defined.*

Formal definition. *A* combination *on a set S is a partial binary operation*

$$* : S \times S \rightharpoonup S.$$

The "partial" arrow $\rightharpoonup$ emphasizes that some pairs $(x, y) \in S \times S$ may have no defined product $x * y$ (e.g. composing two actions that do not match at their interfaces, or combining two modules with incompatible ports). Unless stated otherwise, no algebraic laws are assumed: $*$ need not be associative, commutative, or have an identity. When such laws do hold, they can be added as extra structure (for instance, an associative everywhere-defined $*$ yields an ordinary semigroup operation).

Concept 27 (Combination System)**.** *Appendix label:* `concept:CombinationSystem`*.*
Body definition label: `hsdef:CombinationSystem` *(see § 111).*

Informal definition. *A combination system is the package: a collection of things together with a specified way of combining them. It tells you what objects you are allowed to talk about and what it means (when it is allowed) to combine two of them into one.*

Formal definition. *A* combination system *is a pair $(S, *)$ where S is a set and $* : S \times S \rightharpoonup S$ is a partial binary operation.*

The point of bundling $(S, *)$ is that the meaning of "compositionality" depends on the chosen universe of objects. For example, if S is a set of programs and $*$ is sequential composition, then definability of $x * y$ may encode typing constraints (output type of x matches input type of y). If S is a set of subsystems and $*$ is physical assembly, definability may encode interface compatibility and resource bounds. In Hyperseed-style uses, $(S, *)$ often serves as the target of a representation map: raw processes are mapped into symbols in S, and $*$ specifies which symbolic compositions are considered meaningful.

Concept 28 (Combinational Dynamical Causal Model)**.** *Appendix label:* `concept:CombinationalDynamicalCaus`
Body definition label: `hsdef:CombinationalDynamicalCausalModel` *(see § 114).*

Informal definition. *This is a way of scoring causal influence when outcomes come from interactions. The model assigns a number saying how much "the interaction of a and b caused c." Crucially, the score is required to respect the representational choices you have made: if your representation treats two processes as the same symbol, then the causal model is not allowed to secretly distinguish them. So causality is computed relative to a chosen representational alphabet (and thus relative to an ontology).*

Formal definition. *Let $(D, **)$ be a dynamical process domain. A combinational dynamical causal model is a function*

$$\Gamma : D \times D \times D \to [0, 1],$$

where $\Gamma(a, b, c)$ is interpreted as the degree to which "interaction of a and b caused c." Given a combination-preserving representational mapping $f : D \to S$ into a symbol system $(S, *)$, we say Γ is valid relative to f *if*

$$f(a) = f(a'),\ f(b) = f(b'),\ f(c) = f(c') \implies \Gamma(a, b, c) = \Gamma(a', b', c')$$

for all $a, b, c, a', b', c' \in D$.

The validity condition can be read as an invariance (or quotient) requirement: Γ *must factor through the equivalence relation induced by* f*. Equivalently,* Γ *may depend only on the symbolic triple* $(f(a), f(b), f(c))$ *and not on any hidden micro-details of* a, b, c *that are erased by the representation. This captures the idea that causal attributions are ontology-relative: choosing a coarser* f *forces a coarser causal model, while choosing a finer* f *permits (but does not guarantee) more discriminating causal scores.*

The role of "combination-preserving" is to ensure that the interaction notion in D *aligns with the symbolic combination in* S*, so that when the domain says "*a *interacts with* b*" the representation can express that interaction as a well-formed composition. In many concrete instantiations,* Γ *may be derived from counterfactual comparisons, perturbation experiments, information-theoretic influence measures, or learned attribution models; the definition above isolates only the structural constraint needed for representation consistency.*

Concept 29 (Combinatorial-Categorical Pattern)**.** *Appendix label:* `concept:CombinatorialCategoricalPattern` *Body definition label:* `hsdef:CombinatorialCategoricalPattern` *(see § 110).*

Informal definition. *A combinatorial-categorical pattern is a pattern you find after you first convert a structure into a new "feature space" using a categorical construction. The point is to get a clean docking point between (1) categorical ways of building derived structures (which can expose important relationships) and (2) pattern mining on combinatorial/labeled objects. You first use the categorical machinery to produce a derived labeled structure, and then you search for compressive regularities (patterns) in that derived object.*

Formal definition. *Fix a context* C *and assume a pattern mining scheme has been defined on labeled structures. A pattern candidate* P *is a combinatorial-categorical pattern in* S *relative to* T *and* m_0 *if* P *is a (standard) pattern in the derived structure* $\mathrm{sub}(T, S, m_0)$*.*

The derived object $\mathrm{sub}(T, S, m_0)$ *should be thought of as a categorical "view" of the original data, constructed so that certain morphisms, limits/colimits, slices, or other categorical operations become explicit as combinatorial labels. The purpose of this two-step definition is modularity: any improvements in the categorical construction (better derived representation) or in the pattern mining scheme (better search and scoring of regularities) can be swapped in without changing the surrounding conceptual interface.*

Concretely, a typical workflow is: start with a structure S *(e.g. a labeled graph, a process network, or a database instance), apply a categorical recipe determined by* T *and* m_0 *(e.g. form a subobject classifier-like encoding, compute a pullback-derived relation, or construct a fibered representation), then mine frequent or compressive substructures in the resulting labeled object. Patterns found at this level can correspond to non-obvious regularities in the original structure because the categorical step can expose invariants or interaction motifs that are not syntactically adjacent in the raw representation.*

Concept 30 (Computers and Programs)**.** *Appendix label:* `concept:ComputersAndPrograms`*.* *Body definition label:* `hsdef:ComputersAndPrograms` *(see § 65).*

Informal definition. *A computer is a machine that can be cheaply reconfigured to behave like many different other machines. A program is the set of signals (instructions) you give it to specify which behavior it should emulate. The key idea is not "electronic" versus "mechanical," but flexible emulation under modest reconfiguration effort.*

Formal definition. *A computer is a machine* C *equipped with:*

(a) a set (or category) of admissible programs Syn_C *(the program signals the user can provide); and*

(b) an execution mechanism that, for many $p \in \mathrm{Syn}_C$, yields a physical realization of $[\![p]\!]$ (Definition 360 below);

such that the family $\{[\![p]\!] : p \in \mathrm{Syn}_C\}$ spans (approximately) a large variety of machine behaviors within the relevant engineering domain, and reconfiguration (from p to p') has modest effort cost for the relevant user class.

The phrase "set (or category)" is meant to allow both unstructured program collections and richer situations where programs have compositional structure (e.g. typing, compilation stages, or program transformations as morphisms). The approximation qualifier in "spans (approximately)" acknowledges practical limits: real devices only emulate behaviors within some tolerance, resource envelope, and timescale. The "relevant user class" clause makes the notion explicitly socio-technical: a system may be a computer for one class of users (who can reconfigure it easily) but not for another (for whom reconfiguration is effectively impossible due to tooling, access control, or required expertise).

In this framing, a "program" is primarily an externally supplied control signal drawn from Syn_C, and $[\![p]\!]$ denotes the behavior (or behavior-specification) realized when the machine is run under that control. This definition is intended to encompass digital computers, reconfigurable hardware, programmable biological or chemical systems (where Syn_C may be a set of intervention protocols), and mechanical computers, provided the reconfiguration cost remains modest relative to the intended domain of use.

Concept 31 (Compassion)**.** *Appendix label:* `concept:Compassion`*.*
Body definition label: `hsdef:Compassion` *(see § 18.3 and § 18.4.1).*

Informal definition. *Compassion means that you treat other beings' suffering and well-being as something that matters in your decisions. A compassionate choice is one that tends to help others (reduce their suffering and/or increase their happiness), even if it does not directly benefit you.*

Formal definition. *Let A be a set of agents and fix an acting agent $a \in A$. Assume that for each $b \in A$ we have p-bit (outcome-evidence) evaluations*

$$JO_b(s,a) \in V \quad \textit{and} \quad WO_b(s,a) \in V$$

representing (respectively) evidence for joy and woe outcomes for agent b when the acting agent takes action a in situation/state s. Define the aggregated other-joy and other-woe fields by

$$EO_{\to j}(s,a;\mathrm{joy}) := \bigoplus_{b \in A \setminus \{a\}} JO_b(s,a), \qquad EO_{\to w}(s,a;\mathrm{woe}) := \bigoplus_{b \in A \setminus \{a\}} WO_b(s,a).$$

Define the compassion evaluation field by combining "others' joy" with "not others' woe":

$$EO(s,a;\mathrm{compassion}) \ := \ \frac{1}{2}\, EO_{\to j}(s,a;\mathrm{joy}) \ \otimes \ \frac{1}{2}\, \neg EO_{\to w}(s,a;\mathrm{woe}),$$

where $\neg$ is p-bit negation (swapping positive/negative evidence components) and $\oplus, \otimes$ are the chosen aggregators in the core quantale.

Concept 32 (Compositional Simplicity)**.** *Appendix label:* `concept:CompositionalSimplicity`*.*
Body definition label: `hsdef:CompositionalSimplicity` *(see § 30.5).*

Informal definition. *An object is compositionally simple if you can build it out of a small number of parts, where each part is itself simple, and the way the parts fit together is not complicated.*

In other words: the whole looks complicated only until you discover the right "break it into pieces" description, after which it becomes simple again.

Formal definition. *Fix a combination operation $*$ on entities (Section 9) and a base simplicity score $s_C : X \to [0, \infty]$ (relative to context C). Define the compositional simplicity score*

$$s_C^*(x) \;:=\; \inf\left\{\sum_{i=1}^{n} s_C(x_i) \;:\; x = x_1 * x_2 * \cdots * x_n\right\}.$$

We call x compositionally simple *(in context C) if $s_C^*(x)$ is small and the infimum is achieved (or well-approximated) by a decomposition in which each component x_i is itself simple according to s_C.*

Concept 33 (Concrete)**.** *Appendix label:* `concept:Concrete`.
Body definition label: `hsdef:Concrete` *(see § 28.3).*

Informal definition. *Something is concrete (in a given context) if it has enough specific detail that you cannot harmlessly lump it together with lots of other things. If you try to compress or "abstract away" too much, you quickly lose important distinctions that matter for what you are doing. Concrete things resist being treated as interchangeable.*

Formal definition. *Fix a context C and a family of concreteness/abstraction constraints K_c (Hyperseed-Concept 124). Let X_C be the entity-domain as represented in context C. We say that $x \in X_C$ is C-*concrete *if, for every admissible abstraction (quotienting) map*

$$q : X_C \twoheadrightarrow A$$

that respects the constraints K_c, the fiber $q^{-1}(q(x))$ is small (i.e., x is not merged with many other distinct entities without violating K_c). Informally: no K_c-admissible abstraction can identify x with a large equivalence class of other items.

Concept 34 (Conscious / Unconscious)**.** *Appendix label:* `concept:ConsciousUnconscious`.
Body definition label: `hsdef:ConsciousUnconscious` *(see § 695).*

Informal definition. *A thought, perception, or feeling is* conscious *when it is in your mental spotlight: you can notice it, report it, and it can influence many other things you do (planning, speech, deliberate action). Something is* unconscious *when it is still being processed, but only in the background: it may guide you indirectly (habits, reflexes, priming) without becoming a reportable, globally shared "workspace" content.*

Formal definition. *Let L_{Ob} be the observation language and let an evidence state be a map $E : L_{\mathrm{Ob}} \to V$. Let W be the workspace operator (Definition 228). We say that E is* workspace-stable *if*

$$W(E) = E$$

(Definition 229). We say that E is a conscious evidence state *if it is workspace-stable and reachable from module integration:*

$$E = W(\Gamma_a(E^\bullet))$$

for some module-level evidence collection $E^\bullet$ and attention profile a (Definition 229). Given a threshold θ, define the conscious proposition set *of E by*

$$\mathrm{Con}_\theta(E) \;:=\; \{\varphi \in L_{\mathrm{Ob}} : E^+(\varphi) \geq \theta\},$$

where $E^+(\varphi)$ is the positive-evidence component of the p-bit $E(\varphi)$. A proposition φ is called conscious at E *if $\varphi \in \mathrm{Con}_\theta(E)$, and* unconscious at E *otherwise.*

Concept 35 (Consciousness). *Appendix label:* `concept:Consciousness`*.*
Body definition label: `hsdef:Consciousness` *(see § 239).*

Informal definition. *Consciousness is the overall condition of having an integrated "point of view" inside a mind: some information is not just processed locally, but becomes globally available so that many different parts of the mind can use it. This is what makes a mind able to have a unified, reportable experience that can guide deliberate reasoning and action, rather than just running isolated background routines.* ***Formal definition.*** *Using the workspace operator W and module-integration maps Γ_a (Definitions 228–229), define the set of reachable workspace-fixed points*

$$\mathrm{ConscStates}(M) \;:=\; \left\{ E \in V^{L_{\mathrm{Ob}}} \;:\; E = W(E) \;\; \textit{and} \;\; \exists (E^{\bullet}, a) \textit{ with } E = W(\Gamma_a(E^{\bullet})) \right\}.$$

We say that the mind-model M has consciousness at threshold θ *if there exists $E \in \mathrm{ConscStates}(M)$ such that $\mathrm{Con}_{\theta}(E)$ is nonempty (where Con_{θ} is as in Concept 34). Informally: M has at least one nontrivial, stable, globally-integrated evidence state with some reportable content.*

Concept 36 (Contexts and Aspects). *Appendix label:* `concept:ContextsAndAspects`*.*
Body definition label: `hsdef:ContextsAndAspects` *(see § 35.2).*

Informal definition. *A context is a particular "lens" for looking at things that decides what differences you care about and what differences you ignore. An aspect is the simplified description you get after applying that lens (for example: just the color, just the shape, just the role in a story). Changing context changes what counts as "the same" and what patterns you can notice and talk about.*

Formal definition. *A context structure is modeled as a poset $(\mathrm{Ctx}, \sqsubseteq)$, where $C \sqsubseteq D$ means that D is a finer (more detailed) context than C. For each $C \sqsubseteq D$ there is an aspect-extraction (forgetful) map*

$$\mathrm{Ext}_{D\to C} : X_D \to X_C$$

satisfying the functoriality/compatibility condition: if $C \sqsubseteq E \sqsubseteq D$, then

$$\mathrm{Ext}_{D\to C} \;=\; \mathrm{Ext}_{E\to C} \circ \mathrm{Ext}_{D\to E}.$$

For $x \in X_D$, we write $x|_C := \mathrm{Ext}_{D\to C}(x)$ for "the aspect of x seen in context C."

Concept 37 (Control). *Appendix label:* `concept:Control`*.*
Body definition label: `hsdef:Control` *(see § 36.6).*

Informal definition. *To control an outcome means that by choosing an action, you can reliably make that outcome happen (or prevent it). For example, you control "the light turns on" if flipping the switch usually makes the light turn on. In this framework, control is not a mysterious extra ingredient: it is measured by how strongly an action implies a goal.*

Formal definition. *Let $\mathcal{A} \subseteq E$ be a designated set of action event types and let $G \in E$ be a goal condition. For $A \in \mathcal{A}$ define the control strength of A over G by*

$$\mathrm{Ctrl}_{O,\Delta}(A \to G) \;:=\; \mathrm{CImp}_{O,\Delta}(A, G),$$

i.e., control is causal implication restricted to antecedents interpreted as actions (relative to observer/context O and lag window Δ).

Concept 38 (Control Hierarchy). *Appendix label:* `concept:ControlHierarchy`*.*
Body definition label: `hsdef:ControlHierarchy` *(see § 36.6).*

Informal definition. *A control hierarchy is when control is organized in layers: higher-level parts of a system set goals, priorities, or constraints, while lower-level parts handle the detailed* *execution. The ordering does not need to be a single chain; in real systems, some modules may be incomparable or form local loops, but there is still a general "above/below" direction in who constrains whom.*

Formal definition. *A control hierarchy is a partial order* $(\mathcal{M}, <)$ *on a family of modules* $\mathcal{M}$ *such that*

$$M_1 < M_2$$

is aligned with the interpretation "module M_1 *has (potentially asymmetric) control over module* M_2*."*

Concept 39 (Cosmos and Eurycosmos)**.** *Appendix label:* `concept:CosmosAndEurycosmos`*.*
Body definition label: `hsdef:CosmosAndEurycosmos` *(see § 25.5 and § 25.8).*

Informal definition. *We use* cosmos *for "the whole world" as seen from a particular stable viewpoint (often the everyday physical world for an embodied mind). But different minds, or different ways of sensing and coupling to the world, can pick out different "whole worlds" (different cosmos notions). The* eurycosmos *is the bigger collection you get when you consider all these different cosmos notions together across many minds.*

Formal definition. *Let* SigClass *be a set of signal classes. For an observer/mind* S*, a signal class* $C \in \mathrm{SigClass}$*, and a threshold* η*, let* $\mathrm{Univ}_{C,\eta}(S)$ *denote the observer-indexed universe induced by* C *(Definitions 395–396). Fix (when appropriate) a canonical signal class* C_{can} *(e.g. a "physical/body-channel" class for embodied minds). Define the* cosmos *of* S *(at threshold* η*) by*

$$\mathrm{Cosmos}_\eta(S) \;:=\; \mathrm{Univ}_{C_{\mathrm{can}},\eta}(S).$$

For a collection of minds Mind*, define the* eurycosmos *(compare the eurycosm construction) by*

$$\mathrm{Eurycosmos}_\eta(\mathrm{Mind}) \;:=\; \bigcup_{S\in\mathrm{Mind}} \; \bigcup_{C\in\mathrm{SigClass}} \mathrm{Univ}_{C,\eta}(S),$$

i.e., the union of the observer-indexed universes (and thus cosmos notions) induced across minds and signal classes.

Concept 40 (Creative Inspiration)**.** *Appendix label:* `concept:CreativeInspiration`*.*
Body definition label: `hsdef:CreativeInspiration` *(see § 17.7.1).*

Informal definition. *Creative inspiration is a temporary state where parts of your mind that do not usually talk to each other suddenly connect, so that you can form new combinations of ideas. In that moment, unusual associations become easy, new metaphors and solutions appear, and later you can evaluate and refine them.*

Concept 41 (Culture)**.** *Appendix label: concept:Culture.*
Body definition label: hsdef:Culture (see § 343).

Informal definition. *A culture is the collection of shared habits, beliefs, stories, norms, skills, and ways of doing things that people in a society learn from each other and pass along. Culture is not only "what everyone agrees on": it also includes widely shared disputes, tensions, and mixed messages (for example, a society can strongly praise and strongly criticize the same practice in different places or subgroups).*

Formal definition. *A cultural state for a society is a population-level intensity assignment*

$$C : \mathcal{P} \to [0,1] \qquad \textit{or} \qquad C : \mathcal{P} \to V,$$

defined as an aggregation of individual intensities and artifact-embedded intensities, e.g.

$$C(P) := \left(\bigoplus_{i \in A} w_i \otimes I_i(P) \right) \oplus \left(\bigoplus_{a \in \mathcal{A}} u_a \otimes I_a(P) \right),$$

where A is the agent population, $\mathcal{A}$ is the set of shared artifacts, w_i, u_a are weights (importance, population fraction, accessibility), and $\otimes$ is scalar or p-bit scaling as in Section 22.5. A culture at threshold θ is the set

$$\mathrm{Cult}_\theta := \{P \in \mathcal{P} : \pi(C(P)) \geq \theta\},$$

where π is a chosen projection $V \to [0,1]$ if needed.

Concept 42 (Cultural Morality)**.** *Appendix label: concept:CulturalMorality.*
Body definition label: hsdef:CulturalMorality (see § 263).

Informal definition. *A cultural morality is a group's shared "moral background": the values people in the group talk about, which values they treat as most important, what they consider acceptable versus unacceptable, and which rules-of-thumb ("do this", "don't do that") get socially encouraged or punished. People in the same group can disagree, but a cultural morality describes what is common enough to shape behavior and social pressure.*

Formal definition. *Let G be a society (or group), and suppose its members share (at least approximately) a value vocabulary D_{val}. A cultural morality for G consists of:*

1. *a group-level evaluative field $E_G : \Omega_G \times D_{\mathrm{val}} \to B$ (e.g. $B = [0,1]^2$ as p-bit truth values), assigning to each outcome/history $\omega \in \Omega_G$ and each value dimension $d \in D_{\mathrm{val}}$ an evaluation $E_G(\omega; d)$;*

2. *for each $d \in D_{\mathrm{val}}$, a weight $\lambda_d^{(G)}$ and thresholds $\tau_d^{(G)}, \eta_d^{(G)}$ encoding group-level importance and adequacy/aspiration cutoffs on that dimension;*

3. *a set of socially endorsed maxims $M(G)$ (with some prevalence/strength measure, e.g. N_G), where maxims in $M(G)$ have high social resonance (Sections 12 and 18.5) in the sense that they are reinforced by communication and imitation.*

Concept 43 (Dependency)**.** *Appendix label: concept:Dependency.*
Body definition label: hsdef:Dependency (see § 1).

Informal definition. *A dependency is a "prerequisite" relationship: concept A depends on concept B if you cannot really define or use A until you already have B in place. The Hyperseed concept inventory is organized using a dependency graph so that earlier concepts supply the ingredients needed for later ones. When two ideas seem mutually dependent in the original presentation, the formal writeup may pick a direction just to keep the exposition moving.*

Formal definition. *Let $\mathcal{C}$ be the set of Hyperseed concepts (as listed in Appendix B). An expository dependency DAG is a directed acyclic graph $G = (\mathcal{C}, \to)$ such that for concepts $A, B \in \mathcal{C}$, an edge $A \to B$ means:*

"In this paper's formalization, the definition (or primary semantics) of B uses A as a primitive or as an already-

If the original Hyperseed presentation treats A and B as mutually interdefinable, we may still orient one direction for exposition; such choices are explicitly recorded as "cuts".

Concept 44 (Dependency Tower). *Appendix label: concept:DependencyTower.*
Body definition label: hsdef:DependencyTower (see § 511).

Informal definition. *A dependency tower is a way to build progressively better "simplified versions" of something complicated. The kth level represents what you can capture if you are only allowed to use dependencies of complexity up to level k (or only run tests up to that level). Each level must match the original on everything a k-limited observer could check, and among all models that match those checks, you pick the simplest or best one according to the chosen semantics (for example, least-squares error in a Hilbert-space model).*

Formal definition. *A dependency tower for F is a family $\{F_{\leq k}\}_{k\geq 0}$ such that:*

1. *(Monotonicity) $F_{\leq k}$ becomes more faithful as k increases.*
2. *(k-ary indistinguishability) For all $O \in \mathcal{O}_{\leq k}$, $O(F_{\leq k}) = O(F)$.*
3. *(Optimality/minimality) Among all G satisfying the same indistinguishability constraints, $F_{\leq k}$ is "best" in the chosen semantics (e.g. minimal L^2 error).*

Concept 45 (Development). *Appendix label: concept:Development.*
Body definition label: hsdef:Development (see § 219). ***Informal definition.*** *Development is a kind of change over time where a system stays recognizably "the same system" (it keeps its identity and doesn't randomly reset), but it gains abilities: it can do more things, or do the same things better, across time. Importantly, development is not just adding new tricks; it also tends to keep earlier abilities instead of throwing them away.*

Formal definition. *Fix a context C and a system S with a self-continuity score* $\mathrm{SCS}(\,\cdot \to \cdot\,)$ *between time-intervals and a capability profile* $\mathrm{Cap}_S(\,\cdot\,)$ *on intervals. A development path for S in C is a sequence of intervals*

$$I_0 \to I_1 \to I_2 \to \cdots$$

such that:

1. *(Continuity) there exists a threshold θ such that for all k,*
$$\mathrm{SCS}(I_k \to I_{k+1}) \geq \theta.$$
2. *(Expanding capability) for infinitely many k,*
$$\mathrm{Cap}_S(I_k) \prec \mathrm{Cap}_S(I_{k+1}).$$
3. *(Enrichment bias) for typical goals/tasks $g \in T_C$ such that* $\mathrm{Cap}_S(I_k)(g)$ *is high, the value* $\mathrm{Cap}_S(I_{k+1})(g)$ *does not sharply decrease (new capability tends to come with retention rather than catastrophic loss).*

Concept 46 (Difference). *Appendix label: concept:Difference.*
Body definition label: hsdef:Difference (see § 28.1).

Informal definition. *A difference is how much one thing fails to match another, relative to what you care about in the moment (the context). In Hyperseed this is often treated as directed: "how does x differ from y?" can be different from "how does y differ from x" because one item might be a rough template and the other a detailed, noisy instance (so the instance may fit the template better than the template fits the instance).*

Formal definition. *Given a context c, define the directed difference evaluator*

$$\mathrm{Diff}_c(x \to y) := \delta_c(x, y) \in V.$$

The positive channel $\mathrm{Diff}_c(x \to y)^+$ *is evidence that* x *diverges from* y*. The negative channel* $\mathrm{Diff}_c(x \to y)^-$ *is evidence that* x *does not diverge from* y *(e.g.* x *is absorbed into, explained by, or indistinguishable-from* y *along the relevant aspect).*

Concept 47 (Dissonance)**.** *Appendix label: concept:Dissonance.*
Body definition label: hsdef:Dissonance (see § 24).

Informal definition. *When multiple influences pull in different directions, they can partly cancel out. Dissonance measures how much cancellation happens when you combine a bunch of "vector-like" contributions: if they mostly agree, cancellation is small; if they strongly disagree, cancellation is large.*

Formal definition. *Let* $a = (a_i)_{i \in I}$ *be a finite family of complex numbers (phasors). Define*

$$\mathrm{Res}(a) := \left| \sum_{i \in I} a_i \right|, \qquad \mathrm{Dis}(a) := \sum_{i \in I} |a_i| - \mathrm{Res}(a).$$

Thus $\mathrm{Dis}(a)$ *is large when the phasors point in different directions and cancel in the sum.*

Concept 48 (Distinction)**.** *Appendix label: concept:Distinction.*
Body definition label: hsdef:Distinction (see § 30.2).

Informal definition. *A distinction is a rule for what you treat as "the same" versus "different". Two things are distinct for you if your current way of looking keeps them separate; they are indistinct if you lump them together as "close enough". Distinctions depend on context, and in real life they can be imperfect or asymmetric (you might treat* x *as indistinct from* y *for a purpose even though you would not treat* y *as indistinct from* x*).*

Formal definition. *Fix a finite universe* X *(of entities, states, events, or features relevant in context* C*). An indistinction policy is a subset* $H \subseteq X \times X$*, interpreted as:*

- xHy *means "*x *is treated as indistinct from* y*" (the observer does not distinguish* x *from* y*).*

No symmetry, reflexivity, or transitivity is assumed in general. Write $H_C \subseteq \mathcal{P}(X \times X)$ *for the set of admissible policies for context* C*. A (directed) distinction is then any ordered pair* (x, y) *such that* $(x, y) \notin H$*.*

Concept 49 (Dreaming)**.** *Appendix label: concept:Dreaming.*
Body definition label: hsdef:Dreaming (see § 17.7.1).

Informal definition. *Dreaming is a state in which most of what you experience is generated from inside your own mind (images, stories, emotions), with relatively weak control from current sensory input. Because the outside world is not strongly steering the stream, the mind can jump between scenes, blend ideas, and form narratives that would be unlikely in ordinary waking life.*

Formal definition. *In the regime-parameter description of conscious modes (Section 17.7.1), dreaming corresponds to low external coupling* λ_{ext}*, high internal coupling* λ_{int}*, variable reflective coupling* λ_{ref}*, and a lower coherence preference (allowing more internally generated blends and narrative jumps).*

Concept 50 (Effort)**.** *Appendix label: concept:Effort.*
Body definition label: hsdef:Effort (see § 30.1).

Informal definition. *Effort is the cost of doing something: how much time, energy, attention, or other resources it takes. Doing two steps in a row usually costs about the sum of their efforts, and when you have a choice between ways to do something, you usually pick the cheaper way. Hyperseed* *models effort using a simple algebraic structure that makes these common-sense rules precise and usable inside the later math.* ***Formal definition.*** *Let*

$$E := ([0, \infty], \geq, \inf, +, 0),$$

where the order is reversed (so that $a \leq_E b$ means $a \geq b$ as real numbers), the join in the quantale order is inf *(ordinary minimum), and the monoidal product is + (sequential composition of costs) with unit 0. Then E is a commutative quantale: + distributes over arbitrary infima, i.e.*

$$a + \inf_i b_i \ = \ \inf_i (a + b_i).$$

Concept 51 (Abstract)**.** *Appendix label: concept:Abstract.*
Body definition label: hsdef:Abstract (see § 28.3).

Informal definition. *Something is* abstract *when you treat many different concrete examples as the same kind of thing, by ignoring details that do not matter for your current purpose. For instance, many different handwritten marks can all count as the letter "A," and many different physical triangles can all count as "a triangle." Abstracting is a controlled kind of forgetting: you keep what is shared and drop what is incidental.*

Formal definition. *Let c be a context with entity set X_c. An abstraction of c is a surjection*

$$q : X_c \twoheadrightarrow A$$

to a set A of abstracta. The abstraction collapses distinctions by identifying elements of the same fiber. Equivalently, q determines an equivalence relation

$$x \sim_q y \iff q(x) = q(y).$$

Concept 52 (After)**.** *Appendix label: concept:After.*
Body definition label: hsdef:After (see § 7.1).

Informal definition. After *means "later than". Hyperseed models the basic structure of time using the idea of an ordering: some moments/events come after others. To be consistent, nothing can be after itself, and "after" must not produce cycles like "A after B after C after A".*

Formal definition. *A* strict partial order *on a set T is a binary relation $<$ on T such that:*

1. *(Irreflexive) for all $t \in T$, not $(t < t)$,*

2. *(Transitive) for all $t_1, t_2, t_3 \in T$, if $t_1 < t_2$ and $t_2 < t_3$ then $t_1 < t_3$.*

We say t_1 is before *t_2 if $t_1 < t_2$, and t_2 is* after *t_1.*

Concept 53 (Aesthetics / Art)**.** *Appendix label: concept:AestheticsArt.*
Body definition label: hsdef:AestheticsArt (see § 383).

Informal definition. *In Hyperseed, something counts as* art *(relative to a group of people) if encountering it tends to reliably trigger an experience of beauty for many of them. The key point is that art is not defined only by the object in isolation: it is defined by the object* and *the way it affects a population of experiencers. Different communities can disagree about what is art, because their typical reactions can differ.*

Formal definition. *Fix a class of experiencers $X \subseteq \mathrm{Mind}$. An art object A (relative to X) is any entity such that, for many $m \in X$, encountering A induces a designated beauty proposition* $\mathrm{Beaut}(A)$ *in m's valuation. Equivalently, it induces a high rate of beauty episodes in the population X.*

Concept 54 (Alive / Dead)**.** *Appendix label: concept:AliveDead. Body definition label: hsdef:AliveDead (see § 41.6).*

Informal definition. Alive *and* dead *are treated as time-dependent, evidence-based notions. Roughly: "dead now" is not just "not alive now," but "was alive recently and is not alive now." This matches ordinary thinking (something can be uncertain or borderline), and it also allows conflicting evidence streams (some signs of life, some signs of death).*

Formal definition. *Fix a lookback window length $\tau \in \mathbb{N}$. Define the "was-alive" evidence by*

$$\mathrm{WasAlive}_O(S,t) \;:=\; \bigoplus_{u\in\{t-\tau,\ldots,t-1\}} \mathrm{Alive}_O(S,u),$$

where $\oplus$ is the p-bit *join (componentwise max) from Section 3.4. Define*

$$\mathrm{Dead}_O(S,t) \;:=\; \mathrm{WasAlive}_O(S,t) \otimes \neg\, \mathrm{Alive}_O(S,t),$$

using the p-bit *negation and monoidal product $\otimes$ from the core.*

Concept 55 (Algebraically Asymmetric Physical Reality)**.** *Appendix label: concept:AlgebraicallyAsymmetricPhysic Body definition label: hsdef:AlgebraicallyAsymmetricPhysicalReality (see § 25.4).*

Informal definition. *Hyperseed claims there is a built-in mismatch between how* physics *is structured and how* mental / intersubjective *descriptions usually work. A mental description often keeps only coarse, relational, or pattern-level facts ("these things are connected", "this resembles that") and leaves out many precise details (exact geometry, forces, equations, etc.). Because of that loss of detail, you usually cannot reconstruct the full physical situation from the mental-level description alone: going from "mental" back to "physical" requires adding extra structure and constraints. This one-way loss is the "algebraic asymmetry."*

A useful way to read the claim is: when we pass from the physical world to a shared description of it, we are performing an abstraction *in the sense of Concept 51 (many distinct physical microstates are treated as "the same situation" for communicative, cognitive, or practical purposes). The asymmetry is that this abstraction is typically* many-to-one*, so the inverse problem—recovering the original microstate from the abstracted report—is underdetermined. In everyday terms: multiple distinct physical configurations can support the same appearance, the same narrative, or the same coarse causal graph, and the mental/intersubjective level does not (by default) carry the additional degrees of freedom needed to pick the unique physical realization.*

This is "algebraic" because the mismatch is not merely epistemic ("we do not know") but structural: the map from a more structured domain (physics) to a less structured domain (mental/intersubjective description) behaves like a structure-forgetting morphism. For example, if a mental model keeps adjacency information (a graph of "connected to") while the physical model has full geometry, then distinct geometries can induce the same graph; the relational signature is invariant under many physical deformations, so information has been quotiented out.

Formal definition. *Let* **Phys** *be a category (or structured state space) of physical situations, and let* **Ment** *be a category of mental/intersubjective descriptions (e.g. relational models, coarse narratives, pattern summaries). An* abstraction/forgetful map *is a functor (or homomorphism)*

$$U : \mathbf{Phys} \to \mathbf{Ment}$$

that sends each physical situation to its associated mental-level description by discarding some physical structure. We say physical reality is algebraically asymmetric *(relative to* **Ment***) when this map is not reconstructible up to equivalence; concretely, the following conditions hold generically:*

1. *(Many-to-one on situations) there exist* $P_1 \not\cong P_2$ *in* **Phys** *such that*

$$U(P_1) \cong U(P_2)$$

in **Ment***, i.e. distinct physical situations induce equivalent mental-level descriptions;*

2. *(No inverse without extra choices) there is no functor* $R : \mathbf{Ment} \to \mathbf{Phys}$ *such that*

$$U \circ R \cong \mathrm{Id}_{\mathbf{Ment}} \quad \text{and} \quad R \circ U \cong \mathrm{Id}_{\mathbf{Phys}},$$

so U *does not present* **Ment** *as merely a re-labeling of* **Phys** *(it is not an equivalence of categories, nor does it admit a canonical section on the physical side).*

Equivalently (in set-level terms), one may treat U *as inducing a surjection on underlying sets of situations, with fibers* $U^{-1}(M)$ *typically containing multiple physically distinct realizations of the same mental-level description* M*. Reconstructing a physical candidate from* M *then requires adding external constraints (priors, measurements, dynamics, symmetry-breaking conventions, etc.), which are not contained in* M *itself.*

Concept 56 (Answers)**.** *Appendix label: concept:Answers.*
Body definition label: hsdef:Answers (see § 292).

Informal definition. *An* answer *is defined by what it does, not by what it looks like. It is anything that helps resolve a question by shrinking the set of reasonable possibilities. A complete answer might identify the exact right choice, but many useful answers are partial: they can rule out options, tell you where to look, or tell you which options are more likely.*

Formal definition. *An answer to a question* (τ, Exp) *is any artifact that reduces uncertainty about* $\mathrm{Inst}(\tau)$*. Concretely, an answer may be:*

- *a particular instantiation* $\iota \in \mathrm{Inst}(\tau)$*;*
- *a constraint* $C \subseteq \mathrm{Inst}(\tau)$ *that prunes candidates;*
- *a distribution (or* p-bit*-valued scoring) over* $\mathrm{Inst}(\tau)$*; or*
- *any representation that yields an entropy reduction or computational simplification relative to baseline inference.*

Concept 57 (Anthropic Principle)**.** *Appendix label: concept:AnthropicPrinciple.*
Body definition label: hsdef:AnthropicPrinciple (see § 25.9).

Informal definition. *The anthropic principle is treated as a plain selection effect: the fact that* you exist as an observer *is information. So when comparing different models of the universe, you should downweight models in which observers like you could not exist, and upweight models where observers are likely. This is not an "explanation" of why the universe is the way it is; it is a rule for how an observer should update beliefs given that the observer exists.*

Formal definition. *Let* Θ *be a parameter space of universe models (physical constants, laws, initial conditions, etc.). Let* $\pi(\theta)$ *be a prior distribution over* Θ*. Let* A *be an "anthropic" event such as "observers of type* O *exist." The anthropic posterior is*

$$\pi(\theta \mid A) \propto \pi(\theta)\, P(A \mid \theta).$$

Concept 58 (Archetypes)**.** *Appendix label: concept:Archetypes.*
Body definition label: hsdef:Archetypes (see § 382).

Informal definition. *An* archetype *is a recognizable template that shows up across many different systems (people, stories, cultures, texts, etc.) even though the detailed versions can differ a lot. For example, "the trickster" or "the hero" can appear in many cultures with different names and plots. Hyperseed emphasizes three features: it appears in many places, the instantiations are not mere copies, and the widespread appearance is not trivial (it is "surprising" given how specific the template is).*

Formal definition. *Fix a class of systems (minds, texts, cultures, etc.) indexed by J. An archetype is a template τ together with an instantiation map sending each $j \in J$ to a (possibly empty) set of instantiations $\mathrm{Inst}_j(\tau)$, such that:*

1. *τ has high support across J (many j have $\mathrm{Inst}_j(\tau) \neq \emptyset$), and*
2. *the typical instantiations are diverse (not near-copies), and*
3. *the support is "surprising" relative to the description complexity of τ (e.g. high occurrence despite nontrivial $\kappa(\tau)$).*

Concept 59 (Association)**.** *Appendix label: concept:Association.*
Body definition label: hsdef:Association (see § 91).

Informal definition. *An* association *score says how strongly two things are linked* in a particular context*. A high association means they tend to show up together, or they share many important properties; a low association means they rarely co-occur and have little in common (for the purposes of that context). The same pair can have different association scores in different contexts, depending on what properties the context cares about.*

Formal definition. *A (static) association score in context C is a symmetric map*

$$\mathrm{assoc}_C : E_C \times E_C \to [0,1]$$

intended to measure "how much A and B tend to occur together" or "how many properties/patterns they share."

(One canonical implementation used later in the text is via overlap between property-sets; see Definition 100.)

Concept 60 (Attention / Attentional Focus)**.** *Appendix label: concept:AttentionalFocus.*
Body definition label: hsdef:AttentionalFocus (see § 37.3).

Informal definition. *Attention is modeled as a limited mental budget spread over many possible things you could be tracking. You have* attentional focus *when most of that budget is concentrated on only a few items, instead of being thinly spread over many. The parameters (θ, k) let you say what counts as "most" (θ) and "a few" (k).* ***Formal definition.*** *Fix parameters $\theta \in (0,1)$ (mass threshold) and $k \in \mathbb{N}$ (size bound). Here θ sets how much of the total attentional weight must be captured to count as "focused," while k limits how many distinct items can jointly constitute that focus (so the definition distinguishes "concentrated" attention from attention that is merely spread across many small contributions). We say S has an attentional focus at time t (at level (θ, k)) if there exists a subset $F_t \subseteq P$ with $|F_t| \leq k$ such that*

$$\alpha_t(F_t) := \sum_{p \in F_t} \alpha_t(p) \geq \theta.$$

Intuitively, F_t is a "small support" witnessing that attention is not diffuse: the set F_t may be thought of as the currently dominant objects, concepts, or processes in P whose combined weight crosses the *threshold. Equivalently, if $\alpha_t^{\downarrow}$ is the nonincreasing rearrangement of the weights $(\alpha_t(p))_{p\in P}$, then focus holds iff*

$$\sum_{j=1}^{k} \alpha_t^{\downarrow}(j) \geq \theta.$$

This rearranged form makes explicit that it suffices to look at the k largest weights at time t: among all subsets of size at most k, the maximum possible total weight is attained by choosing the k heaviest elements, so the condition is independent of how ties are broken when several $p \in P$ share the same weight.

Concept 61 (Autocatalytic Sets)**.** *Appendix label: concept:AutocatalyticSets.*
Body definition label: hsdef:AutocatalyticSets (see § 237).

Informal definition. *An autocatalytic set is a collection of processes (often chemical reactions) that "help make themselves": each process in the collection is sped up (catalyzed) by something produced within the same collection. Because of this mutual support, once the set is present it can keep running and regenerating as long as it keeps getting basic inputs. In this sense, the defining feature is not that the set is closed to matter or energy, but that the* catalytic dependencies *required for activity are internally satisfied: the "control" or "enabling" factors for reactions are generated by the network itself.*

Formal definition. *Fix a threshold $\theta \in (0,1]$. Let R be a finite set of reactions and let $C = (c_{ij})_{i,j\in R}$ be a catalysis matrix with $c_{ij} \in [0,1]$ interpreted as the strength of evidence that reaction i catalyzes reaction j. Define the thresholded reaction graph $G_\theta(R,C)$ to be the directed graph with vertex set R and an edge $i \to j$ iff $c_{ij} \geq \theta$. A subset $S \subseteq R$ is a θ-autocatalytic set if every vertex of the induced subgraph $G_\theta(R,C)[S]$ has in-degree at least one; equivalently, for every $j \in S$ there exists some $i \in S$ with $c_{ij} \geq \theta$. The in-degree condition expresses the minimal "internal support" requirement: each reaction in S has at least one sufficiently strong incoming catalytic link from within S. Note that the definition does not require a single catalyst to support all reactions, nor does it require direct self-loops $j \to j$; support may be distributed across different reactions and may occur via cycles (e.g. i catalyzes j, j catalyzes ℓ, and ℓ catalyzes i). The threshold θ makes the notion robust to weak or noisy evidence by discarding catalytic claims below the chosen confidence/strength level.*

Concept 62 (Becoming)**.** *Appendix label: concept:Becoming.*
Body definition label: hsdef:Becoming (see § 62).

Informal definition. *We say that x* becomes *y when, over time, the system transitions from clearly being (or behaving like) x to clearly being (or behaving like) y. Crucially, the transition is not instant: there is a "boundary period" where the identity is genuinely unclear, so it can be reasonable (given the available evidence) to treat the two as both distinct and not-distinct. Away from that boundary, the two are more cleanly separated again. This captures the common situation in which categories or identities have a stable regime on either side of a change, but the change itself passes through an indeterminate corridor in which classical either/or classification is not well-supported.*

Formal definition. *Fix a proto-time $(T,<)$ and a time-indexed distinction relation* Dist*. We say $x \in E$ becomes $y \in E$ (along $(T,<)$) if there exist $t_1 < t_2$ and an interval (or neighborhood) $U \subseteq T$ with $t_1 \leq u \leq t_2$ for all $u \in U$ such that:*

1. (Temporal succession) *x is salient/present up to (near) t_1 and y is salient/present from (near) t_2 onward.*

2. (Boundary non-duality) *for all $u \in U$ near the transition, x and y display non-dual variety at u.*

3. (Outside the boundary) *away from U, x and y are (comparatively) more distinguishable (e.g.* $\mathrm{Dist}(u; x, y)$ *is not strongly paraconsistent).*

The role of U is to isolate the transition region: it is not required that x and y be indistinguishable throughout all time between t_1 and t_2, but rather that there is a neighborhood around the transition in which evidence of distinctness and evidence of non-distinctness are both materially present (as encoded by the behavior of Dist*). Condition (1) anchors the "before" and "after" regimes so that becoming is directional in time, while (3) ensures the indeterminacy is local rather than pervasive (preventing the definition from collapsing into a permanent ambiguity in which x and y never re-separate).*

Concept 63 (Before)**.** *Appendix label: concept:Before.*
Body definition label: hsdef:Before (see § 56).

Informal definition. *In everyday thinking, "before" is a simple yes/no idea: either one event happened earlier than another, or it did not. In messy real situations, evidence can be incomplete or even conflicting, so we may want a more careful notion. Here, "before" is represented by two numbers: one measuring how much evidence supports "t_1 happened before t_2", and one measuring how much evidence supports the opposite (or otherwise counts against that ordering). This lets the model record uncertainty and disagreement instead of forcing an early all-or-nothing decision. In particular, this two-component representation can encode situations where both directions have some support (e.g. from different witnesses or sensors), as well as situations where neither direction is well supported (lack of information), without conflating these cases.*

Formal definition. *Let $V = [0,1]^2$ be the p-bit quantale from Section 3.4. A p-bit-valued temporal evidence relation is a map*

$$B : T \times T \to V, \qquad B(t_1, t_2) = (B^+(t_1, t_2), B^-(t_1, t_2)).$$

Here $B^+(t_1, t_2)$ is positive evidence for $t_1 < t_2$, and $B^-(t_1, t_2)$ is negative evidence. Conceptually, $B^-(t_1, t_2)$ may be read as evidence for $\neg(t_1 < t_2)$, which can include direct evidence for $t_2 < t_1$ as well as evidence that t_1 and t_2 are simultaneous/overlapping or otherwise not strictly ordered. The codomain $V = [0,1]^2$ keeps these two channels separate, so high B^+ does not automatically force low B^- (and vice versa), matching the intended paraconsistent or non-classical treatment of temporal information.

Concept 64 (Belief System)**.** *Appendix label: concept:BeliefSystem.*
Body definition label: hsdef:BeliefSystem (see § 304).

Informal definition. *A belief system is the connected set of beliefs and reasoning habits that a person or community uses to make sense of the world (Hyperseed-Concept 14). It is not just a pile of separate opinions: the beliefs support each other, explain each other, and guide what counts as evidence. A belief system is called* productive *when it has a stable "core" that does not constantly fall apart, but it is also capable of learning and creating new ideas and questions instead of getting stuck. This definition treats a belief system as partly structural (how beliefs hang together) and partly dynamic (how it responds to evidence and generates new commitments), so productivity is meant to capture both resilience under updating and openness to growth.*

Formal definition. *A belief system (for a community M) is a pair (B, R) where $B \subseteq L$ is a focal belief set and R is a rule set, such that $\mathrm{Coh}_R(B; \beta_M)$ exceeds a chosen threshold. Here B may be interpreted as the currently foregrounded or socially enforced commitments (rather than all entertained propositions), R as the inference/justification norms taken as acceptable within M, and β_M as the community-dependent weighting or evidential state relative to which coherence is evaluated. A belief system is productive if, in addition:*

(a) (Individuation) *there exists a "core" subset $B_{\text{core}} \subseteq B$ that remains stable under typical evidence updates (high persistence of key commitments), and*

(b) (Self-transcendence) *the system regularly generates new high-SAI beliefs or new questions whose answers lead to novel patterns, without collapsing coherence.*

Condition (a) is intended to rule out mere volatility (where the system cannot maintain identity long enough to accumulate insight), while condition (b) is intended to rule out mere rigidity (where the system can remain coherent only by refusing to extend itself). The "without collapsing coherence" clause means that novelty is not counted as productive if it systematically drives $\mathrm{Coh}_R(B; \beta_M)$ below threshold, i.e. if expansion typically produces fragmentation rather than organized growth.

Concept 65 (Beliefs)**.** *Appendix label: concept:Beliefs.*
Body definition label: hsdef:Beliefs (see § 301). Beliefs, in this glossary, are understood as elements of a language L (or appropriately typed cognitive states) that can be aggregated into sets such as $B \subseteq L$ and assessed via community-dependent weights or evidential profiles. In particular, the surrounding concepts treat beliefs not only as isolated propositional contents but as nodes in a network that can receive support, face counterevidence, and shift salience over time, which is why later definitions naturally connect beliefs to coherence measures and to update dynamics.

Informal definition. *A belief is what an agent takes to be true (or likely true), possibly to a degree rather than perfectly. When multiple agents form a community, we can also talk about the community's overall stance by combining individual beliefs. The key idea is to weight each agent's contribution by something like trust, authority, or attention, and then merge the weighted contributions. Allowing weights with a negative component lets the model represent not only trust but also distrust or adversarial influence in a graded way.*

Formal definition. *Let M be a finite set of agents, each with a belief state $\beta_i : L \to V$. Define the community aggregate belief state by*

$$\beta_M(\varphi) := \bigoplus_{i \in M} w_i \otimes \beta_i(\varphi),$$

where weights $w_i \in V$ model trust/authority/attention and the operations are those of the p-bit quantale.

Concept 66 (Big Bounce)**.** *Appendix label: concept:BigBounce.*
Body definition label: hsdef:BigBounce (see § 46.7).

Informal definition. *"Big Bounce" is a speculative cosmology idea (Hyperseed-Concept 16): instead of the universe beginning once and for all in a single Big Bang, the universe might go through cycles where a contraction phase (sometimes called a "Big Crunch") is followed by a "bounce" into a new expansion. In Hyperseed this phrase is used cautiously, mainly as a hypothesis or metaphor for very large-scale cycles and for the possibility that some patterns could persist or reappear across such a transition.*

Concept 67 (Blend)**.** *Appendix label: concept:Blend.*
Body definition label: hsdef:Blend (see § 9.6).

Informal definition. *C is a blend of A and B when C is "mix-like" in the sense that many of the important properties of C are also properties of A or of B. This does not mean C is exactly half-and-half; it means a substantial portion of what characterizes C can be traced to one source or the other.*

Formal definition. *Fix C and choose a threshold $\theta \in (0,1]$. Define the property overlap mass of C with (A,B) as*

$$\mathrm{ov}_C(C;A,B) := \sum_{P\in P_C} \min\Big\{\mathrm{Prop}_C(C)(P),\ \max\big(\mathrm{Prop}_C(A)(P), \mathrm{Prop}_C(B)(P)\big)\Big\}.$$

Define the blend score

$$\mathrm{blendscore}_C(C;A,B) := \begin{cases} \mathrm{ov}_C(C;A,B)/\|\mathrm{Prop}_C(C)\|_1, & \|\mathrm{Prop}_C(C)\|_1 > 0, \\ 0, & \|\mathrm{Prop}_C(C)\|_1 = 0. \end{cases}$$

We say C is a blend of A and B (in context C) if $\mathrm{blendscore}_C(C;A,B) \geq \theta$*.*

Concept 68 (Biological)**.** *Appendix label: concept:Biological.*
Body definition label: hsdef:Biological (see § 286).

Informal definition. *A lifeform is called* biological *if, at the level we are describing it, it is mainly built from organic chemistry (like cells and biochemistry). A lifeform can also be called* synthetic *if it was primarily designed and assembled intentionally by an intelligent engineering process, and* evolved *if it arose through unguided evolutionary and self-organization processes. These labels can overlap (for example, a genetically engineered organism is both biological and engineered), so the framework allows them to be multi-valued or p-bit-valued when needed.*

Formal definition. *A lifeform S is:*

- *biological if its dominant implementation substrate is organic chemistry (at the relevant descriptive level);*
- *synthetic if its design/assembly was primarily guided by an intelligent engineering process (as opposed to arising via unguided population-level dynamics);*
- *evolved if it arose via evolutionary and self-organization processes without intentional design.*

These labels are not mutually exclusive at all descriptive levels (e.g. bio-engineered organisms), so we allow them to be multi-valued or p-bit-valued when needed.

Concept 69 (Biological Lifecycle)**.** *Appendix label: concept:BiologicalLifecycle.*
Body definition label: hsdef:BiologicalLifecycle (see § 286).

Informal definition. *A biological lifecycle is the sequence of typical stages a biological organism goes through as it develops and ages, such as infant, young, mature, old, and elderly, together with the typical transitions between these stages. The point of the concept is to talk about "where in its life" an organism is, not just what it is made of.*

Concept 70 (Cause)**.** *Appendix label: concept:Cause.*
Body definition label: hsdef:Cause (see § 36.5).

Informal definition. *In this framework, "A causes B" is a context-relative claim: it depends on what the observer counts as an event, how time is segmented, and what time-scale is being used. Informally, A causes B when A tends to happen before B, and when information about A makes B more predictable (for example, using co-occurrence statistics such as* $\mathrm{Cond}_{O,\Delta}$ *and lag summaries like* $\mathrm{lag}(A,B)$*). Because the underlying "before/after" structure is treated as observer-relative, causal indicators are also understood as relative to O (and to the chosen window Δ).* ***Formal definition.*** *Fix a lag window Δ and a mixing parameter $\lambda \in [0,1]$. Define the causal implication strength*

$$\mathrm{CImp}_{O,\Delta}(A,B) := \Big(\lambda\,\sigma(\mathrm{PAtt}^{\mathrm{ext}}_{O,\Delta}(A,B)) + (1-\lambda)\,\sigma(\mathrm{PAtt}^{\mathrm{int}}_{O,\Delta}(A,B))\Big) \cdot \mathbf{1}[A \prec B],$$

where $\mathbf{1}[A \prec B]$ *is an indicator that* A *typically precedes* B *in the relevant context, and* $\sigma : [-1,1] \to [0,1]$ *is the affine rescaling* $\sigma(x) = (1+x)/2$*. Define also the strong (product) variant*

$$\mathrm{CImp}^{\times}_{O,\Delta}(A,B) := \sigma(\mathrm{PAtt}^{\mathrm{ext}}_{O,\Delta}(A,B))\ \sigma(\mathrm{PAtt}^{\mathrm{int}}_{O,\Delta}(A,B))\ \mathbf{1}[A \prec B].$$

Concept 71 (Categorical Imperative)**.** *Appendix label:* `concept:CategoricalImperative`*.*
Body definition label: `hsdef:CategoricalImperative` *(see § ??).*

Informal definition. *The categorical imperative is a way to test a proposed rule for action (a "maxim") by asking: "What would happen if everyone followed this rule in relevantly similar situations?" If the world that results from universal adoption of the rule tends to be acceptable along key ethical dimensions (for example compassion, honesty, nonviolence), then the maxim passes the test; if universal adoption would predictably lead to unacceptable outcomes or a self-defeating situation, the maxim fails. In this document, the key idea is to make the test operational: it is evaluated using an observer's world-model and an explicit set of ethical dimensions, rather than being treated as a purely verbal slogan.*

Formal definition. *Fix a set* $D_{\mathrm{eth}} \subseteq D$ *of ethical dimensions (typically including compassion and possibly truth, nonviolence, etc.). Define the universalized ethical evaluation*

$$E^{\mathrm{univ}}_{O}(m; d) := \mathbb{E}_{\omega \sim P_O(\cdot|\mathrm{Univ}(m))}[\, E_O(\omega; d)\,],$$

where $E_O(\omega; d)$ *is the* p-bit *evidence that the realized history* ω *promotes/opposes* d *(obtained by aggregating stepwise evidence across the history using* $\oplus, \otimes$*). We say* m *passes a threshold categorical imperative if*

$$J\big(E^{\mathrm{univ}}_{O}(m; d)\big) \geq \tau_d \quad \textit{and} \quad W\big(E^{\mathrm{univ}}_{O}(m; d)\big) \leq \eta_d \qquad \forall d \in D_{\mathrm{eth}},$$

for fixed thresholds $\tau_d, \eta_d \in [0,1]$*.*

Concept 72 (Closing)**.** *Appendix label:* `concept:Closing`*.*
Body definition label: `hsdef:Closing` *(see § 30.2).*

Informal definition. *A closing is a deliberate move toward* making finer distinctions*. You stop treating some pairs of situations (or objects, or states) as "basically the same" and start treating them as importantly different. In other words, you tighten your indistinction policy: you collapse fewer differences. Closing is the opposite direction of an opening (Hyperseed-Concept 125), which relaxes distinctions by collapsing more pairs.*

Formal definition. *Given two indistinction policies* $H, H' \in H_C$*:*

- *The transition* $H \to H'$ *is an* opening *(relaxation of distinctions) if* $H \subseteq H'$*.*
- *The transition* $H \to H'$ *is a* closing *(tightening of distinctions) if* $H' \subseteq H$*.*

Concept 73 (Cognitive Synergy)**.** *Appendix label:* `concept:CognitiveSynergy`*.*
Body definition label: `hsdef:CognitiveSynergy` *(see § 37.7).*

Informal definition. *Cognitive synergy means that two different kinds of knowledge (or two different reasoning methods) help each other in a way that makes the overall explanation* simpler *than what you could get by using each one separately and then combining the results. Put plainly: when you let the two knowledge sources interact, you can reach the same level of explanatory adequacy with fewer "extra assumptions" or less complicated story-telling.*

Formal definition. *Let* T_1, T_2 *be two disjoint sets of knowledge types and fix* $\tau \in (0,1]$*. We say there is cognitive synergy at level* τ *between* T_1 *and* T_2 *if*

$$\mathrm{Con}^*(T_1 \cup T_2; \tau) < \mathrm{Con}^*(T_1; \tau) + \mathrm{Con}^*(T_2; \tau).$$

The synergy gain is the positive part

$$\Sigma(T_1, T_2; \tau) := \left(\mathrm{Con}^*(T_1; \tau) + \mathrm{Con}^*(T_2; \tau) - \mathrm{Con}^*(T_1 \cup T_2; \tau)\right)_+ .$$

Concept 74 (Colleague)**.** *Appendix label:* `concept:Colleague`*.*
Body definition label: `hsdef:Colleague` *(see § 342).*

Informal definition. *Two people are colleagues when they are working together on the same ongoing project and coordinating with each other as (roughly) peers. They share information, divide up tasks, and repeatedly coordinate their actions toward a shared goal. This is different from a boss/worker relationship, where one person primarily gives commands and the other primarily follows them in exchange for resources.*

Formal definition. *Fix an interval/episode I and agents i, j. We say i and j are* colleagues on *I if there exists a collaborative project during I, meaning a sustained multi-agent pattern of activity aimed at a shared goal (cf. the goal/value machinery of Section 18), such that:*

- *i and j are both recurrent participants in the project activity pattern on I; and*
- *there are repeated coordination acts between them on I (communication and/or artifact-mediated); and*
- *intermediate results are shared between them (messages, plans, partial work-products, or other artifacts).*

Concept 75 (Collective Consciousness Location)**.** *Appendix label:* `concept:CollectiveConsciousnessLocation`*.*
Body definition label: `hsdef:CollectiveConsciousnessLocation` *(see § ??).*

Informal definition. *A collective consciousness location is a rough "where are we, as a group?" description of a collective mind (or institution, or community) at a time. The idea is that groups can be in different qualitative regimes: highly coordinated and integrated, fragmented into factions, stuck spending most of their energy on internal story/identity maintenance, etc. The location labels (often written $C_0, C_1, C_2, C_3, \ldots$) are meant to summarize these regimes using measurable signals like how much members disagree about what to do (* discord*), and how much of the group's limited resources are spent maintaining narratives/identities (* narrative capture*), along with whatever integration/coherence measures are appropriate for the model.*

Formal definition. *Let $y_i(t)$ denote the policy/proposal signal produced by agent i at time t, and let D_O be a (model-dependent) distance on the space of such signals. Define the (time-t) discord as*

$$D_O(t) := \mathrm{Var}\big(\{y_i(t)\}\big),$$

for some variance functional induced by D_O. Define narrative capture as a scalar $N_O(t) \in [0, 1]$, interpreted as the fraction of the collective resource budget devoted to narrative/identity-maintenance patterns. A collective location C_k (e.g. C_0, C_1, C_2, C_3) is then a qualitative regime describable via thresholds on (at least) discord $D_O(t)$, narrative capture $N_O(t)$, and an (optional/model-dependent) integration/coherence score.

Concept 76 (Combination)**.** *Appendix label:* `concept:Combination`*.*
Body definition label: `hsdef:Combination` *(see § 111).*

Informal definition. *A combination is just a rule for "putting two things together to get a new thing." Examples include concatenating two strings, composing two actions into a longer action, or combining two subsystems into a larger system. In many settings, not every pair can be combined, so the rule may be only partially defined.*

Formal definition. *A* combination *on a set S is a partial binary operation*

$$* : S \times S \rightharpoonup S.$$

Concept 77 (Combination System). *Appendix label:* `concept:CombinationSystem`*.*
Body definition label: `hsdef:CombinationSystem` *(see § 111).*

Informal definition. *A combination system is the package: a collection of things together with a specified way of combining them. It tells you what objects you are allowed to talk about and what it means (when it is allowed) to combine two of them into one.*

Formal definition. *A* combination system *is a pair $(S, *)$ where S is a set and $* : S \times S \rightharpoonup S$ is a partial binary operation.*

Concept 78 (Combinational Dynamical Causal Model). *Appendix label:* `concept:CombinationalDynamicalCaus`
Body definition label: `hsdef:CombinationalDynamicalCausalModel` *(see § 114).*

Informal definition. *This is a way of scoring causal influence when outcomes come from interactions. The model assigns a number saying how much "the interaction of a and b caused c." Crucially, the score is required to respect the representational choices you have made: if your representation treats two processes as the same symbol, then the causal model is not allowed to secretly distinguish them. So causality is computed relative to a chosen representational alphabet (and thus relative to an ontology).*

Formal definition. *Let $(D, **)$ be a dynamical process domain. A combinational dynamical causal model is a function*

$$\Gamma : D \times D \times D \to [0, 1],$$

where $\Gamma(a, b, c)$ is interpreted as the degree to which "interaction of a and b caused c." Given a combination-preserving representational mapping $f : D \to S$ into a symbol system $(S, *)$, we say Γ is valid relative to f *if*

$$f(a) = f(a'),\ f(b) = f(b'),\ f(c) = f(c') \implies \Gamma(a, b, c) = \Gamma(a', b', c')$$

for all $a, b, c, a', b', c' \in D$.

Concept 79 (Combinatorial-Categorical Pattern). *Appendix label:* `concept:CombinatorialCategoricalPattern`
Body definition label: `hsdef:CombinatorialCategoricalPattern` *(see § 110).*

Informal definition. *A combinatorial-categorical pattern is a pattern you find after you first convert a structure into a new "feature space" using a categorical construction. The point is to get a clean docking point between (1) categorical ways of building derived structures (which can expose important relationships) and (2) pattern mining on combinatorial/labeled objects. You first use the categorical machinery to produce a derived labeled structure, and then you search for compressive regularities (patterns) in that derived object.*

Formal definition. *Fix a context C and assume a pattern mining scheme has been defined on labeled structures. A pattern candidate P is a combinatorial-categorical pattern in S relative to T and m_0 if P is a (standard) pattern in the derived structure $\mathrm{sub}(T, S, m_0)$.*

Concept 80 (Computers and Programs). *Appendix label:* `concept:ComputersAndPrograms`*.*
Body definition label: `hsdef:ComputersAndPrograms` *(see § 65).* ***Informal definition.*** *A computer is a machine that can be cheaply reconfigured to behave like many different other machines. A program is the set of signals (instructions) you give it to specify which behavior it should emulate. The key idea is not "electronic" versus "mechanical," but flexible emulation under modest reconfiguration effort.*

Formal definition. *A computer is a machine C equipped with:*

(a) a set (or category) of admissible programs Syn_C (the program signals the user can provide); and

(b) *an execution mechanism that, for many $p \in \mathrm{Syn}_C$, yields a physical realization of $[\![p]\!]$ (Definition 360 below);*

such that the family $\{[\![p]\!] : p \in \mathrm{Syn}_C\}$ spans (approximately) a large variety of machine behaviors within the relevant engineering domain, and reconfiguration (from p to p') has modest effort cost for the relevant user class.

Concept 81 (Compassion)**.** *Appendix label:* `concept:Compassion`*.*
Body definition label: `hsdef:Compassion` *(see § 18.3 and § 18.4.1).*

Informal definition. *Compassion means that you treat other beings' suffering and well-being as something that matters in your decisions. A compassionate choice is one that tends to help others (reduce their suffering and/or increase their happiness), even if it does not directly benefit you.*

Formal definition. *Let A be a set of agents and fix an acting agent $a \in A$. Assume that for each $b \in A$ we have p-bit (outcome-evidence) evaluations*

$$JO_b(s,a) \in V \quad \textit{and} \quad WO_b(s,a) \in V$$

representing (respectively) evidence for joy and woe outcomes for agent b when the acting agent takes action a in situation/state s. Define the aggregated other-joy and other-woe fields by

$$EO_{\to j}(s,a;\mathrm{joy}) := \bigoplus_{b \in A\setminus\{a\}} JO_b(s,a), \qquad EO_{\to w}(s,a;\mathrm{woe}) := \bigoplus_{b \in A\setminus\{a\}} WO_b(s,a).$$

Define the compassion evaluation field by combining "others' joy" with "not others' woe":

$$EO(s,a;\mathrm{compassion}) \;:=\; \frac{1}{2}\, EO_{\to j}(s,a;\mathrm{joy}) \;\otimes\; \frac{1}{2}\, \neg EO_{\to w}(s,a;\mathrm{woe}),$$

where $\neg$ is p-bit negation (swapping positive/negative evidence components) and $\oplus, \otimes$ are the chosen aggregators in the core quantale.

Concept 82 (Compositional Simplicity)**.** *Appendix label:* `concept:CompositionalSimplicity`*.*
Body definition label: `hsdef:CompositionalSimplicity` *(see § 30.5).*

Informal definition. *An object is compositionally simple if you can build it out of a small number of parts, where each part is itself simple, and the way the parts fit together is not complicated. In other words: the whole looks complicated only until you discover the right "break it into pieces" description, after which it becomes simple again.*

Formal definition. *Fix a combination operation $*$ on entities (Section 9) and a base simplicity score $s_C : X \to [0,\infty]$ (relative to context C). Define the compositional simplicity score*

$$s_C^*(x) \;:=\; \inf\left\{ \sum_{i=1}^{n} s_C(x_i) \;:\; x = x_1 * x_2 * \cdots * x_n \right\}.$$

We call x compositionally simple *(in context C) if $s_C^*(x)$ is small and the infimum is achieved (or well-approximated) by a decomposition in which each component x_i is itself simple according to s_C.*

Concept 83 (Concrete)**.** *Appendix label:* `concept:Concrete`*.*
Body definition label: `hsdef:Concrete` *(see § 28.3).*

Informal definition. *Something is concrete (in a given context) if it has enough specific detail that you cannot harmlessly lump it together with lots of other things. If you try to compress* *or "abstract away" too much, you quickly lose important distinctions that matter for what you are doing. Concrete things resist being treated as interchangeable.*

Formal definition. *Fix a context C and a family of concreteness/abstraction constraints K_c (Hyperseed-Concept 124). Let X_C be the entity-domain as represented in context C. We say that $x \in X_C$ is C-*concrete *if, for every admissible abstraction (quotienting) map*

$$q : X_C \twoheadrightarrow A$$

that respects the constraints K_c, the fiber $q^{-1}(q(x))$ is small (i.e., x is not merged with many other distinct entities without violating K_c). Informally: no K_c-admissible abstraction can identify x with a large equivalence class of other items.

Concept 84 (Conscious / Unconscious)**.** *Appendix label:* `concept:ConsciousUnconscious`*.*
Body definition label: `hsdef:ConsciousUnconscious` *(see § 695).*

Informal definition. *A thought, perception, or feeling is* conscious *when it is in your mental spotlight: you can notice it, report it, and it can influence many other things you do (planning, speech, deliberate action). Something is* unconscious *when it is still being processed, but only in the background: it may guide you indirectly (habits, reflexes, priming) without becoming a reportable, globally shared "workspace" content.* ***Formal definition.*** *Let L_{Ob} be the observation language and let an evidence state be a map $E : L_{\mathrm{Ob}} \to V$. Let W be the workspace operator (Definition 228). We say that E is* workspace-stable *if*

$$W(E) = E$$

(Definition 229). We say that E is a conscious evidence state *if it is workspace-stable and reachable from module integration:*

$$E = W(\Gamma_a(E^\bullet))$$

for some module-level evidence collection $E^\bullet$ and attention profile a (Definition 229). Given a threshold θ, define the conscious proposition set *of E by*

$$\mathrm{Con}_\theta(E) \ :=\ \{\varphi \in L_{\mathrm{Ob}} : E^+(\varphi) \geq \theta\},$$

where $E^+(\varphi)$ is the positive-evidence component of the p-bit $E(\varphi)$. A proposition φ is called conscious at E *if $\varphi \in \mathrm{Con}_\theta(E)$, and* unconscious at E *otherwise.*

Concept 85 (Consciousness)**.** *Appendix label:* `concept:Consciousness`*.*
Body definition label: `hsdef:Consciousness` *(see § 239).*

Informal definition. *Consciousness is the overall condition of having an integrated "point of view" inside a mind: some information is not just processed locally, but becomes globally available so that many different parts of the mind can use it. This is what makes a mind able to have a unified, reportable experience that can guide deliberate reasoning and action, rather than just running isolated background routines.*

Formal definition. *Using the workspace operator W and module-integration maps Γ_a (Definitions 228–229), define the set of reachable workspace-fixed points*

$$\mathrm{ConscStates}(M) \ :=\ \left\{E \in V^{L_{\mathrm{Ob}}} \ :\ E = W(E) \ \ \textit{and} \ \ \exists (E^\bullet, a) \ \textit{with} \ E = W(\Gamma_a(E^\bullet))\right\}.$$

We say that the mind-model M has consciousness at threshold θ *if there exists $E \in \mathrm{ConscStates}(M)$ such that $\mathrm{Con}_\theta(E)$ is nonempty (where Con_θ is as in Concept 34). Informally: M has at least one nontrivial, stable, globally-integrated evidence state with some reportable content.*

Concept 86 (Contexts and Aspects)**.** *Appendix label:* `concept:ContextsAndAspects`*.*
Body definition label: `hsdef:ContextsAndAspects` *(see § 35.2).*

Informal definition. *A context is a particular "lens" for looking at things that decides what differences you care about and what differences you ignore. An aspect is the simplified description you get after applying that lens (for example: just the color, just the shape, just the role in a story). Changing context changes what counts as "the same" and what patterns you can notice and talk about.*

Formal definition. *A context structure is modeled as a poset* $(\mathrm{Ctx}, \sqsubseteq)$*, where* $C \sqsubseteq D$ *means that* D *is a finer (more detailed) context than* C*. For each* $C \sqsubseteq D$ *there is an aspect-extraction (forgetful) map*

$$\mathrm{Ext}_{D\to C} : X_D \to X_C$$

satisfying the functoriality/compatibility condition: if $C \sqsubseteq E \sqsubseteq D$*, then*

$$\mathrm{Ext}_{D\to C} \;=\; \mathrm{Ext}_{E\to C} \circ \mathrm{Ext}_{D\to E}.$$

For $x \in X_D$*, we write* $x|_C := \mathrm{Ext}_{D\to C}(x)$ *for "the aspect of* x *seen in context* C*."*

Concept 87 (Control)**.** *Appendix label:* `concept:Control`*.*
Body definition label: `hsdef:Control` *(see § 36.6).*

Informal definition. *To control an outcome means that by choosing an action, you can reliably make that outcome happen (or prevent it). For example, you control "the light turns on" if flipping the switch usually makes the light turn on. In this framework, control is not a mysterious extra ingredient: it is measured by how strongly an action implies a goal.*

Formal definition. *Let* $\mathcal{A} \subseteq E$ *be a designated set of action event types and let* $G \in E$ *be a goal condition. For* $A \in \mathcal{A}$ *define the control strength of* A *over* G *by*

$$\mathrm{Ctrl}_{O,\Delta}(A \to G) \;:=\; \mathrm{CImp}_{O,\Delta}(A, G),$$

i.e., control is causal implication restricted to antecedents interpreted as actions (relative to observer/context O *and lag window* Δ*).*

Concept 88 (Control Hierarchy)**.** *Appendix label:* `concept:ControlHierarchy`*.*
Body definition label: `hsdef:ControlHierarchy` *(see § 36.6).*

Informal definition. *A control hierarchy is when control is organized in layers: higher-level parts of a system set goals, priorities, or constraints, while lower-level parts handle the detailed execution. The ordering does not need to be a single chain; in real systems, some modules may be incomparable or form local loops, but there is still a general "above/below" direction in who constrains whom.*

Formal definition. *A control hierarchy is a partial order* $(\mathcal{M}, <)$ *on a family of modules* $\mathcal{M}$ *such that*

$$M_1 < M_2$$

is aligned with the interpretation "module M_1 *has (potentially asymmetric) control over module* M_2*."*

Concept 89 (Cosmos and Eurycosmos)**.** *Appendix label:* `concept:CosmosAndEurycosmos`*.*
Body definition label: `hsdef:CosmosAndEurycosmos` *(see § 25.5 and § 25.8).* ***Informal definition.*** *We use* cosmos *for "the whole world" as seen from a particular stable viewpoint (often the everyday physical world for an embodied mind). But different minds, or different ways of sensing and coupling to the world, can pick out different "whole worlds" (different cosmos notions). The*

eurycosmos *is the bigger collection you get when you consider all these different cosmos notions together across many minds. In other words, a cosmos is not intended to be "the world in itself" but the world-as-structured by a particular observer's stable access channels, modeling choices, and habitual invariants; it is the domain within which that observer can reliably track objects, causes, and meanings. The point of introducing the eurycosmos is to make explicit that "what counts as the whole world" can vary with sensing modalities, embodiment, training, and coordination protocols, and that a theory meant to talk across minds must have a place to put all of these observer-indexed wholes at once.*

Formal definition. *Let* SigClass *be a set of signal classes. For an observer/mind S, a signal class $C \in \mathrm{SigClass}$, and a threshold η, let $\mathrm{Univ}_{C,\eta}(S)$ denote the observer-indexed universe induced by C (Definitions 395–396). Fix (when appropriate) a canonical signal class C_{can} (e.g. a "physical/body-channel" class for embodied minds). Define the* cosmos *of S (at threshold η) by*

$$\mathrm{Cosmos}_\eta(S) \;:=\; \mathrm{Univ}_{C_{\mathrm{can}},\eta}(S).$$

This definition emphasizes that a cosmos is a choice *of induced universe: one takes the general universe construction $\mathrm{Univ}_{C,\eta}(S)$ and selects a privileged C_{can} to represent the observer's default "world" (for example, the channel class corresponding to ordinary perception-action loops). The threshold η can be read as a resolution or inclusion cutoff (e.g. for what counts as reliably present/trackable), so changing η can enlarge or shrink what is treated as part of the observer's practical world even when S and C_{can} are held fixed. For a collection of minds* Mind*, define the* eurycosmos *(compare the eurycosm construction) by*

$$\mathrm{Eurycosmos}_\eta(\mathrm{Mind}) \;:=\; \bigcup_{S\in\mathrm{Mind}} \;\bigcup_{C\in\mathrm{SigClass}} \mathrm{Univ}_{C,\eta}(S),$$

i.e., the union of the observer-indexed universes (and thus cosmos notions) induced across minds and signal classes. Conceptually, the outer union over S captures inter-observer diversity, while the inner union over C captures intra-observer diversity across different couplings (e.g. vision-like vs language-like channels, or instrument-extended sensing). The use of a set-theoretic union here is deliberately permissive: it allows overlap between induced universes without forcing identification of "the same" element across observers or channels unless additional equivalence relations are later imposed. In particular, $\mathrm{Eurycosmos}_\eta(\mathrm{Mind})$ *is intended as a container for comparison and translation, not yet a claim that all perspectives can be merged into a single coherent ontology without loss.*

Concept 90 (Creative Inspiration)**.** *Appendix label:* `concept:CreativeInspiration`*.*
Body definition label: `hsdef:CreativeInspiration` *(see § 17.7.1).*

Informal definition. *Creative inspiration is a temporary state where parts of your mind that do not usually talk to each other suddenly connect, so that you can form new combinations of ideas. In that moment, unusual associations become easy, new metaphors and solutions appear, and later you can evaluate and refine them. A useful way to read this is as a transient change in effective connectivity: boundaries between specialized sub-processes soften, so representations that are normally kept separate can interact. The "later you can evaluate and refine them" clause matters because the inspired state is not being equated with correctness; it is a regime that increases generative breadth (candidate production), after which more ordinary constraint-checking, testing, and editing can reassert themselves. This also helps distinguish inspiration from mere noise: the characteristic signature is not randomness alone, but the appearance of structured recombinations that can subsequently be stabilized into communicable plans, explanations, or artifacts.*

In the surrounding framework, the reference to cross-subweb coupling is meant to signal that the same overall mind can behave like a collection of semi-autonomous modules most of the time, and that inspiration corresponds to an episode in which coupling parameters shift so that information flows across previously weakly connected regions. The "temporary" aspect is therefore not incidental: the regime is valuable precisely because it can be entered and exited, permitting both divergent generation and convergent selection rather than permanently blurring all distinctions.

Concept 91 (Culture)**.** *Appendix label: concept:Culture.*
Body definition label: hsdef:Culture (see § 343).

Informal definition. *A culture is the collection of shared habits, beliefs, stories, norms, skills, and ways of doing things that people in a society learn from each other and pass along. Culture is not only "what everyone agrees on": it also includes widely shared disputes, tensions, and mixed messages (for example, a society can strongly praise and strongly criticize the same practice in different places or subgroups). This informal definition treats culture as a distributed pattern that persists through learning, imitation, and communication, rather than as a single agreed-upon doctrine. The mention of disputes and mixed messages is meant to highlight that cultural patterns can be internally inconsistent while still being socially real: what is common is the* presence *and salience of certain themes, narratives, and practices, even when they pull in different directions.*

Formal definition. *A cultural state for a society is a population-level intensity assignment*

$$C : \mathcal{P} \to [0,1] \qquad or \qquad C : \mathcal{P} \to V,$$

defined as an aggregation of individual intensities and artifact-embedded intensities, e.g.

$$C(P) := \left(\bigoplus_{i \in A} w_i \otimes I_i(P) \right) \oplus \left(\bigoplus_{a \in \mathcal{A}} u_a \otimes I_a(P) \right),$$

where A is the agent population, $\mathcal{A}$ is the set of shared artifacts, w_i, u_a are weights (importance, population fraction, accessibility), and $\otimes$ is scalar or p-bit scaling as in Section 22.5. A culture at threshold θ is the set

$$\mathrm{Cult}_\theta := \{P \in \mathcal{P} : \pi(C(P)) \geq \theta\},$$

where π is a chosen projection $V \to [0,1]$ if needed. This formalization makes two commitments explicit: first, that culture can be represented as a field over a shared property space $\mathcal{P}$ (topics, practices, norms, narratives, skills, etc.); and second, that it arises from both people and durable external supports. The artifact term allows books, laws, tools, media, institutions, and other persistent carriers to contribute cultural intensity even when no particular individual is currently attending to them, which helps model intergenerational transmission and the stabilizing effects of infrastructure. The operators $\oplus$ and $\otimes$ are left abstract to accommodate different aggregation logics (e.g. averaging, max-like pooling, log-odds pooling, p-bit combination), so that the same schema can represent "majority prevalence," "elite-driven importance," or "broadcast amplification" by appropriate choices of weights and combination rules. The thresholded set Cult_θ is then a way to extract the culturally salient subset of $\mathcal{P}$ for a given application, with π acting as a bridge back to a scalar salience measure when the underlying value domain V is richer than $[0,1]$.

Concept 92 (Cultural Morality)**.** *Appendix label: concept:CulturalMorality.*
Body definition label: hsdef:CulturalMorality (see § 263).

Informal definition. *A cultural morality is a group's shared "moral background": the values people in the group talk about, which values they treat as most important, what they consider acceptable versus unacceptable, and which rules-of-thumb ("do this", "don't do that") get socially* *encouraged or punished. People in the same group can disagree, but a cultural morality describes what is common enough to shape behavior and social pressure. This notion is meant to cover not only explicit moral rules but also the implicit evaluative atmosphere: what kinds of outcomes are celebrated, what kinds provoke shame, what tradeoffs are treated as normal, and which justifications are regarded as intelligible. The emphasis on shaping behavior and social pressure points to a functional criterion: even with disagreement, if people reliably anticipate praise/blame patterns and adjust accordingly, the group has a cultural morality in the operational sense intended here.*

Formal definition. *Let G be a society (or group), and suppose its members share (at least approximately) a value vocabulary D_{val}. A cultural morality for G consists of:*

1. *a group-level evaluative field $E_G : \Omega_G \times D_{\mathrm{val}} \to B$ (e.g. $B = [0,1]^2$ as p-bit truth values), assigning to each outcome/history $\omega \in \Omega_G$ and each value dimension $d \in D_{\mathrm{val}}$ an evaluation $E_G(\omega; d)$;*
2. *for each $d \in D_{\mathrm{val}}$, a weight $\lambda_d^{(G)}$ and thresholds $\tau_d^{(G)}, \eta_d^{(G)}$ encoding group-level importance and adequacy/aspiration cutoffs on that dimension;*
3. *a set of socially endorsed maxims $M(G)$ (with some prevalence/strength measure, e.g. N_G), where maxims in $M(G)$ have high social resonance (Sections 12 and 18.5) in the sense that they are reinforced by communication and imitation.*

Here Ω_G can be read broadly as the space of socially relevant histories (individual actions, institutional outcomes, public events), so that E_G encodes how the group tends to evaluate what happens, not merely what it says it values. Allowing B to be a richer domain (such as p-bit values) permits ambivalence, conflict, or mixed evaluations to be represented directly rather than forced into a single scalar; this aligns with the informal point that groups can contain stable tensions. The weights and thresholds separate at least three different aspects of moral life: what dimensions are talked about or tracked (D_{val}), how important each dimension is in tradeoffs ($\lambda_d^{(G)}$), and what counts as "acceptable" versus "aspirational" performance on that dimension ($\tau_d^{(G)}, \eta_d^{(G)}$). Finally, $M(G)$ captures the compressions that are easiest to transmit: slogans, proverbs, rules-of-thumb, and exemplary stories. Treating them as a set with prevalence/strength is meant to model the fact that a maxim can be culturally central even if many individuals violate it, provided it remains a focal point for justification, condemnation, and coordination.

Concept 93 (Dependency)**.** *Appendix label: concept:Dependency.*
Body definition label: hsdef:Dependency (see § 1).

Informal definition. *A dependency is a "prerequisite" relationship: concept A depends on concept B if you cannot really define or use A until you already have B in place. The Hyperseed concept inventory is organized using a dependency graph so that earlier concepts supply the ingredients needed for later ones. When two ideas seem mutually dependent in the original presentation, the formal writeup may pick a direction just to keep the exposition moving. This is a pragmatic notion of dependency: it is about explanatory order and definitional load-bearing, not necessarily about metaphysical priority. In particular, the dependency graph is intended to guide a reader (and a formal development) through a sequence where symbols and constructions become available before they are invoked, reducing circularity in the presentation. Apparent mutual dependencies are handled by choosing an orientation that makes the definitions go through (often by introducing a weaker or more schematic version of one concept first, and strengthening it later), so that the graph supports a workable build order even when the underlying ideas are tightly coupled.*

Formal definition. *Let $\mathcal{C}$ be the set of Hyperseed concepts (as listed in Appendix B). An expository dependency DAG is a directed acyclic graph $G = (\mathcal{C}, \to)$ such that for concepts $A, B \in \mathcal{C}$, an edge $A \to B$ means:*

"In this paper's formalization, the definition (or primary semantics) of B uses A as a primitive or as an already-

If the original Hyperseed presentation treats A and B as mutually interdefinable, we may still orient one direction for exposition; such choices are explicitly recorded as "cuts".

Concept 94 (Dependency Tower)**.** *Appendix label: concept:DependencyTower.*
Body definition label: hsdef:DependencyTower (see § 511).

Informal definition. *A dependency tower is a way to build progressively better "simplified versions" of something complicated. The kth level represents what you can capture if you are only allowed to use dependencies of complexity up to level k (or only run tests up to that level). Each level must match the original on everything a k-limited observer could check, and among all models that match those checks, you pick the simplest or best one according to the chosen semantics (for example, least-squares error in a Hilbert-space model).*

Formal definition. *A dependency tower for F is a family $\{F_{\le k}\}_{k\ge 0}$ such that:*

1. *(Monotonicity) $F_{\le k}$ becomes more faithful as k increases.*
2. *(k-ary indistinguishability) For all $O \in \mathcal{O}_{\le k}$, $O(F_{\le k}) = O(F)$.*
3. *(Optimality/minimality) Among all G satisfying the same indistinguishability constraints, $F_{\le k}$ is "best" in the chosen semantics (e.g. minimal L^2 error).*

Concept 95 (Development)**.** *Appendix label: concept:Development.*
Body definition label: hsdef:Development (see § 219).

Informal definition. *Development is a kind of change over time where a system stays recognizably "the same system" (it keeps its identity and doesn't randomly reset), but it gains abilities: it can do more things, or do the same things better, across time. Importantly, development is not just adding new tricks; it also tends to keep earlier abilities instead of throwing them away.*

Formal definition. *Fix a context C and a system S with a self-continuity score $\mathrm{SCS}(\cdot \to \cdot)$ between time-intervals and a capability profile $\mathrm{Cap}_S(\cdot)$ on intervals. A development path for S in C is a sequence of intervals*

$$I_0 \to I_1 \to I_2 \to \cdots$$

such that:

1. *(Continuity) there exists a threshold θ such that for all k,*
$$\mathrm{SCS}(I_k \to I_{k+1}) \ge \theta.$$
2. *(Expanding capability) for infinitely many k,*
$$\mathrm{Cap}_S(I_k) \prec \mathrm{Cap}_S(I_{k+1}).$$
3. *(Enrichment bias) for typical goals/tasks $g \in T_C$ such that $\mathrm{Cap}_S(I_k)(g)$ is high, the value $\mathrm{Cap}_S(I_{k+1})(g)$ does not sharply decrease (new capability tends to come with retention rather than catastrophic loss).*

Concept 96 (Difference). *Appendix label: concept:Difference.*
Body definition label: hsdef:Difference (see § 28.1).

Informal definition. *A difference is how much one thing fails to match another, relative to what you care about in the moment (the context). In Hyperseed this is often treated as directed: "how does x differ from y?" can be different from "how does y differ from x" because one item might be a rough template and the other a detailed, noisy instance (so the instance may fit the template better than the template fits the instance).*

Formal definition. *Given a context c, define the directed difference evaluator*

$$\mathrm{Diff}_c(x \to y) := \delta_c(x, y) \in V.$$

The positive channel $\mathrm{Diff}_c(x \to y)^+$ *is evidence that x diverges from y. The negative channel* $\mathrm{Diff}_c(x \to y)^-$ *is evidence that x does not diverge from y (e.g. x is absorbed into, explained by, or indistinguishable-from y along the relevant aspect).*

Concept 97 (Dissonance). *Appendix label: concept:Dissonance.*
Body definition label: hsdef:Dissonance (see § 24).

Informal definition. *When multiple influences pull in different directions, they can partly cancel out. Dissonance measures how much cancellation happens when you combine a bunch of "vector-like" contributions: if they mostly agree, cancellation is small; if they strongly disagree, cancellation is large.*

Formal definition. *Let* $a = (a_i)_{i \in I}$ *be a finite family of complex numbers (phasors). Define*

$$\mathrm{Res}(a) := \left| \sum_{i \in I} a_i \right|, \qquad \mathrm{Dis}(a) := \sum_{i \in I} |a_i| - \mathrm{Res}(a).$$

Thus $\mathrm{Dis}(a)$ *is large when the phasors point in different directions and cancel in the sum.*

Concept 98 (Distinction). *Appendix label: concept:Distinction.*
Body definition label: hsdef:Distinction (see § 30.2).

Informal definition. *A distinction is a rule for what you treat as "the same" versus "different". Two things are distinct for you if your current way of looking keeps them separate; they are indistinct if you lump them together as "close enough". Distinctions depend on context, and in real life they can be imperfect or asymmetric (you might treat x as indistinct from y for a purpose even though you would not treat y as indistinct from x).* ***Formal definition.*** *Fix a finite universe X (of entities, states, events, or features relevant in context C). An indistinction policy is a subset* $H \subseteq X \times X$*, interpreted as:*

- xHy *means "x is treated as indistinct from y" (the observer does not distinguish x from y).*

No symmetry, reflexivity, or transitivity is assumed in general. Write $H_C \subseteq \mathcal{P}(X \times X)$ *for the set of admissible policies for context C. A (directed) distinction is then any ordered pair* (x, y) *such that* $(x, y) \notin H$*.*

Explanation. *Thinking of H as a directed relation (rather than an equivalence relation) allows the model to represent asymmetric coarsening. For example, an observer might treat a detailed state x as "close enough" to a simplified proxy y (so xHy holds) without also treating the proxy as indistinct from the detail (so yHx may fail). Likewise, dropping transitivity lets the policy encode bounded attention or limited inference: the observer may ignore the difference between x and y, and between y and z, while still reacting differently to x versus z. The admissible-set notation* H_C *emphasizes that which indistinction policies are even available can depend on the* *context (instrumentation, time pressure, norms, incentives, or permissible abstractions). Under this convention, "making a distinction" is identified with excluding a pair from H; thus distinctions can be counted, constrained, or optimized over in later constructions by reasoning directly about membership in $X \times X$.*

Concept 99 (Dreaming)**.** *Appendix label: concept:Dreaming.*
Body definition label: hsdef:Dreaming (see § 17.7.1).

Informal definition. *Dreaming is a state in which most of what you experience is generated from inside your own mind (images, stories, emotions), with relatively weak control from current sensory input. Because the outside world is not strongly steering the stream, the mind can jump between scenes, blend ideas, and form narratives that would be unlikely in ordinary waking life.*

Formal definition. *In the regime-parameter description of conscious modes (Section 17.7.1), dreaming corresponds to low external coupling λ_{ext}, high internal coupling λ_{int}, variable reflective coupling λ_{ref}, and a lower coherence preference (allowing more internally generated blends and narrative jumps).*

Explanation. *Operationally, "low external coupling" means that moment-to-moment updates are only weakly constrained by real-time sensory evidence (e.g. muted correction of implausible transitions), while "high internal coupling" means internally generated associations, memories, and affective dynamics strongly determine what comes next. The qualifier "variable" for λ_{ref} is meant to cover the familiar range from largely unreflective immersion (typical dreams) to lucid dreaming, where reflective monitoring and deliberate control can partially re-enter. The "lower coherence preference" should be read as a shift in the system's internal objective: consistency, scene stability, and global narrative plausibility are de-emphasized relative to locally compelling imagery or affective continuation, making discontinuities (scene cuts, identity swaps, impossible geometry) comparatively cheap. This parameterization is intended to be descriptive rather than definitional of any particular sleep stage, and it supports graded mixtures (e.g. hypnagogic imagery as intermediate λ_{ext} with rising λ_{int}).*

Concept 100 (Effort)**.** *Appendix label: concept:Effort.*
Body definition label: hsdef:Effort (see § 30.1).

Informal definition. *Effort is the cost of doing something: how much time, energy, attention, or other resources it takes. Doing two steps in a row usually costs about the sum of their efforts, and when you have a choice between ways to do something, you usually pick the cheaper way. Hyperseed models effort using a simple algebraic structure that makes these common-sense rules precise and usable inside the later math.*

Formal definition. *Let*

$$E := ([0,\infty], \geq, \inf, +, 0),$$

where the order is reversed (so that $a \leq_E b$ means $a \geq b$ as real numbers), the join in the quantale order is inf *(ordinary minimum), and the monoidal product is $+$ (sequential composition of costs) with unit 0. Then E is a commutative quantale: $+$ distributes over arbitrary infima, i.e.*

$$a + \inf_i b_i \;=\; \inf_i (a + b_i).$$

Explanation. *The reversed order is a bookkeeping device that makes "better" (lower real-valued cost) coincide with "larger" in the lattice-theoretic sense used by quantales: with $\geq$ as the underlying order, the least upper bound (join) becomes* inf *in the usual numeric order, so taking a join corresponds to choosing the cheaper option. Interpreting $+$ as sequential composition captures* *the everyday additive behavior of many costs (time spent, energy consumed, attention expended), while still allowing $+\infty$ to represent infeasible or forbidden actions. The distributivity law*

$$a + \inf_i b_i \;=\; \inf_i (a + b_i)$$

encodes a standard optimization intuition: if you must pay an upfront cost a and then choose among alternatives b_i, the optimal total cost is achieved by choosing the cheapest continuation. Commutativity here reflects that the numerical addition on $[0, \infty]$ is commutative; in applications one may still track noncommutative structure elsewhere (e.g. when the availability *of actions depends on order), while using E purely as the cost aggregator. The unit 0 corresponds to "doing nothing" or an action with no additional resource expenditure.*

Concept 101 (Life and Energy)**.** *Appendix label: concept:LifeAndEnergy.*
Body definition label: hsdef:LifeAndEnergy (see § 41).

Informal definition. *Hyperseed uses a very broad notion of "life": any system that can keep itself going over time by staying within a range of "safe" conditions, even while the world perturbs it. Doing that generally requires managing resources (food, fuel, battery charge, time, attention, etc.). In this document those resource-management constraints are modeled using a general-purpose "energy-like" budget (genenergy). This "life and energy" layer is meant to sit between the generic pattern-process layer (Sections 9–12) and the mind/agency layers (Sections 13–21): it is the part of the story where "persistence" becomes "staying viable while paying costs and replenishing capacity."*

Formal definition. *Fix an observer/context O. Let S be a state space and let $g \in \mathbb{R}_{\geq 0}$ be a genenergy budget coordinate. A viability set for O is a subset*

$$V_O \subseteq S \times \mathbb{R}_{\geq 0}.$$

A policy π is homeostatic for (V_O, T, δ) if

$$\Pr_\pi\Big((s_t, g_t) \in V_O \text{ for all } t \in \{0, 1, \ldots, T\}\Big) \geq 1 - \delta.$$

An energy budget process couples the budget (g_t) to an effort cost function $c_O : A \to \mathbb{R}_{\geq 0}$ by requiring $c_O(a_t) \leq g_t$ and updating the budget by

$$g_{t+1} = g_t - c_O(a_t) + \Delta g_t,$$

where Δg_t represents replenishment dynamics (e.g. via resource conversion).

Explanation. *The augmented state space $S \times \mathbb{R}_{\geq 0}$ makes viability explicitly depend not only on the physical/informational state s_t but also on available budget g_t; intuitively, some states are safe only when sufficient reserves remain. The probability threshold $1 - \delta$ is included to accommodate stochastic environments and imperfect control: "homeostatic" here means the policy keeps the system in the viable region with high probability over a finite horizon T, rather than guaranteeing safety in every realization. The constraint $c_O(a_t) \leq g_t$ enforces feasibility (you cannot spend what you do not have), while the update equation separates depletion due to chosen actions from replenishment Δg_t due to the environment or internal conversion processes (e.g. charging, eating, resting, repairing). The observer index O is important: what counts as "viable," what actions are available, and how costs are assessed can differ across measurement granularities, modeling choices, or stakeholder perspectives. This framework is intended to be flexible enough to cover biological metabolism, robotic battery management, and cognitive/attentional budgeting under a single mathematical template.*

Concept 102 (Lifeform). *Appendix label: concept:Lifeform.*
Body definition label: hsdef:Lifeform (see § 285).

Informal definition. *A lifeform is a system that (in its usual operating mode) does three things: it keeps itself within a "survival range" instead of immediately falling apart (homeostasis), it takes in resources and converts them into usable capacity to act and maintain itself (metabolism), and it is part of a process that makes new similar systems over generations (reproduction). In real life, whether something does these things "routinely" can be a matter of degree, which is why borderline cases like hibernation, spores, sterilized organisms, viruses, and prions can be hard to classify.*

Formal definition. *Fix an observer/context O. A system S is a lifeform (for O) if:*

- *S is a complex interactive system (Definition above),*
- *S routinely satisfies a homeostatic constraint for O (i.e. it tends to remain viable rather than drifting into non-viable states),*
- *S routinely carries out metabolism (Section 19.4), and*
- *S routinely participates causally in reproduction events within some species C (Section 19.5).*

("Routinely" is intentionally graded: a crisp version would require nontrivial frequency over long horizons, while a fuzzy/paraconsistent version can treat routine-ness as evidence.)

Explanation. *The definition is intentionally observer-relative because the classification depends on what is being tracked: under a fine-grained biochemical observer an entity may fail to metabolize, while under a higher-level ecological observer it may still function as part of a life cycle that includes metabolizing stages. The "routine" qualifier is doing substantial work: it excludes one-off or accidental episodes (e.g. a transient self-maintaining chemical reaction) while allowing for dormancy and phase changes (e.g. spores and hibernation) where the relevant activities occur intermittently yet reliably across the system's normal history. The reproduction clause is phrased in terms of causal participation within a species C to allow division of labor and multi-component reproduction mechanisms (e.g. sterile workers in eusocial colonies contributing to colony-level reproduction, or symbiotic assemblies whose reproductive unit is larger than an individual organism). Borderline cases such as viruses and prions can be represented as failing some clauses under some observers (e.g. lacking autonomous metabolism), while still being treated as near-life or life-adjacent processes in analyses that emphasize lineage propagation and ecological embedding.*

Concept 103 (Lifting from Instances to Groups). *Appendix label: concept:LiftingFromInstancesToGroups.*
Body definition label: hsdef:LiftingFromInstancesToGroups (see § 9.7).

Informal definition. *Often we know how to describe a relationship between individual things (for example, whether a particular person matches a particular job). But we also talk about relationships between groups (for example, whether a group of people matches a group of jobs). "Lifting from instances to groups" means turning an individual-level relation into a group-level relation. Different lifts capture different everyday meanings, such as "on average," "everyone has at least one match," or "there is one especially good match that works for everyone."*

Formal definition. *Fix finite sets X and Y, and a soft relation $C : X \times Y \to [0,1]$. For $A \subseteq X$ and $B \subseteq Y$, define three lifted relations:*

$$C_{\text{avg}}(A,B) := \frac{1}{|A||B|}\sum_{a\in A}\sum_{b\in B} C(a,b),$$

$$C_{\forall\exists}(A,B) := \min_{a\in A}\ \max_{b\in B}\ C(a,b), \qquad C_{\exists\forall}(A,B) := \max_{a\in A}\ \min_{b\in B}\ C(a,b).$$

These are the average-like, ∀∃-like, and ∃∀-like lifts, respectively.

Concept 104 (Logical / Empirical Truth)**.** *Appendix label: concept:LogicalEmpiricalTruth. Body definition label: hsdef:LogicalEmpiricalTruth (see § 20.8).*

Informal definition. *There are two common reasons we call something "true." Sometimes it is true because it follows from the rules of a system (logical truth), like "all squares have four sides." Other times it is true because careful observation keeps supporting it (empirical truth), like "dropping objects makes them fall." Hyperseed models science as an organized way of combining these: you add new evidence from experiments and observations, and then you also apply the accepted rules of reasoning to see what else must follow.*

Formal definition. *Let L be a language of claims and let V be the chosen evidence-value space. A belief state is a map $\beta : L \to V$. Given an experiment $e \in E$ with observation $o = \mathrm{Obs}(e)$, an empirical evidence increment is a map $\epsilon_{e,o} : L \to V$ that assigns positive/negative evidence to claims depending on whether they agree with (e, o). A scientific update step is*

$$\beta \leftarrow \mathrm{Cl}_R\big(\beta \oplus \epsilon_{e,o}\big),$$

where $\oplus$ aggregates evidence and Cl_R is closure under a rule set R that includes both domain rules and methodological rules (statistics, measurement models, etc.).

Concept 105 (Logical Entropy)**.** *Appendix label: concept:LogicalEntropy. Body definition label: hsdef:LogicalEntropy (see § 92).*

Informal definition. *Logical entropy measures how often two independent random draws land in different categories. Imagine you sort outcomes into bins (a partition). If you pick two outcomes at random, logical entropy is the probability that they end up in different bins. This makes it a very direct way to quantify "how many distinctions your categorization is making," and it aligns with Ellerman's development of logical entropy [17]. It is also closely connected to Hyperseed's primitive of distinction (Hyperseed-Concept 48).*

Formal definition. *Let $\pi = \{B_1, \ldots, B_k\}$ be a partition of X. Given a distribution p on X, define the block masses*

$$p_i := \sum_{x \in B_i} p(x).$$

The logical entropy of (π, p) is

$$h(\pi, p) := 1 - \sum_{i=1}^{k} p_i^2.$$

Concept 106 (Machines)**.** *Appendix label: concept:Machines. Body definition label: hsdef:Machines (see § 65).*

Informal definition. *A machine is something engineered out of parts so that pushing on some parts predictably changes what other parts do. What makes a machine a machine is the stable, repeatable "wiring" between components: gears mesh with gears, circuits connect components through wires, software components communicate through interfaces. When many machines share standardized parts and connections, you can combine them like building blocks and get an internal "language" of parts and compositions.*

Formal definition. *A machine is an engineered physical system M (Definition 355) that can be decomposed into components $(M_i)_{i \in I}$ such that:*

- *each component M_i is (typically) a tool for acting on other components; and*

- *the internal causal interaction structure among the components induces a stable input-output behavior of the whole M that exhibits nontrivial patterns (Section 9) with high intensity relative to the decomposition baseline.*

Concept 107 (Mathematics)**.** *Appendix label: concept:Mathematics.*
Body definition label: hsdef:Mathematics (see § 2.7).

Informal definition. *Mathematics is the practice of making ideas precise enough that you can check them step by step and reliably build on them. In this document, the mathematical development is organized as a dependency graph of definitions and results: later parts depend on earlier parts. The point of the remark in § 2.7 is that you do not need every technical detail to follow the main story; only a few dependency edges are "load-bearing" for choosing the formal core (Section 3) and for deciding whether the rest of the ontology reduces cleanly.*

Listed in the concept inventory without a dedicated formal definition in this version.

Concept 108 (Mature)**.** *Appendix label: concept:Mature.*
Body definition label: hsdef:Mature (see § 2.3). ***Informal definition.*** *"Mature" is a life-stage term. Roughly, an organism (or more generally, a lifeform) is mature when it has finished most of its growth and development and can reliably maintain itself and reproduce. In many contexts it is useful to distinguish immature stages (where development dominates) from mature stages (where stable functioning and reproduction dominate), even though the transition can be gradual.*

Listed in the concept inventory without a dedicated formal definition in this version.

Concept 109 (Metabolism)**.** *Appendix label: concept:Metabolism.*
Body definition label: hsdef:Metabolism (see § 41.4).

Informal definition. *Metabolism is the set of processes by which a lifeform takes in resources from its environment and converts them into usable capacity to act and maintain itself, while expelling waste. In Hyperseed, metabolism is not limited to biochemistry: at the right descriptive level, any system that reliably turns some "resource" into more usable budget-for-action counts as metabolic (food into biological energy, fuel into motion, battery charge into robot actions, compute/time/attention into cognitive work, and so on).*

Formal definition. *Metabolism in context O is a stochastic energy-budget process (g_t) together with a time-indexed resource conversion map Met_t that (on average) increases the budget by converting environmental resources. Concretely, one models:*

$$g_{t+1} = g_t - c_O(a_t) + \mathrm{Met}_t(s_t, a_t, \omega_t),$$

where $c_O(a_t)$ is the genenergy cost of action a_t, and $\mathrm{Met}_t(\cdot)$ is the (possibly stochastic) genenergy gain produced by resource conversion at time t.

Concept 110 (Meta-Goal)**.** *Appendix label: concept:MetaGoal.*
Body definition label: hsdef:MetaGoal (see § 595).

Informal definition. *A meta-goal is a "goal about goals": it is the part of an agent that determines what kinds of goals it should pursue and how it should revise its goals over time. For example, someone might have a short-term goal like "get good grades," but a meta-goal like "keep learning things that matter and help others" influences which short-term goals they adopt and how they change course when circumstances change. In this sense, meta-goals describe a relatively stable "way of caring" that shapes many downstream choices.*

Formal definition. *Let $\Theta \subseteq \mathbb{R}^d$ be the space of meta-goal parameters. A mind at (discrete) time t has meta-goal state $\theta_t \in \Theta$.*

Concept 111 (Mind). *Appendix label: concept:Mind.*
Body definition label: hsdef:Mind (see § 35.3).

Informal definition. *A mind is a self-sustaining system that (i) takes in information from the world through some "input gateway" (registration; Hyperseed-Concept 153), (ii) builds and maintains internal stand-ins for things it encounters (representation; Hyperseed-Concept 157), and (iii) has a way of linking those stand-ins to what they are about (reference; Hyperseed-Concept 152). What the mind's internal stand-ins "mean" is always relative to a context or aspect: a particular way of carving up and distinguishing the world (Hyperseed-Concept 36). A mind is not just a storage box of facts; it is an organized set of interacting processes that keeps updating its internal stand-ins as it registers new input, and then uses those stand-ins to guide what it does next.*

Formal definition. *A mind is a system $M = (P, E)$ equipped with additional structure:*

1. *A distinguished registration interface (a "sensory" subgraph) $S_{\text{in}} \subseteq M$.*

2. *A representation space R (objects, tokens, or states that can stand in for other entities).*

3. *A reference relation $\text{Ref}_C \subseteq R \times U$ for each context/aspect C, where U denotes the ambient universe of entities under discussion.*

4. *An update rule that turns registrations into representational changes (e.g. $r_{t+1} = \text{Update}(r_t, \text{Reg}_t)$ for some internal state $r_t \in R$).*

Concept 112 (Mind-World Correspondence). *Appendix label: concept:MindWorldCorrespondence.*
Body definition label: hsdef:MindWorldCorrespondence (see § 221).

Informal definition. *Mind-world correspondence measures how well a system's internal "map" matches the real structure of what is outside it. The core idea is: if you look at the patterns of influence and dependence among the mind's internal tokens, can you interpret those tokens as standing for real things in the world in a way that preserves the important relationships? A high correspondence score means there is some good translation from internal symbols/states to external entities such that the mind's internal pattern-flow mirrors (at least approximately) the world's pattern-flow over the time interval of interest. This is the formal way of asking whether the mind's internal representations are not just self-consistent, but actually connected to the world in a structure-respecting way.*

Formal definition. *The mind-world correspondence score of S on interval I is*

$$\text{MWCS}(I) := \sup_{f: X^{\text{in}}_{S,I} \to X^{\text{out}}_{S,I}} \deg\big(f; M_{S,I}, E_{S,I}\big).$$

We say that S has θ-mind-world correspondence on I if $\text{MWCS}(I) \geq \theta$.

Concept 113 (Mindplex). *Appendix label: concept:Mindplex.*
Body definition label: hsdef:Mindplex (see § ??). ***Informal definition.*** *A mindplex is a "mind made of minds": a tightly integrated collection of subminds (or agents) that together function like a larger, higher-level mind. Each part can have its own internal processing, but the coupling among parts is strong enough that the whole has stable large-scale coherence (it acts like one organized system rather than a loose crowd). Crucially, a mindplex is also robust: you can often swap out a part for another similar part without destroying the coherence of the whole. In many cases, the whole can also exhibit genuinely collective episodes of coordinated attention/control (a collective GCC episode) that persist for a meaningful duration, rather than being just momentary alignment.*

Formal definition. *Fix an observer O and a coherence score $\text{Coh}_O(\cdot)$ on candidate minds. A system M is notably coherent if $\text{Coh}_O(M)$ is a local maximum relative to small modifications of*

M. A mindplex is a notably coherent mind M that decomposes into notably coherent minds $\{M_i\}$ such that:

(a) each M_i is approximately pattern-preserving as a restriction of M, and

(b) replacing any M_i by another comparably coherent mind M_i' does not destroy the coherence of M (robustness/replaceability).

(Approximate/weak form used in the text.) Fix $\epsilon \geq 0$ and a time horizon T. A system M is an (ϵ, T)-weak mindplex if it satisfies the mindplex conditions up to error ϵ (approximate coherence and approximate replaceability) and, in addition, exhibits a collective GCC episode of duration at least T.

Concept 114 (Morphic Anti-Resonance)**.** *Appendix label: concept:MorphicAntiResonance. Body definition label: hsdef:MorphicAntiResonance (see § 34.5).*

Informal definition. *Morphic anti-resonance is the "push-away" counterpart of morphic resonance: instead of one system's strongly supported patterns making similar patterns more likely elsewhere, one system's strongly rejected patterns create pressure elsewhere to avoid (or invert) those patterns. Intuitively, the target does not just fail to copy the source; it is actively nudged in the opposite direction. In the two-channel (p-bit) evidence picture, this is naturally modeled by swapping the "evidence-for" and "evidence-against" channels coming from the source, then transmitting that swapped signal into the target through a coupling rule. This captures Hyperseed's idea of Morphic Anti-Resonance (Hyperseed-Concept 114): not absence of resonance, but propagation of reversal pressure.*

Formal definition. *Assume $V = [0,1]^2$ and p-bit negation is $\neg(v^+, v^-) = (v^-, v^+)$. Let $K^{\text{anti}}_{\ell_0 \to \ell} : P_{\ell_0} \times P_\ell \to V$ be a V-valued coupling kernel. Define the anti-resonant coupling input from context ℓ_0 to ℓ by*

$$\text{AntiRes}_{\ell_0 \to \ell}(s_{\ell_0,t}) \;:=\; K^{\text{anti}}_{\ell_0 \to \ell} \;?\; (\neg s_{\ell_0,t}),$$

where $(\neg s)(p) := \neg(s(p))$ applies negation pointwise to p-bit values, and $(K?s)(q) := \bigoplus_{p \in P_{\ell_0}} K(p,q) \otimes s(p)$ denotes kernel action.

Concept 115 (Morphic Resonance)**.** *Appendix label: concept:MorphicResonance. Body definition label: hsdef:MorphicResonance (see § 50).*

Informal definition. *Morphic resonance is the idea that when a pattern becomes strong and stable in one place (one context, mind, culture, or system), that makes it easier for a similar pattern to become strong elsewhere, even without the usual direct causal pathway. In the model, each context has its own internal habit-reinforcement dynamics; morphic resonance adds an extra "cross-context input" term so that stabilized patterns in one context can seed support in another. This is the specific, intended reading associated with morphic resonance in Hyperseed (Hyperseed-Concept 115) and is historically linked to morphic field narratives [13].*

Formal definition. *Let ℓ range over a set of contexts L. For each $\ell \in L$, let P_ℓ be a pattern class, let $s_{\ell,t} : P_\ell \to V$ be the habit-support state, let $A_\ell : P_\ell \times P_\ell \to V$ be an internal kernel, let $d_\ell \in V$ be a decay scalar, let $u_{\ell,t} : P_\ell \to V$ be an input, and for $\ell_0 \neq \ell$ let $K_{\ell_0 \to \ell} : P_{\ell_0} \times P_\ell \to V$ be a coupling kernel with induced input*

$$(K_{\ell_0 \to \ell} ? s_{\ell_0,t})(q) \;:=\; \bigoplus_{p \in P_{\ell_0}} K_{\ell_0 \to \ell}(p,q) \otimes s_{\ell_0,t}(p).$$

Then the coupled update is

$$s_{\ell,t+1} \;=\; u_{\ell,t} \;\oplus\; (d_\ell \odot s_{\ell,t}) \;\oplus\; (A_\ell ? s_{\ell,t}) \;\oplus\; \bigoplus_{\ell_0 \neq \ell} (K_{\ell_0 \to \ell} ? s_{\ell_0,t}).$$

We call this a morphic resonance dynamics when the couplings $K_{\ell_0 \to \ell}$ are intended to encode cross-context propagation of habit bias, rather than ordinary local causal influence.

Concept 116 (Multiverse)**.** *Appendix label: concept:Multiverse.*
Body definition label: hsdef:Multiverse (see § ??).

Informal definition. *A multiverse (in this formalism) is a branching space of possible "next worlds": given how an observer models reality, there are multiple possible continuations, and the multiverse is the whole structure of those possible continuations and transitions. A guidable multiverse is a multiverse where the observer can systematically influence which branch they end up in, by taking actions or sending signals. In ordinary physics, guidability is limited by the physical causal channels available; Hyperseed also considers (as a conceptual possibility) that broader signal classes could exist, which would make the multiverse more guidable relative to a mind.* ***Formal definition.*** *Let S_1 and S_2 be two signal classes and let O be an observer. A guidable multiverse (relative to S_1, S_2, O) is a multiverse U defined using S_1-reachability such that, in universe U as modeled by O, signals in class S_2 can systematically influence which element of U the observer will be in after a transition. Formally, this means there is an action set A (implementing S_2 signals) and a controlled transition kernel*

$$P(\cdot \mid U; a)$$

on U.

Concept 117 (Mutual Information)**.** *Appendix label: concept:MutualInformation.*
Body definition label: hsdef:MutualInformation (see § 89).

Informal definition. *Mutual information measures how strongly two random quantities are related. It is the amount of "uncertainty reduction" you get about one variable when you learn the other. If two variables are independent, the mutual information is zero. If knowing one gives you a strong clue about the other, the mutual information is large.*

Formal definition. *The mutual information between random variables X and Y is*

$$I(X;Y) \;:=\; H(X) + H(Y) - H(X,Y).$$

Equivalently,

$$I(X;Y) \;=\; D_{\mathrm{KL}}\big(p(x,y) \,\|\, p(x)p(y)\big).$$

Concept 118 (Narrow Intelligence)**.** *Appendix label: concept:NarrowIntelligence.*
Body definition label: hsdef:NarrowIntelligence (see § 881).

Informal definition. *Narrow intelligence means being extremely good at a limited kind of task, but not broadly capable across many different kinds of tasks. A narrow system can look "superhuman" inside its domain (like chess, protein folding, or one style of image labeling) while still being weak or helpless outside that domain. In other words: high skill in a small region, low generalization across the larger landscape of tasks.*

Formal definition. *Using the competence and breadth notions from the main text: fix a task environment $(\mathcal{T}, D)$ and tolerance $\epsilon \in [0,1]$. Define the breadth*

$$\mathrm{Br}_\epsilon(\mathrm{Ag}; \mathcal{T}, D) \;:=\; D\Big(\big\{T \in \mathcal{T} : \mathrm{Comp}(\mathrm{Ag}; T) \geq 1 - \epsilon\big\}\Big).$$

We say an agent is (relatively) narrow on $(\mathcal{T}, D)$ (at tolerance ϵ) when $\mathrm{Br}_\epsilon(\mathrm{Ag}; \mathcal{T}, D)$ is small, i.e. the agent achieves near-top competence on only a small fraction of tasks under D (even if it may attain very high competence on some specialized subset of tasks).

Concept 119 (Natural Autonomy)**.** *Appendix label: concept:NaturalAutonomy. Body definition label: hsdef:NaturalAutonomy (see § 50).*

Informal definition. *Natural autonomy is the ability to keep yourself viable: from any state where you are still functioning, there is always some action you could take that keeps you in the "safe/flexible" region rather than falling out of it. It does not say you will always choose the right action; it says the option exists at every step. Equivalently, there is a policy (a "will") that, for every viable state, picks a viability-preserving action. The key logical point is the swap between "for every state there exists an action" and "there exists a single rule that chooses an action for every state."*

Formal definition. *Let $D_u : S_{\mathrm{Ob}} \to S_{\mathrm{Ob}}$ be the update induced by intervention $u \in U$ and let $V \subseteq S_{\mathrm{Ob}}$ be a viable set. Then the following are equivalent:*

1. *(Natural autonomy) $\forall s \in V\ \exists u \in U :\ D_u(s) \in V$.*

2. *(Viable will policy) $\exists\,\mathrm{Will} : V \to U\ \forall s \in V :\ D_{\mathrm{Will}(s)}(s) \in V$.*

Concept 120 (Non-Dual Variety)**.** *Appendix label: concept:NonDualVariety. Body definition label: hsdef:NonDualVariety (see § 61).*

Informal definition. *Non-dual variety is what it feels like to be in a genuine gray zone of "substitutability": there are strong reasons to treat two things as interchangeable (you can swap them without much changing what matters), and at the same time strong reasons to treat them as not interchangeable (swapping them breaks something important). The point is not confusion or vagueness; it is that both pressures are real and non-negligible at once. Examples include gradual morphs (where classification is pulled in two directions), the Ship of Theseus (identity supported by continuity yet challenged by replacement), or social/organizational roles that are interchangeable for scheduling but not interchangeable for responsibility.*

Formal definition. *Fix thresholds $\tau_\iota \in (0,1)$. For $x \neq y$ in X_c, define*

$$\mathrm{NDVar}_c(x,y) \iff \iota_c(x,y)^+ \geq \tau_\iota \text{ and } \iota_c(x,y)^- \geq \tau_\iota .$$

Equivalently: the (p-bit) interchangeability/indistinction signal $\iota_c(x,y) \in [0,1]^2$ is strongly paraconsistent, with both evidence channels simultaneously above threshold.

Concept 121 (Non-Duality)**.** *Appendix label: concept:NonDuality. Body definition label: hsdef:NonDuality (see § 28.1).*

Informal definition. *Non-duality means that a mind has genuine reasons to treat two things as separate, and also genuine reasons to treat them as not-separate, at the same time. For example, an ambiguous picture can strongly support two incompatible ways of seeing it; or you can experience another person as "not me" and also as "part of me/us." The point is not to declare that "everything is one," but to represent honest mixed evidence without forcing an immediate, artificial choice [24].*
Formal definition. *Fix thresholds $\tau_\delta, \tau_\iota \in (0,1)$. For $x \neq y$ in X_c define:*

$$\begin{aligned} \mathrm{NonDual}_c(x,y) &\iff \mathrm{Dist}_c(x,y)^+ \geq \tau_\delta \text{ and } \mathrm{Dist}_c(x,y)^- \geq \tau_\delta, \\ \mathrm{NDVar}_c(x,y) &\iff \iota_c(x,y)^+ \geq \tau_\iota \text{ and } \iota_c(x,y)^- \geq \tau_\iota . \end{aligned}$$

Thus non-duality is "distinct and not-distinct" (paraconsistent distinctness), while non-dual variety is "interchangeable and not interchangeable" (paraconsistent substitutability).

Concept 122 (Number)**.** *Appendix label: concept:Number. Body definition label: hsdef:Number (see § 2.3).*

Informal definition. *A number is an abstract way to say "how many" or "how much." We use numbers to count objects (3 apples), to measure quantities (2.5 meters), and to compare amounts (7 is bigger than 5). Numbers also let us do arithmetic so we can combine, split, and predict quantities.*

Listed in the concept inventory without a dedicated formal definition in this version.

Concept 123 (Oceanic Consciousness)**.** *Appendix label: concept:OceanicConsciousness. Body definition label: hsdef:OceanicConsciousness (see § 17.7.1).*

Informal definition. *Oceanic consciousness is a kind of experience where the usual feeling of being a sharply separate "self" softens, and there is a strong felt sense of connectedness with the world or with other people. It is often described as feeling "merged," "boundaryless," or "one with everything," while still having a coherent, unified overall experience. In the model, this is naturally associated with reduced self/other boundary sharpness (Section 16) together with high global coherence.*

Formal definition. *In the regime classification of § 17.7.1, oceanic consciousness is modeled by a consciousness-regime parameter tuple*

$$\Lambda_{\text{oceanic}} := (\lambda_{\text{ext}}, \lambda_{\text{int}}, \lambda_{\text{ref}}, \lambda_{\text{coh}})$$

with λ_{ext} moderate-to-low, λ_{int} high, λ_{ref} moderate, and λ_{coh} high.

Concept 124 (Occasions of Experience)**.** *Appendix label: concept:OccasionsOfExperience. Body definition label: hsdef:OccasionsOfExperience (see § 37).*

Informal definition. *An "occasion of experience" is a single episode or moment of experience: one snapshot of what is happening in consciousness. A key point is that we do not always treat two occasions as either perfectly identical or totally different. Instead, we often treat them as "the same enough" in different ways (for example, recognizing the same object from different angles, or treating two similar feelings as the same kind of feeling). The groupoid idea captures this: instead of only having strict equality, we also track reversible "ways to identify" one occasion with another, and we track whether those identifications fit together coherently.*

Formal definition. *An occasion space is a small $(\infty, 1)$-groupoid E. Its objects $\mathrm{Ob}(E)$ are occasions. A 1-morphism $f : o \to o'$ represents an admissible "identification" or "transport" between occasions (e.g. recognizing the same thing under a change of viewpoint), and higher morphisms encode coherent equivalences between such identifications.*

In toy models one may replace E by an ordinary groupoid, or even by a set E (regarding only equality), by applying the truncation π_0.

Concept 125 (Opening)**.** *Appendix label: concept:Opening. Body definition label: hsdef:Opening (see § 30.2).*

Informal definition. *An opening is when you deliberately loosen your distinctions: you decide to treat more pairs of things as "not importantly different" for your current purposes. This can make thinking and acting easier (you compress the world into fewer categories). A closing is the opposite: you tighten distinctions and start treating fewer pairs as interchangeable, so your categories become more fine-grained. It is useful to note the direction: if H is the set of pairs you collapse, then $H \subseteq H'$ is an opening because H' collapses more pairs.*

Formal definition. *Given two policies $H, H' \in H_C$:*

- *The transition $H \to H'$ is an opening (relaxation of distinctions) if $H \subseteq H'$.*
- *The transition $H \to H'$ is a closing (tightening of distinctions) if $H' \subseteq H$.*

Concept 126 (Open-Ended Benefit). *Appendix label: concept:OpenEndedBenefit. Body definition label: hsdef:OpenEndedBenefit (see § ??).*

Informal definition. *Open-ended benefit is the idea of improving the world in a way that keeps creating more good possibilities over time, rather than locking everything into one narrow outcome. It is "open-ended" because goals and values can grow, refine, and reorganize as new situations arise; it is "benefit" because that growth is guided by the idea of making it easier (not harder) for multiple beings to have good lives — for example by reducing avoidable harm, improving cooperation, and expanding the set of futures where many agents can realize joy and reduce woe.*

(No dedicated standalone formal definition is given in this version; the main text points to including compassion and non-destructive coordination constraints in the revision rule for D_t.)

Concept 127 (Open-Ended Intelligence). *Appendix label: concept:OpenEndedIntelligence. Body definition label: hsdef:OpenEndedIntelligence (see § ??).* ***Informal definition.*** *Open-ended intelligence is the ability of an agent to keep learning and reorganizing what it cares about (and how it reasons) over time, without falling into incoherence. It means the agent can keep some values stable long enough to act, can revise or expand its value vocabulary when needed, and can still make nontrivial decisions after revisions (it does not become "anything goes" or paralyzed).*

Formal definition. *Let D_t be the set of active value dimensions at proto-time t and $E_{O,t}$ the corresponding evaluative field. An observer exhibits open-ended intelligence on an interval if:*

1. *(stability) there exist nontrivial dimensions in D_t that remain stable for substantial sub-intervals (values do not dissolve into noise);*
2. *(revisability) there exist times $t < t'$ such that $D_{t'} \neq D_t$ (the value vocabulary can grow or reorganize);*
3. *(coherence under revision) revisions do not make action selection trivial; i.e. the agent retains a non-degenerate Pareto set and nontrivial resonance structure.*

Concept 128 (Ordinary Waking Consciousness). *Appendix label: concept:OrdinaryWakingConsciousness. Body definition label: hsdef:OrdinaryWakingConsciousness (see § 17.7.1).*

Informal definition. *Ordinary waking consciousness is the normal, everyday awake state: your experience is mostly driven by sensory input from the outside world, your sense of being a separate self is relatively crisp, and your thoughts tend to stay anchored to what is happening around you. You can reflect and plan, but the experience is usually organized around staying consistent with what your senses and actions are telling you.*

Formal definition. *In the regime classification of § 17.7.1, ordinary waking consciousness is modeled by a consciousness-regime parameter tuple*

$$\Lambda_{\text{wake}} := (\lambda_{\text{ext}}, \lambda_{\text{int}}, \lambda_{\text{ref}}, \lambda_{\text{coh}})$$

with λ_{ext} high, λ_{int} moderate, λ_{ref} moderate, and λ_{coh} tuned to prefer sensory-consistent closure.

Concept 129 (Pain). *Appendix label: concept:Pain. Body definition label: hsdef:Pain (see § ??).*

Informal definition. *Pain is a strongly negative kind of experience: it is the felt sense that something is wrong, harmful, or needs to stop. This includes physical pain, but it also includes emotional and social pain (grief, shame, heartbreak, anxiety) when the mind evaluates a situation as deeply bad. In this framework, pain is not just a raw sensation; it is an evaluative state: a "woe-dominant" summary of how the current situation scores across what the agent cares about, possibly including both internal and external processes.*

Formal definition. *Let JO and WO denote joy- and woe-intensity signals derived from an evaluative field (so JO captures positive evaluative intensity and WO captures negative evaluative intensity). Fix an aggregation operator* Agg *that combines values across a set of value dimensions and a time window W. Define aggregated joy and woe:*

$$\overline{JO} := \mathrm{Agg}\{JO(s_{t'}, a_{t'}; d) : d \in D_t,\ t' \in W\},$$
$$\overline{WO} := \mathrm{Agg}\{WO(s_{t'}, a_{t'}; d) : d \in D_t,\ t' \in W\}.$$

A simple formalization of pain-intensity is then any scalar summary that increases with woe and decreases with joy; for example,

$$\mathrm{Pain} := \max(0,\ \overline{WO} - \overline{JO}),$$

so pain is large exactly when woe is dominant after the chosen aggregations.

Concept 130 (Pattern)**.** *Appendix label: concept:Pattern.*
Body definition label: hsdef:Pattern (see § 28).

Informal definition. *A pattern is a repeatable structure or regularity: a set of relationships that tend to go together, so that when you see some pieces you can often expect the others. A shape like a triangle is a pattern; a habit or routine can be a pattern; a grammar rule can be a pattern. In the formalism, a pattern can be treated as a bundle of smaller constraints (simple "this relation should hold" requirements). A context supports the pattern when there is strong evidence that all (or most) of those constraints are satisfied together.*

Formal definition. *Given a context relation R and a pattern P (modeled as a set of required pairs (u, v)), define the (conjunctive) pattern support*

$$S_R(P) := \bigotimes_{(u,v)\in P} R(u, v) \in V.$$

In particular,

$$S_R(P)^+ = \prod_{(u,v)\in P} R(u, v)^+, \qquad S_R(P)^- = \prod_{(u,v)\in P} R(u, v)^-.$$

Concept 131 (Pattern Flow Networks)**.** *Appendix label: concept:PatternFlowNetworks.*
Body definition label: hsdef:PatternFlowNetworks (see § 215).

Informal definition. *A pattern-flow network is a snapshot (over a chosen time interval) of how patterns or information move around inside a modeled system. You choose a set of nodes that stand for concrete "pattern-tokens" inside the system (for example: a particular belief, memory, concept, percept, goal, or action schema). Then, for each ordered pair of nodes (a, b), you record how strongly activity/content associated with a tends to be followed by activity/content associated with b during that interval. In plain terms, it is a map of "what tends to lead to what" inside the system, so the system's dynamics can be compared across different times and different domains. (This directly packages Hyperseed's emphasis on Pattern and Process; see Hyperseed-Concepts 130 and 140.)* ***Formal definition.*** *Fix a system S (as modeled by observer O) and a time interval I. A pattern-flow network for S on I is a V-graph*

$$F_{S,I} : X_{S,I} \times X_{S,I} \to V,$$

where $X_{S,I}$ is a set of nodes representing specific entities or pattern-tokens, and where $F_{S,I}(a, b)$ quantifies the extent to which pattern that "first appears" in a subsequently appears in b over the interval I. The precise estimator used to compute $F_{S,I}(a, b)$ is observer-dependent and may include sub-interval weighting (temporal discounting).

Concept 132 (Pattern Web)**.** *Appendix label: concept:PatternWeb.*
Body definition label: hsdef:PatternWeb (see § 345).

Informal definition. *A pattern web is a network that connects things according to which patterns they share. Imagine you have a collection of entities (objects, experiences, concepts, memories, symbols, etc.). Two entities are linked when they are similar in the sense that many of the same patterns "show up" in both of them (or show up with similar strengths). The result is usually a web rather than a single tree: one thing can be similar to many others for different reasons, so clusters can overlap and multiple routes can connect the same items. In a mind, a pattern web can be read as a structured "association network" among represented items; in a society, many local pattern webs (inside different minds and artifacts) can be combined and then stitched together by communication and coordination links to form a larger collective web. The symbol $\sqcup$ is used informally to suggest a disjoint/typed union of webs: we keep track of which subweb came from which source, but we allow added edges that connect them.*

Formal definition. *Fix a set X of entities and a set P of patterns, together with a pattern-intensity assignment $I : P \times X \to [0,1]$. Define the pattern profile of $x \in X$ to be the function $F_x : P \to [0,1]$ given by $F_x(p) := I(p,x)$. Choose a metric D on $[0,1]^P$ and define the pattern-based pseudometric*

$$d_P(x,y) := D(F_x, F_y).$$

Choose any monotone decreasing kernel $\kappa : [0,\infty) \to [0,1]$ and define the induced similarity

$$s(x,y) := \kappa(d_P(x,y)).$$

A pattern web on X is then a weighted graph

$$W = (X, E_W, w_W)$$

constructed from s (for example by thresholding, k-nearest-neighbors, or taking the complete graph), with weights $w_W(x,y)$ derived from $s(x,y)$.

(Collective/merged web construction used in the text.) Let W_i denote agent i's internal pattern web (Section ??), and let W_a denote the pattern web embedded in an artifact a (external memory, procedures, institutions). The collective pattern web of a society is the (weighted) union

$$W_{\mathrm{col}} := \left(\bigsqcup_i W_i \right) \sqcup \left(\bigsqcup_a W_a \right) \sqcup W_{\mathrm{comm}},$$

where W_{comm} adds edges corresponding to communication and coordination links. Weights on W_{comm} are derived from K and attention/effort constraints (Sections ?? and 8).

Concept 133 (Perceptual Hierarchy)**.** *Appendix label: concept:PerceptualHierarchy.*
Body definition label: hsdef:PerceptualHierarchy (see § 188).

Informal definition. *A perceptual hierarchy is a layered organization of perception in which "higher" layers recognize larger and more abstract patterns by using the output of "lower" layers, and then send control back down by selecting, stabilizing, or re-weighting what the lower layers should pay attention to. For example, in vision: edges and textures support shapes, shapes support objects, and objects support scene understanding. The key idea is that perception is not purely passive recording; it is an active, layered control process that continually chooses which patterns to lock onto and how to integrate them.*

Formal definition. *A perceptual hierarchy is a control hierarchy in which the relevant control events are instances of pattern recognition (Section 13): controlling a module consists in selecting, stabilizing, or transforming the patterns it registers.*

Concept 134 (Perception)**.** *Appendix label: concept:Perception.*
Body definition label: hsdef:Perception (see § 116).

Informal definition. *Perception is what happens when something impacts a mind and the mind does more than just briefly register it. In perception, the registration produces (or updates) an internal representation that the mind can later use for thinking, memory, and action. In everyday terms: perception is when sensing turns into "something in your head that stands for the thing" in a way that can guide what you do next.*

Formal definition. *A mind M perceives an entity A at time t (in context C) if:*

1. *M registers A at time t (Definition 161), and*
2. *this registration causally triggers the emergence of a representation token $R \in \mathcal{R}$ with $\mathrm{Ref}_C(R, A \mid C)$ nontrivial.*

In slogan form: perception is registration that causes representation.

Concept 135 (Physical Reality / Body)**.** *Appendix label: concept:PhysicalRealityBody.*
Body definition label: hsdef:PhysicalRealityBody (see § 46.3). ***Informal definition.*** *A mind's body is the part of reality that acts as its interface: it receives the mind's percepts (signals that inform the mind about what is going on) and carries the mind's actions (signals by which the mind changes things). A mind is in a "physical reality" when its body is contained in that reality and, for most practical purposes, the mind's influence on that reality goes through the body-channel (and information from the reality reaches the mind through bodily perception channels). This makes "physical reality" an operational idea: it is about which causal paths are dominant for prediction and control, not just a metaphysical label. The stronger it is that mind-to-world influence must run through the body, the "more physical" the reality is relative to that mind.*

Formal definition. *(Embodied mind and body.) Let M be a mind modeled as a dynamical subsystem with internal states* Mind*, percept tokens* Percepts*, and action tokens* Acts*. A body for M is a pattern-system B together with a distinguished interface map*

$$\iota : (\mathrm{Percepts}, \mathrm{Acts}) \to B$$

such that there is a highly significant mutual causal relationship between M and B.

(Physical reality.) A physical reality for an embodied mind M is a reality-system R such that:

(a) *the body B is largely contained in R (i.e. $B \subseteq R$ as a pattern-subsystem);*

(b) *most percepts and actions of M are perceptions/actions of entities in R;*

(c) *body-channel mediation: for any action-effect morphism $f : M \to R$ there exist morphisms $g : M \to B$ and $h : B \to R$ with*

$$f \approx h \circ g,$$

where "$\approx$" denotes approximation in the enrichment (e.g. bounded residual weakness or bounded prediction-error increase when replacing f by $h \circ g$).

(Graded physicalness score used in § 46.3.) One way to quantify "how physical" R is for M relative to body B is

$$\mathrm{phys}(M, R; B) := 1 - \sup_{f:M\to R} \inf_{g:M\to B,\, h:B\to R} d(f,\ h \circ g)\,,$$

for a chosen discrepancy measure d with $0 \le d \le 1$.

Concept 136 (Physical Realizations)**.** *Appendix label: concept:PhysicalRealizations.*
Body definition label: hsdef:PhysicalRealizations (see § 56).

Informal definition. *A physical realization is a way an abstract process (like an algorithm, a rule, or a mathematical transformation) gets carried out by physical stuff. You take an abstract input, encode it into a physical state (for example, bits in memory or voltages in a circuit), let the physical substrate evolve according to its dynamics (possibly with control), and then decode the resulting physical state back into an abstract output. Realizations are not "perfect by default": how good a realization is depends on evidence (tests, proofs, models) that the physical behavior matches the intended abstract process.*

Formal definition. *Let $f : A \to B$ be an abstract process in* Abs*. A physical realization of f is a tuple*

$$R = (P, \mathrm{enc}, \mathrm{dec}, \phi)$$

where:

- *P is a physical substrate (an object of* Phys*),*
- $\mathrm{enc} : A \to \mathrm{State}(P)$ *is an encoding of abstract inputs into physical states,*
- $\mathrm{dec} : \mathrm{State}(P) \to B$ *is a decoding of physical states into abstract outputs, and*
- $\phi : \mathrm{State}(P) \to \mathrm{State}(P)$ *is (a model of) the relevant physical dynamics of P induced by the realization setting (including any control signals regarded as part of the realization),*

such that $\mathrm{dec} \circ \phi \circ \mathrm{enc}$ *approximates f in the intended sense.*

Concept 137 (Pleasure)**.** *Appendix label: concept:Pleasure.*
Body definition label: hsdef:Pleasure (see § 18.2.2).

Informal definition. *Pleasure is the kind of positive feeling that comes from an evaluation of "this is good for me" or "this is going well" relative to what the system cares about. It is not treated here as just a raw physical sensation. A system can take pleasure (or experience pain) about external events, internal thoughts, social interactions, achievements, or imagined futures, because the core is evaluative: it is tied to the system's values and goals. In the Hyperseed framing, pleasure is "joy-dominant affect" (and pain is "woe-dominant affect"), meaning pleasure is what it feels like when the system's positive evaluative evidence outweighs the negative, after the system has summarized many values and time horizons into a small control-relevant signal.*

Formal definition. *(As specified in the text.) Joy/woe intensities are defined as projections of a p-bit $v = (v^+, v^-) \in [0,1]^2$:*

$$J(v) := v^+ \quad \textit{(joy intensity)}, \qquad W(v) := v^- \quad \textit{(woe intensity)}.$$

Given an evaluative field E_O, define (for value dimension d):

$$JO(s, a; d) := J(E_O(s, a; d)), \qquad WO(s, a; d) := W(E_O(s, a; d)).$$

Pleasure and pain are then treated as scalar summaries of (JO, WO) after aggregating across value dimensions and time horizons; the document deliberately leaves the aggregation operator open (observer- and system-dependent). A simple toy aggregation mentioned in the text is: average JO and WO over a chosen subset of dimensions and a short temporal window, and then compare the two.

Concept 138 (Presentational Immediacy). *Appendix label: concept:PresentationalImmediacy. Body definition label: hsdef:PresentationalImmediacy (see § 28.2).* ***Informal definition.*** *At any moment, experience has a "foreground/background" structure: some things feel vivid, central, and right in front of you, while other things are faint, peripheral, or barely noticed. Presentational immediacy is a simple way to represent that structure: it assigns each presented item a number between 0 and 1 indicating how much it is present to the mind right now in a given context.*

It is useful to read this number as a purely phenomenological "salience weight" rather than as a probability: a highly immediate item is not necessarily more likely to be true, but rather more available to guide attention, thought, and action. The foreground/background distinction can also be multi-layered (several items may be jointly vivid), so the assignment is not required to pick a single winner; it is a graded profile over what is presented.

Formal definition. *A presentational immediacy function in context c is a map*

$$I_c : X_c \to [0, 1].$$

If $I_c(x)$ is near 1, x is in the foreground of experience in c. If $I_c(x)$ is near 0, x is in the background.

No further axioms are assumed here: in particular, $\sum_{x \in X_c} I_c(x) = 1$ is not required, and there is no presumption that immediacies across different contexts c agree or are comparable. One can, however, impose additional structure when helpful (e.g. continuity in c, Lipschitz bounds under small context-changes, or monotonicity constraints under "zooming in" on an item). In applications, I_c can be read as a quick proxy for attentional allocation, working-memory accessibility, or the degree to which x is poised to enter explicit report, depending on what X_c is taken to represent.

Concept 139 (Probability). *Appendix label: concept:Probability. Body definition label: hsdef:Probability (see § 10.2).*

Informal definition. *Probability is a way of modeling uncertainty about events. In this document it is explicitly observer-relative: what counts as an "event" depends on what distinctions the observer can actually make. If an observer cannot tell certain cases apart, then it does not meaningfully assign separate probabilities to them; instead it assigns probabilities only to coarser events that are observable at its resolution. In this sense, a probability model is partly a model of the world and partly a model of the observer's limitations.*

This observer-relativity can be understood as a disciplined form of coarse-graining: two underlying world-states that differ in ways invisible to O are treated as the same for the purposes of probabilistic prediction and decision. Equivalently, the probability model encodes not only "what may happen" but also "what would count as a difference" to O when registering outcomes. This makes it natural to relate probability to perception and measurement, since any measurement device (biological or artificial) has finite resolution and thus a built-in notion of which distinctions are operationally meaningful.

Formal definition. *Fix an observer/context O. An event observable to O is a predicate on X whose truth value is determined at the resolution of O. Formally, we model the collection of O-observable events as a sigma-algebra $\Sigma_O \subseteq 2^X$. A probability model for O is a probability measure*

$$P_O : \Sigma_O \to [0, 1].$$

The triple (X, Σ_O, P_O) is the observer-indexed probability space.

Concretely, Σ_O often arises from an O-dependent partition or equivalence relation on X capturing which microstates are indistinguishable to O; in that case, O-observable events are unions of equivalence classes, and P_O assigns probabilities only to those unions. When O changes (e.g. by gaining a new sensor, learning a new concept, or shifting attention), the sigma-algebra can *refine, thereby enabling finer events and potentially changing the induced probabilities. This also clarifies how "probability updates" can mix Bayesian conditioning with representational change: the former updates P_O on a fixed Σ_O, while the latter may replace Σ_O itself by a different observable event-structure.*

Concept 140 (Process)**.** *Appendix label: concept:Process.*
Body definition label: hsdef:Process (see § 30.1).

Informal definition. *A process is simply "a system unfolding over time": it specifies what state the system is in at each moment (or each occasion), and how later states relate to earlier ones. The key point is that Hyperseed starts from proto-time (a before/after ordering, not necessarily a single clock line). So a process is defined relative to whatever time-ordering the observer/system is using: it is the structured assignment of system-states along that ordering.*

In everyday terms, a process can be deterministic (each earlier state fixes the later one), stochastic (later states are uncertain given earlier ones), or partially specified (only certain constraints are imposed). The definition here is deliberately broad: it isolates the minimal scaffolding needed to talk about "change" in a way that is compatible with non-linear or branching temporal organization. For instance, if two events are incomparable in proto-time, the process description need not force an ordering between them, which is important when modeling concurrent, distributed, or multi-stream cognition.

Formal definition. *Let $(T, <)$ be a proto-time. Consider the thin category $\mathbf{T}$ whose objects are elements of T and with a unique morphism $t_1 \to t_2$ iff $t_1 < t_2$. A process over T is a functor*

$$S : \mathbf{T} \to \mathrm{Sys}$$

into a chosen category of system states Sys *(e.g. sets, measurable spaces, or V-enriched structures).*

The functoriality condition packages the idea that "later includes or follows from earlier" in a way that respects composition: if $t_1 < t_2 < t_3$, then the induced transition $S(t_1) \to S(t_3)$ factors as $S(t_1) \to S(t_2) \to S(t_3)$. In a thin category this is automatic at the level of arrows (there is at most one), but it becomes substantive once Sys *has nontrivial morphisms: specifying S amounts to choosing compatible transition-structure between states along the proto-time order. Examples include: (i)* $\mathrm{Sys} = \mathbf{Set}$ *with morphisms as update functions; (ii)* $\mathrm{Sys} = \mathbf{Meas}$ *with morphisms as measurable maps; (iii)* Sys *as a category of probabilistic kernels (Markov processes) where arrows encode stochastic evolution.*

Concept 141 (Process and Pattern)**.** *Appendix label: concept:ProcessAndPattern.*
Body definition label: hsdef:ProcessAndPattern (see § 114).

Informal definition. *A process is something that changes over time: a river flowing, a person learning, a conversation unfolding, a planet orbiting. A pattern is a regularity you can notice in what is happening: a rhythm, a repeating shape, a rule that keeps showing up, or a stable relationship between parts of the system. Hyperseed treats these as two sides of the same coin: processes are the "happening," while patterns are the "structure in the happening." In a given context/aspect C, we assume there is a repertoire of patterns P_C that the observer knows how to talk about (Hyperseed-Concept 130). Patterns are not just present-or-absent: they can show up weakly or strongly. The quantale V (Section 3) is used as a graded scale for "how much" a pattern is present, and $\mathrm{Int}_{S,t}(P)$ means "the intensity (degree of embodiment) of pattern P in system-state S at time t."*

The key interpretive point is that "pattern" here is not restricted to visually obvious repetition: it can include statistical regularities, causal dependencies, semantic roles in a discourse, or functional organization in a control loop, as long as the context/aspect C provides a vocabulary P_C for naming them. Likewise, intensity is meant to cover both crisp satisfaction (a rule fully holds) and graded *approximation (the rule is only approximately realized), with V chosen to match the intended notion of gradedness (e.g. $[0, 1]$ with multiplication, a max-plus semiring, or a lattice of qualitative levels).*

Formal definition. *Fix a context/aspect C and a set of candidate patterns P_C (Hyperseed-Concept 130), and let V be the quantale of intensity-values from Section 3. Let $(T, <)$ be a proto-time, and let* Sys *be a chosen category of system-states. A process is modeled (as in the process view) by a functor $S : \mathbf{T} \to \mathrm{Sys}$, so each $t \in T$ has a state $S(t)$. Assume that for each time t, the state $S(t)$ induces an intensity map*

$$\mathrm{Int}_{S(t),t} : P_C \to V.$$

Then the process/pattern interface is given by these intensities: each pattern $P \in P_C$ determines a time-indexed "pattern trace" $t \mapsto \mathrm{Int}_{S(t),t}(P)$, and conversely the pattern content of the process S (in aspect C) is the family of traces $\{\mathrm{Int}_{S(t),t}(\cdot)\}_{t\in T}$.

This interface can be read in two complementary directions. In the analysis direction, one starts with a process S and extracts a set of traces as observables/features, thereby projecting complex dynamics into a space of pattern-coordinates indexed by P_C. In the synthesis direction, one can treat a desired collection of traces as constraints and ask for processes whose states realize those intensities (possibly up to approximation in V). When V is a quantale, it also supports combining pattern-evidence across subsystems or time-slices using the quantale multiplication (or tensor), which makes it possible to model how multiple weak cues can compose into a stronger overall manifestation of a higher-level pattern.

Concept 142 (Proto-Time)**.** *Appendix label: concept:ProtoTime.*
Body definition label: hsdef:ProtoTime (see § 55).

Informal definition. *Proto-time is time "before clocks": it is just the idea that some experiences or events come before others. For example, you might remember eating breakfast before going to school, or noticing a sound after seeing a flash. Proto-time does not assume everything lines up on a single timeline; it only assumes you have some way to say "this happened before that" (and sometimes two things may be incomparable). The set T can be whatever the system treats as its time-points: occasions of experience (Hyperseed-Concept 124), events in an event calculus, or internal representational states. The key structure is the precedence relation $<$ recording "before/after" at the system's current resolution.*

Incomparability is not a bug but a feature: it allows proto-time to represent concurrency (two streams unfolding without a known order), indeterminacy (the system cannot currently decide which came first), or mere underspecification (the modeler chooses not to impose an order). Proto-time can therefore be shared between very different implementations: a biological agent with partial temporal access, a distributed computation with parallel steps, or a narrative representation in which only some ordering relations are asserted.

Formal definition. *A proto-time is a pair $(T, <)$ where T is a set of temporal indices (e.g. occasions, events, or representations of them) and $<$ is a strict partial order on T.*

Being a strict partial order means (i) irreflexive: never $t < t$, and (ii) transitive: if $t_1 < t_2$ and $t_2 < t_3$ then $t_1 < t_3$. It does not require totality: there may exist t_1, t_2 with neither $t_1 < t_2$ nor $t_2 < t_1$. When additional structure is present (e.g. a notion of "immediate successor," timestamps, or a metric), it can be layered on top of proto-time, but the Hyperseed baseline only assumes the order needed to speak about precedence-dependent notions such as "earlier context," "later update," and time-indexed traces of intensities.

Concept 143 (Quantale Weakness)**.** *Appendix label: concept:QuantaleWeakness.*
Body definition label: hsdef:QuantaleWeakness (see § 3.7).

Informal definition. *"Quantale weakness" is a simple way to score how many distinctions an observer is willing to ignore, especially among things the observer considers important. If you treat many pairs of items as "basically the same," then your representation is coarser (and in Hyperseed's sense, often simpler or more general). The weight function μ says which items matter more for this score: ignoring differences between high-weight items counts more than ignoring differences between low-weight items. This is meant as a quantitative proxy for the simplicity/generalization idea [3, 2]. Hyperseed-Concept 202; Hyperseed-Concept 143; Hyperseed-Concept 169.*

Formal definition. *Given a set X, a weight map $\mu : X \to V$, and a failed-distinction set $H \subseteq X \times X$, define the weakness of H by*

$$w(H) := \bigvee_{(u,v)\in H} \mu(u) \otimes \mu(v),$$

where $\bigvee$ is the join/supremum in the quantale V and $\otimes$ is the monoidal product.

Concept 144 (Questions)**.** *Appendix label: concept:Questions.*
Body definition label: hsdef:Questions (see § 291).

Informal definition. *A question is not just a sentence; it is something you do in order to find something out. You ask in a way that forces the world (or your own mind) to respond with information. For example, you might measure a length, run a test, look more closely, ask someone, try an experiment, or do a mental check. The point is to narrow down which situation you are actually in, or which concrete example you are dealing with, among several possibilities.*

Formal definition. *A question for a system S is an action (or action policy) whose intent is to obtain information about* $\mathrm{Inst}(\tau)$ *for some template τ. Formally, we model a question as a pair* (τ, Exp) *where:*

- *τ is a template pattern, and*
- Exp *is an experiment/interaction channel that produces data d which can be used to update beliefs about* $\mathrm{Inst}(\tau)$*.*

Concept 145 (Question Networks)**.** *Appendix label: concept:QuestionNetworks.*
Body definition label: hsdef:QuestionNetworks (see § 299).

Informal definition. *A question network is a map of inquiry: it keeps track of which questions depend on which other questions. Sometimes you cannot answer one question until you have answered (or at least partially answered) others. Importantly, real investigation can have feedback: two questions can support each other, and you may go back and forth refining both.*

Formal definition. *A question network is a directed graph $Q = (V, E)$ where nodes $v \in V$ are questions and an edge $v \to w$ means "answering v requires (or strongly benefits from) answering w." Cycles are permitted.*

Concept 146 (Quantity)**.** *Appendix label: concept:Quantity.*
Body definition label: hsdef:Quantity (see § 2.3).

Informal definition. *A quantity is "how much" of something there is. Sometimes it is a count (how many apples), sometimes it is a measurement (how much water, how much time, how much energy). Quantities let you compare ("more/less"), combine ("add them"), and scale ("twice as much"). In Hyperseed-style modeling, quantities show up everywhere: effort/cost, energy/genenergy, probability, intensity of patterns, and strength of evidence are all treated as quantities in some appropriate mathematical structure.*

No dedicated formal definition of "Quantity" is given in this version; it is listed as a basic concept used throughout.

Concept 147 (Rational Decision). *Appendix label: concept:RationalDecision. Body definition label: hsdef:RationalDecision (see § ??).*

Informal definition. *A rational decision (in the minimal Hyperseed sense) is a way of choosing actions that does not fall apart under conflict, does not pick something clearly worse for no reason, and does not ignore costs and feasibility. It also should not act as if a wildly unlikely outcome is guaranteed unless you have explicitly decided to treat that outcome as a "faith commitment." In other words: even with messy values and limited information, decision-making should remain disciplined rather than turning into "anything goes."*

Formal definition. *Fix a state s. A choice rule $\pi_O(\cdot \mid s)$ is (Hyperseed-minimally) rational if it satisfies:*

1. ***Non-explosion under value conflict:*** *if two actions have incomparable value-vectors (due to paraconsistency), the rule still returns a nonempty admissible set (or distribution) rather than degenerating into arbitrary choice over all actions.*

2. ***Dominance respect:*** *if an action a Pareto-dominates a' (under $\preceq_{\text{pref}}$ across all value dimensions d and has no greater resistance), then π_O does not prefer a' over a.*

3. ***Resource sensitivity:*** *ceteris paribus, if two actions have equal value evidence, the rule prefers smaller resistance $R_O(s, \cdot)$.*

4. ***Belief/value/action coherence:*** *if the observer's belief model assigns negligible plausibility to an outcome, the value attached to that outcome does not dominate action selection unless explicitly designated as a faith-commitment (Section 20).*

Concept 148 (Rationality). *Appendix label: concept:Rationality. Body definition label: hsdef:Rationality (see § ??).* ***Informal definition.*** *Rationality is the broader, ongoing ability to form good beliefs and good choices over time. It includes: learning from evidence instead of wishful thinking, keeping your beliefs and actions consistent with each other, noticing when something does not add up, and taking limited resources (time, attention, energy) seriously. In Hyperseed, rationality is not "cold logic only": it is connected to emotion/compassion, values/goals, resource constraints (energy/genenergy), belief systems and science, and also the social world (societies, mindplex/global brain, reality-systems), plus cultural and motivational styles (including wu-wei themes). In this sense, rationality is "system-relative": what counts as rational depends on what the agent can represent and do, and on the reality-system it is embedded in.*

No dedicated formal definition of "Rationality" is given in this version; the document provides minimal criteria for rational decision (Concept 147) and an explicit model of reasoning operations (Concept 150), which together serve as formal scaffolding for the broader informal notion here.

Concept 149 (Reality-System). *Appendix label: concept:RealitySystem. Body definition label: hsdef:RealitySystem (see § 367).*

Informal definition. *A reality-system is the shared "world" that a group effectively lives in together: the set of things they treat as real, the shared symbols and roles they recognize, and the web of cause-and-effect and prediction that links these things. It can be as small as two people coordinating a plan, or as large as a scientific community, an economy, or a culture. What makes it a genuine shared reality (not just many separate private worlds) is that people significantly influence and predict each other, and that there are patterns that exist across minds, not only inside each mind.*

Formal definition. *Fix a community C, an interval I, and a community intensity datum w. An intersubjective reality-system for C on I is a triple*

$$R_{C,I} = (E_{C,I}, L_{C,I}, w),$$

where:

- $E_{C,I}$ *is a set of entities-as-modeled-in-community (tokens for persons, objects, shared symbols, joint goals, norms, roles, etc., as represented across the community);*
- $L_{C,I}$ *is a set of weighted links encoding predictive and causal relationships between entities and between minds' representations of entities (e.g. a V-weighted directed hypergraph or simplicial structure on $E_{C,I}$);*
- w *assigns intensities to patterns supported on subcommunities $U \subseteq C$.*

We say $R_{C,I}$ is intersubjective (rather than merely a disjoint union of individual realities) if $L_{C,I}$ contains nontrivial cross-mind links of significant weight and w assigns non-negligible total intensity to patterns supported on $|U| \geq 2$.

Concept 150 (Reason)**.** *Appendix label: concept:Reason.*
Body definition label: hsdef:Reason (see § 466).

Informal definition. *Reason is the deliberate activity of improving what you think by using rules: you take in new evidence, consider possible explanations, and then check what follows from what you currently accept. In practice, this usually happens in loops: you learn something, adjust your beliefs, add or remove an assumption, and then work out the consequences, repeating until you reach a stable view (or until you decide you need better evidence).*

Formal definition. *A (finite) reasoning loop is any finite sequence of operations applied to an initial belief state β_0 where each step is one of:*

- ***Evidence join:*** $\beta \leftarrow \beta \oplus \epsilon$,
- ***Hypothesis injection:*** $\beta \leftarrow \beta \uparrow_s h$,
- ***Closure:*** $\beta \leftarrow \mathrm{Cl}_R(\beta)$.

Concept 151 (Recognition Process)**.** *Appendix label: concept:RecognitionProcess.*
Body definition label: hsdef:RecognitionProcess (see § 114).

Informal definition. *A recognition process is a process inside a system that learns to pick out and track another thing it is interacting with. Over time, the recognizing system comes to internally embody more of the same regularities (patterns) that are present in what it recognizes: it gets better at noticing those patterns, and it stops "missing" them as easily. Everyday examples include learning to recognize a friend's face, learning a melody, or a classifier learning features that reliably detect a kind of object. In Hyperseed this is made precise using the notion of patterns (Hyperseed-Concept 130) and a graded notion of how strongly a pattern is present.* ***Formal definition.*** *Fix a context/aspect C and a set of candidate patterns $\mathcal{P}_C$. Assume each system-state S at time t determines a (possibly fuzzy) intensity map $\mathrm{Int}_{S,t} : \mathcal{P}_C \to V$ into the quantale V from Section 3. A process Y is a* pattern recognition process *aimed at an entity X (in aspect C) if there exists a nonempty set $\mathcal{P}_{X,C} \subseteq \mathcal{P}_C$ such that for each $P \in \mathcal{P}_{X,C}$:*

1. *(alignment)* $\mathrm{Int}_{Y,t}(P) \leq \mathrm{Int}_{X,t}(P)$ *for all relevant t, and*
2. *(learning)* $\mathrm{Int}_{Y,t}(P)$ *is nondecreasing in t (with respect to the order on V), with strict increase for at least one P at least once.*

Concept 152 (Reference)**.** *Appendix label: concept:Reference.*
Body definition label: hsdef:Reference (see § ??).

Informal definition. *A reference is the "aboutness link" between a token inside a mind (a word, image, pointer, memory trace, or internal state) and the thing it is about. For example, the word "Paris" can refer to a particular city; a map can refer to a region; a mental picture can refer to a friend; and a variable name in a program can refer to a stored value. Reference is what makes a representation more than an accidental resemblance: it is the system's commitment that "this internal thing is meant to stand for that external thing," in some context/aspect. This is the link used by registration and representation (Hyperseed-Concept 153, 157).*

Formal definition. *A mind-model includes a representation space $\mathcal{R}$ (states/tokens that can stand in for other entities) and, for each context/aspect C, a reference relation*

$$\mathrm{Ref}_C \subseteq \mathcal{R} \times \mathcal{U}.$$

We read $\mathrm{Ref}_C(r, u)$ as: "the representation token r refers to the entity u in aspect C" (and "$\mathrm{Ref}_C(r, u)$ is nontrivial" as: the reference relation holds in that context).

Concept 153 (Registration)**.** *Appendix label: concept:Registration.*
Body definition label: hsdef:Registration (see § 115).

Informal definition. *Registration is the simplest kind of "taking notice." Something impacts a system, and the system comes to embody some pattern that is compatible with what happened, even if the system does not yet have a rich internal model of the cause. Registration can be vague: you might register that "something moved" or "something is there" without being able to identify it uniquely. In Hyperseed, this vagueness is handled by letting registration depend on the system's current context and on what it treats as indistinguishable (Hyperseed-Concept **??**).*

Formal definition. *Fix a context C and an equivalence relation $\sim_C$ on $\mathcal{U}_C$ (interpreted as "indistinguishable in context C" for the registering system). A system X* registers *an entity A at time t (in context C) if there exists $A' \in \mathcal{U}$ such that $A'|C \sim_C A|C$ and $A'|C$ becomes a pattern in X by time t. Concretely, this can be witnessed by a pattern $P \in \mathcal{P}_C$ such that*

$$\mathrm{Int}_{X,t}(P) \not\leq \theta \qquad \textit{and} \qquad \mathrm{Ref}_C(P, A|C) \textit{ is nontrivial},$$

for some threshold $\theta \in V$.

Concept 154 (Religion)**.** *Appendix label: concept:Religion.*
Body definition label: hsdef:Religion (see § 24.9).

Informal definition. *In Hyperseed's ontology-level language, a religion is a socially stabilized way of transmitting, reinforcing, and coordinating patterns across many minds using shared stories, symbols, practices, and rituals. It functions as a long-running "pattern carrier": repeated participation tends to install or strengthen certain archetypal patterns (and certain value-and-meaning patterns) in the participants, and to synchronize those patterns across a community. This is one natural route to what Hyperseed calls communion: strong cross-mind pattern overlap supported by shared practices.*

Concept 155 (Repetition)**.** *Appendix label: concept:Repetition.*
Body definition label: hsdef:Repetition (see § 28.1).

Informal definition. *A repetition is "the same kind of thing happening again": two events are not literally identical, but they count as the same pattern for the purposes at hand. This requires both (i) that the two instances are distinguishable as separate occurrences, and (ii) that they are interchangeable at the relevant level (swapping one for the other does not change what matters). A* *variety is the contrast: the instances are distinguishable and the difference matters for the current context.*

Formal definition. *Fix thresholds $\tau_\delta, \tau_\iota \in (0,1)$. For $x \neq y$ in X_c define:*

$$\mathrm{Rep}_c(x,y) \iff \mathrm{Dist}_c(x,y)^+ \geq \tau_\delta \text{ and } \iota_c(x,y)^+ \geq \tau_\iota,$$

$$\mathrm{Var}_c(x,y) \iff \mathrm{Dist}_c(x,y)^+ \geq \tau_\delta \text{ and } \iota_c(x,y)^- \geq \tau_\iota.$$

Intuitively, a repetition is distinct-yet-substitutable; a variety is distinct-and-not-substitutable.

Concept 156 (Reproduction (within Species))**.** *Appendix label: concept:Reproduction. Body definition label: hsdef:Reproduction (see § 41.5).* ***Informal definition.*** *Metabolism sustains an individual system; reproduction sustains a* type *of system over time. A reproduction event happens when one system plays a primary causal role in bringing about another system that counts as "the same kind" (within some tolerance) under the observer's notion of similarity. Biological parenthood is the standard example, but the same abstract idea also covers, for example, a machine manufacturing another machine of the same design, or software producing a faithful copy of itself, as long as the similarity criterion is met.*

Formal definition. *Fix an observer/context O. Let $W_O(S,t)$ denote the pattern-web state of system S at time t (relative to O), and let $d_O(\cdot,\cdot)$ be a distance (or dissimilarity) between pattern webs. For $\epsilon > 0$, define within-species similarity by*

$$S \approx_{O,\epsilon} S' \iff \exists\, t, t' \text{ such that } d_O\big(W_O(S,t), W_O(S',t')\big) \leq \epsilon.$$

A reproduction event *from S to S' over a time window $[t_0, t_1]$ is an event in which:*

- *the existence/state of S and its actions in $[t_0, t_1]$ have a strong causal influence on the existence of S' at time t_1, and*
- *$S \approx_{O,\epsilon} S'$ for a chosen species-tolerance parameter ϵ.*

Concept 157 (Representation)**.** *Appendix label: concept:Representation. Body definition label: hsdef:Representation (see § 52).*

Informal definition. *A representation is something that stands in for something else: a map stands in for a territory, a drawing stands in for an object, and a mental model stands in for a situation in the world. In Hyperseed, A represents B (in an aspect) when two conditions hold. First, A is genuinely* about *B (it refers to it; Hyperseed-Concept 152). Second, A preserves some of the same patterns that are present in B in that aspect (inheritance; Hyperseed-Concept* **??***). Both matter: similarity without reference is accidental resemblance, and reference without inherited structure is an empty pointer.*

Formal definition. *Let $A, B \in \mathcal{U}$ and context C be given. We say that A represents B in aspect C if:*

1. *(reference) $\mathrm{Ref}_C(A, B|C)$ is nontrivial, and*
2. *(inheritance) $A|C$ inherits patterns from $B|C$ in the sense of Definition 165.*

Concept 158 (Resistance)**.** *Appendix label: concept:Resistance. Body definition label: hsdef:Resistance (see § 47.6).*

Informal definition. *Resistance measures how much an agent is "forcing" the world away from its default or passive unfolding. If your chosen action-policy behaves very differently from what would happen by default, then it pays a high resistance cost; if it mostly follows the passive* *flow, resistance is low. Acceptance is the complementary idea: high acceptance means your behavior is compatible with the passive dynamics (you are not fighting the flow).*

Formal definition. *Fix passive dynamics P_0. For a policy π, define its instantaneous resistance at state x as*

$$\mathrm{Resist}_\lambda(\pi; x) := \lambda\, \mathrm{KL}\big(P_\pi(\cdot \mid x) \,\|\, P_0(\cdot \mid x)\big).$$

Define its acceptance at x as the complementary score

$$\mathrm{Accept}_\lambda(\pi; x) := \exp\big(-\mathrm{Resist}_\lambda(\pi; x)/\lambda\big) = \exp\big(-\mathrm{KL}(P_\pi \| P_0)(x)\big).$$

Thus acceptance is high exactly when resistance is low.

Concept 159 (Resonance)**.** *Appendix label: concept:Resonance.*
Body definition label: hsdef:Resonance (see § 19).

Informal definition. *Resonance is the idea of "lining up so the effects add instead of cancel." Like waves that are in phase produce a larger wave, aligned contributions in a pattern system can reinforce each other, while misaligned contributions can interfere destructively. In Hyperseed, resonance is built from many local comparisons across a network (Hyperseed-Concept 131; Hyperseed-Concept 132); the local comparison is a normalized alignment score between two evidence contributions.*

Formal definition. *For $v, w \in \mathbb{V}$ with $\sigma_C(v) \neq 0$ and $\sigma_C(w) \neq 0$, define the normalized alignment*

$$\mathrm{align}(v, w) := \frac{\Re\big(\sigma_C(v)\,\overline{\sigma_C(w)}\big)}{|\sigma_C(v)|\,|\sigma_C(w)|} \in [-1, 1].$$

If either $\sigma_C(v) = 0$ or $\sigma_C(w) = 0$, set $\mathrm{align}(v, w) := 0$.

Concept 160 (Reward)**.** *Appendix label: concept:Reward.*
Body definition label: hsdef:Reward (see § ??).

Informal definition. *A reward is a single-number score used to guide or train action: higher reward means "better" according to a chosen summary of what the agent values. Reward is useful because it lets you apply standard optimization and learning tools, but it is also dangerous because it can hide conflicts and tradeoffs by collapsing many values into one scalar. Hyperseed typically treats reward as a proxy: keep multi-dimensional values visible when possible, and use scalars carefully when you need them.*

Formal definition. *Fix weights $\lambda_d \geq 0$ for $d \in D$ and a resistance weight $\beta \geq 0$. Define a scalar reward proxy by*

$$r_O(s, a) := \sum_{d \in D} \lambda_d \big(J_O(s, a; d) - W_O(s, a; d)\big) - \beta\, R_O(s, a).$$

Concept 161 (Reward Maximization)**.** *Appendix label: concept:RewardMaximization.*
Body definition label: hsdef:RewardMaximization (see § ??). ***Informal definition.*** *Reward maximization is a decision style where you compress everything you care about into a single numerical score (a "reward") and then choose actions to make that number as large as possible. This is often a useful engineering shortcut because it gives a clean target for learning and planning algorithms. The downside is that it can hide important tradeoffs: once many competing considerations are collapsed into one number, you can no longer easily see which value got sacrificed to improve which other value. Hyperseed contrasts this with goal seeking, where some constraints are treated as hard (or lexicographically prior) and a reward-like scalar is used only to choose among the remaining feasible options.*

One practical way to read this is: reward maximization turns a multi-criteria problem into a single-criterion problem by selecting an aggregation rule in advance. This can be convenient, but it also makes the aggregation rule a silent "policy choice" that may not match the users actual priorities under distribution shift, partial observability, or when new kinds of failure appear. In particular, once everything is scalarized, violations of a previously "important" consideration can look like ordinary tradeoffs rather than like constraint breaches, which can matter when interpreting behavior, debugging, or auditing.

Formal definition. *Fix weights $\lambda_d \geq 0$ for $d \in D$ and a resistance weight $\beta \geq 0$, and define the scalar reward proxy $r_O(s, a)$ as in Definition 253:*

$$r_O(s, a) := \sum_{d \in D} \lambda_d \big(J_O(s, a; d) - W_O(s, a; d)\big) \; - \; \beta \, R_O(s, a).$$

A one-step reward-maximizing choice rule at state s selects any action $a^* \in A$ satisfying

$$r_O(s, a^*) = \max_{a \in A} r_O(s, a).$$

(Equivalently, maximize the Score defined in Proposition 24.)

Because the choice rule only depends on the scalar $r_O(s, a)$, any two actions with identical proxy reward are interchangeable under this decision style, even if they differ substantially in their underlying vector of consequences. This highlights the role of the weights λ_d and β as a normative encoding: they determine which distinctions survive the compression and which are treated as irrelevant at decision time. When Hyperseed contrasts this with goal seeking, the intended technical contrast is that goal seeking can be represented as (i) first restricting A to a feasible subset $A_{\text{feas}}(s)$ induced by hard/lexicographic constraints, and then (ii) applying a reward-like score only on that restricted set, thereby keeping some distinctions non-compensatory rather than merely "expensive." In that reading, reward maximization corresponds to the special case where the feasible set is all of A and all desiderata are made compensatory through a single scalar.

Concept 162 (Rich-Resource Mind)**.** *Appendix label: concept:RichResourceMind. Body definition label: hsdef:RichResourceMind (see § 1133).*

Informal definition. *A rich-resource mind is an agent with enough resources (time, compute, energy, memory, data, coordination ability, etc.) that it can (i) search broadly for good options rather than settling for the first acceptable one, and (ii) run sufficiently strong verification and error-correction that random noise and sloppy optimization errors can be kept small. When resources become large, qualitatively new strategies can become available (for example, extensive simulation, large-scale model search, or self-replication), and the agent's typical attention-allocation and weakness profile may shift in a way that is not just "more of the same" (Hyperseed-Concept 162; [11]). This matters because the ontology aims to be scale-robust: it should describe not only humans and current machines, but also potential successors.*

A useful diagnostic is that, in a rich-resource mind, failures are less dominated by "could not find any plan" and more dominated by specification/ontology mismatch (choosing the wrong target) or by strategic interactions (other agents reacting). In other words, additional resources can move the main failure mode from search failure toward objective failure, including the possibility that the agent becomes very good at achieving the wrong proxy. The glossary term is therefore not intended as simple praise ("powerful"), but as a marker that some approximations (e.g. assuming high noise, bounded lookahead, or negligible verification) may stop being the right default regime.

Formal definition. *(Resource-rich regime, per Assumption 5.) In the drift-controlled self-modification setting, let $F(\theta)$ be the objective and $D(\theta; \theta_t)$ the drift penalty with weight λ. A* *rich-resource regime is characterized by bounded optimization error and small noise: the update θ_{t+1} is chosen so that*

$$F(\theta_{t+1}) - \lambda D(\theta_{t+1};\theta_t) \ \geq\ \sup_{\theta}\bigl(F(\theta) - \lambda D(\theta;\theta_t)\bigr) \ -\ \eta,$$

for a small optimization gap $\eta \geq 0$, and (when modeled) the noise is sub-Gaussian with scale parameter σ that can be made small. In the deterministic idealization, one sets $\eta = \sigma = 0$.

The parameter η makes explicit that "resource-rich" is not defined as literal global optimality, but as being close enough to the best available update that optimization error is no longer the dominant uncertainty. Similarly, modeling noise as sub-Gaussian with tunable scale σ encodes the idea that the agent can invest in measurement, redundancy, and verification so that stochasticity is not the main driver of outcomes. Within this framing, increasing resources corresponds (in part) to shrinking (η, σ), expanding the effective hypothesis/plan class over which $\sup_\theta$ is taken, and improving the ability to estimate the consequences of updates—all of which can change qualitative behavior even if the formal update equation keeps the same shape.

Concept 163 (Second (Peircean Category))**.** *Appendix label: concept:SecondPeircean. Body definition label: hsdef:SecondPeircean (see § 45).*

Informal definition. *A Second is the basic experience of "pushback" or "difference": something meets resistance, and you get the sense that "this is not that" or "my expectation did not fit what happened." It is inherently about interaction and directionality: comparing x to y can reveal a mismatch even when comparing y to x would not reveal the same mismatch (because the comparison depends on which way you are trying to map or substitute things). In predictive terms, a Second can be read as the primitive discrepancy between a model state and an observation.*

The emphasis on directionality is meant to rule out treating a Second as merely an undirected distance. Many practically relevant "mismatch" notions are asymmetric: e.g. a proposed simplification may fail to capture details of the original (simplification $\to$ original mismatch), while the reverse mapping (original $\to$ simplification) can succeed by forgetting information. Likewise, "prediction error" is naturally directed from prediction to outcome, even if some symmetric loss can be derived later. Hyperseed uses this Peircean notion to keep track of the minimal event of resistance that forces an update in belief, plan, or representation.

Formal definition. *For a context c, a Second is a directed difference event, i.e. an ordered pair $(x, y) \in X_c \times X_c$ together with its directed difference evaluation $\mathrm{Diff}_c(x \to y)$. Seconds are the smallest units at which "reaction" or "opposition" can be represented.*

Here $\mathrm{Diff}_c(\cdot \to \cdot)$ is intentionally left more general than a metric: depending on context, it can be a signed residual, a constraint violation indicator, a likelihood ratio, an edit distance under a chosen code, or any evaluation that says "this attempted substitution/expectation did not fit." The context index c carries the background choices that make a particular directed difference meaningful (representation, allowable transformations, observation channel, and the granularity at which differences are registered). Under this view, many familiar quantities (surprisal, loss, prediction error, constraint slack) can be interpreted as structured families of Seconds once their direction and context are made explicit.

Concept 164 (Second Law of Thermodynamics)**.** *Appendix label: concept:SecondLawOfThermodynamics. Body definition label: hsdef:SecondLawOfThermodynamics (see § 347).*

Informal definition. *In everyday physics language, the second law says that (in a closed system) things tend to evolve toward states that are more "spread out" or "mixed up" (higher entropy), because there are vastly more disordered microstates than ordered ones. Hyperseed's key caution is that entropy and information measures are not purely observer-free numbers: what you* *call "entropy" depends on which variables you track and which distinctions you ignore (your coarse-graining). If you change the description level (the resolution and the choice of state variables), you can change whether entropy appears to increase, decrease, or stay roughly constant. So "second-law-like" claims should be read as statements about an effective description, not as a single context-independent monotonic quantity attached to reality.*

This caution does not deny that there are rigorous second-law theorems under specific assumptions; rather, it highlights that the monotone quantity is tied to a modeling choice (e.g. a macrostate partition, a Markov approximation, a bath/system split, or an assumed equilibrium family). In many applied settings, what is operationally measured as "entropy increase" is really the growth of uncertainty about microstate details relative to a chosen macro-description, or the dissipation of free energy relative to a specified environment. From Hyperseeds perspective, this makes the second law a particularly vivid example of an ontology point: monotonic "progress measures" typically live at a level of abstraction, and changing abstraction can change what looks monotone.

Listed in the concept inventory without a dedicated standalone formal definition in this version; the main text emphasizes the observer-relative/coarse-graining-relative reading (see Remark 347).

Concept 165 (Self vs. Other)**.** *Appendix label: concept:SelfVsOther.*
Body definition label: hsdef:SelfVsOther (see § 211).

Informal definition. *"Self vs. Other" is the distinction an agent draws between (i) what it treats as "me" or "under my control / part of my boundary" and (ii) what it treats as external: the environment, other agents, and generally the sources of uncertainty and resistance. The key point is that this boundary is not automatically the same as the physical boundary of the agents hardware or body. Instead, it is an agent-relative modeling and control choice: tools, collaborators, submodules, future copies, or institutional processes can be treated as "self-like" to varying degrees, while parts of ones own body or cognition can be treated as "other-like" when they are opaque, adversarial, or only weakly controllable.*

In Hyperseed terms, the Self/Other cut is an ontological move that shapes agency: it affects credit assignment (who caused what), planning (which degrees of freedom are optimized vs. treated as exogenous), and moral or normative interpretation (which outcomes count as "my actions"). The boundary can shift with resources and competence: a rich-resource mind may internalize larger toolchains, predictive models, or coordination structures into its effective "self," while simultaneously treating more of the external world as predictable and hence quasi-internal for planning purposes.

This boundary is often not perfectly crisp. For example, you can feel both ownership and alienation about a thought, or both identification and separation from a group. In Hyperseed terms, this is not a bug to be eliminated; it is often real information about a complex, layered system.

Formal definition. *Fix a context c with state space X_c and action interface A. A Self/Other distinction is a partition (or, more generally, a factorization) of the modeled variables into components*

$$X_c \cong X_c^{\mathrm{self}} \times X_c^{\mathrm{other}},$$

together with an attribution rule that assigns which transitions are treated as endogenously controlled ("self-caused") versus exogenously generated ("other-caused"). Equivalently, it is a choice of conditional dynamics model of the form

$$P(x' \mid x, a) \;=\; P\Big(x^{\mathrm{self}\,\prime}, x^{\mathrm{other}\,\prime} \mid x^{\mathrm{self}}, x^{\mathrm{other}}, a\Big),$$

where the modeling assumption specifies which components of x' are treated as directly influenced by a (and thus by the agent) and which are treated as background processes or responses.

This definition is compatible with "soft" boundaries: instead of a hard partition, one may use a graded notion of self-likeness (e.g. a weighting over variables, or a set of partially controllable factors), but the core content remains that the agent commits to a representational boundary for purposes of prediction, control, and responsibility assignment. In particular, a Self/Other cut interacts with directed difference (Seconds): when a mismatch occurs, whether it is interpreted as "my mistake" (update X_c^{self} or the policy) or "world pushback" (update X_c^{other} or the environment model) depends on where the boundary was drawn.

Formal definition: evidential approach *(Self-evidence and self groupings, per Definition 211.) Fix a time interval I. Let X_I be the set of representational tokens (states, features, self-model elements, etc.) available on I. A self-evidence function is a map*

$$\sigma_I : X_I \to [0,1]^2, \qquad \sigma_I(x) = (\sigma_I^+(x), \sigma_I^-(x)),$$

where $\sigma_I^+(x)$ is the evidence that x belongs to self and $\sigma_I^-(x)$ is the evidence that x does not belong to self (no consistency constraint is imposed). Given thresholds $\theta^+, \theta^- \in [0,1]$, define the crisp self grouping

$$\mathrm{Self}_\theta(I) := \{x \in X_I : \sigma_I^+(x) \geq \theta^+ \text{ and } \sigma_I^-(x) \leq \theta^-\},$$

and define $\mathrm{Other}_\theta(I) := X_I \setminus \mathrm{Self}_\theta(I)$.

Concept 166 (Self-Continuity)**.** *Appendix label: concept:SelfContinuity.*
Body definition label: hsdef:SelfContinuity (see § 216).

Informal definition. *Self-continuity is "how much the same self" a system remains over time. A mind can change in many ways while still being recognizably continuous (learning, maturing, forgetting details), but it can also change in ways that break continuity (radical rewrites of core patterns, values, or identity structure). In this formalism, self-continuity is measured by how well the system's internal pattern-flow structure at one time can be matched to its internal pattern-flow structure at a later time, allowing relabeling but requiring that the structural relationships are preserved to a high degree.*

Formal definition. *(Self-continuity score, per Definition 520.) Let F_I and F_J be the relevant internal flow networks (pattern-flow structures) over intervals I and J, with node sets X_I and X_J. Define the self-continuity score from I to J as*

$$\mathrm{SCS}(I \to J) \ := \bigvee_{f : X_I \to X_J} \deg(f; F_I, F_J),$$

i.e. the join (supremum) over all maps f of the approximate-morphism degree $\deg(f; F_I, F_J)$.

Concept 167 (Self-Transcendence)**.** *Appendix label: concept:SelfTranscendence.*
Body definition label: hsdef:SelfTranscendence (see § ??).

Informal definition. *Self-transcendence is the tendency to go beyond your current identity: to expand what you can understand, what you can care about, and what kinds of lives or minds you can become. It includes the willingness to revise your self-model and even your values when you discover something larger, deeper, or more coherent than your current framing. Hyperseed treats self-transcendence as being in real (and often productive) tension with individuation and self-continuity: you want to remain meaningfully yourself, but also to grow beyond your current self (Hyperseed-Concept 96; Hyperseed-Concept 166).*

Formal definition. *(Individuation and self-transcendence as value dimensions, per Definition 257.) Assume* $\mathrm{individuation}, \mathrm{selftranscendence} \in D$ *(value dimensions). High evaluation on* selftranscendence *favors options that expand the representational and motivational space, including revisions or enlargements of D itself (i.e., it is a meta-value that can push toward changing the agent's own value-basis).*

Concept 168 (Self-Weaving Webs)**.** *Appendix label: concept:SelfWeavingWebs.*
Body definition label: hsdef:SelfWeavingWebs (see § 34.4).

Informal definition. *A self-weaving web is a network of patterns that can keep itself going. Roughly: once enough of its patterns are active, they mutually reinforce each other so that each one keeps getting re-produced rather than dying out. This is the cognitive analogue of an autocatalytic set in chemistry: instead of molecules catalyzing each other's production, you have habits, concepts, behaviors, and subroutines that repeatedly regenerate one another's support (Hyperseed-Concept 11). Intuitively, a self-weaving web is a "self-sustaining cluster" inside a larger mind.*

Formal definition. *Fix a reinforcement relation $A : P \times P \to V$ and a threshold $\theta \in V$. A nonempty subset $S \subseteq P$ is called θ-autocatalytic if there exists a state $s : P \to V$ such that:*

1. *(support on S) for all $p \in S$, $s(p) \geq \theta$; and*
2. *(self-production) for all $p \in S$, $(A?s)(p) \geq \theta$.*

A pattern web (P, A) is a self-weaving web (at threshold θ) if it contains a θ-autocatalytic subset.

Concept 169 (Simplicity)**.** *Appendix label: concept:Simplicity.*
Body definition label: hsdef:Simplicity (see § 30.3).

Informal definition. *In this framework, "simplicity" means: how cheaply can you build something from simpler pieces, given a chosen set of building blocks and a chosen way of combining them? An object is simpler if there is a short, low-cost construction that assembles it from simpler parts, paying not only for the parts but also for the overhead of putting them together. If an object cannot be built at all within the allowed combination rules, then (in that system) it is treated as having infinite simplicity-cost.* ***Formal definition.*** *Let $(X_C, *, e)$ be a combination system with overhead t_C. A function $s_C : X_C \to [0, \infty]$ is compositionally admissible if:*

1. *$s_C(e) = 0$, and*
2. *for all $x \in X_C$,*
$$s_C(x) \leq \inf_{y,z \in X_C \,:\, y*z=x} \big(s_C(y) + s_C(z) + t_C(y, z)\big),$$
with the understanding that $\inf \emptyset = \infty$.

Define the compositional simplicity s^*_C to be the least (pointwise) function satisfying these constraints.

Concept 170 (Society)**.** *Appendix label: concept:Society.*
Body definition label: hsdef:Society (see § 332).

Informal definition. *A society is a group of agents who interact in a sustained way, influence one another, and share durable structures that help patterns persist beyond any one individual's moment-to-moment activity. Those durable structures include things like tools, documents, rituals, institutions, shared environments, and shared memory stores. Hyperseed also emphasizes that in many societies there are real material and biological constraints (resources, maintenance, reproduction) that shape what patterns can persist; but for many cognitive and cultural questions, it is enough to model who interacts with whom, how strongly, and what shared artifacts they can access.*

Formal definition. *A society is a tuple*

$$\mathrm{Soc} := (A, G, K, \mathcal{A}, \mathrm{Acc}, D),$$

where: (i) A is a set of agents; (ii) $G = (A, E)$ is an interaction graph; (iii) K is a coupling weight on E; (iv) $\mathcal{A}$ is a set of shared artifacts; (v) $\mathrm{Acc} \subseteq A \times \mathcal{A}$ is an access relation; and (vi) D is *(optional) additional domain structure capturing the resource-flow and reproduction dependencies relevant to the society (metabolism, exchange, child rearing, maintenance of shared infrastructure, etc.).*

Concept 171 (Social Roles)**.** *Appendix label: concept:SocialRoles.*
Body definition label: hsdef:SocialRoles (see § 22.6).

Informal definition. *A social role is a recognizable pattern in how someone tends to interact with others in a group. For example, a "teacher" is someone who usually explains and answers, a "student" is someone who usually asks questions and tries to learn, a "worker" tends to follow directions in exchange for resources, and "colleagues" coordinate as peers. In Hyperseed, roles are not permanent labels on people; they are about what happens in an interaction episode, and a single person can play different roles in different situations (or even partly play multiple roles at once).*

Formal definition. *Fix a set of act types T (e.g. question/response/command/statement) and a set of artifact-operations (e.g. read, write, modify, use). A* role template *is a finite labeled directed graph*

$$R = (V_R, E_R, \lambda),$$

where V_R is a finite set of abstract participant-slots (e.g. "teacher", "student"), and $\lambda : E_R \to T \cup \{\textit{artifact ops}\}$ labels each directed edge by an act type or artifact-operation. Given a society $\mathrm{Soc} = (A, G, K, \mathcal{A}, \mathrm{Acc}, D)$ and an observed interaction episode Ep (a finite subgraph or sequence of acts), an instantiation *of R is a map $\rho : V_R \to A$. A* fit score *is a function*

$$\mathrm{Fit}(R, \rho; \mathrm{Ep}) \in [0, 1]$$

measuring how well the labeled edges of R match the acts/edges observed in Ep under the assignment ρ (optionally weighted by couplings K and attention weights). The role-template R is said to be present *in Ep under ρ when $\mathrm{Fit}(R, \rho; \mathrm{Ep})$ exceeds a chosen threshold.*

Concept 172 (Soggy Predicates)**.** *Appendix label: concept:SoggyPredicates.*
Body definition label: hsdef:SoggyPredicates (see § 35.5).

Informal definition. *A soggy predicate is a way to combine many imperfect "checks" of whether something has a property. Imagine you have several tests, viewpoints, or measurements, and each one gives some evidence that the property is true and some evidence that it is false. A soggy predicate just takes a weighted average of those pieces of evidence, so you get one combined "for" score and one combined "against" score. The point is to keep track of mixed evidence honestly, instead of forcing everything into a single yes/no answer.*

Formal definition. *Fix a universe X. Fix a finite observation set O and weights $w_o \geq 0$ such that $\sum_{o \in O} w_o = 1$. Assume each observation $o \in O$ yields an evidential evaluation $e_o : X \to [0, 1]^2$. The induced* soggy predicate *is the function $F : X \to [0, 1]^2$ defined by*

$$F(x) := \sum_{o \in O} w_o \, e_o(x),$$

where the sum is taken componentwise in $[0, 1]^2$.

Concept 173 (Space)**.** *Appendix label: concept:Space.*
Body definition label: hsdef:Space (see § 222).

Informal definition. *In Hyperseed, a "space" is any setup where you can compare things by saying which ones are closer, more similar, or better matching. Physical space is one example (near vs. far), but you can also have a "meaning space" where ideas are close if they mean similar things.*

Hyperseed uses this idea to compare what is inside a mind (internal tokens, concepts, body-schema items) with what is in the world: you embed both into a shared comparison space, and then closeness in that space expresses how well they correspond. ***Formal definition.*** *A V-space is a V-category S (objects with V-valued hom/similarity) together with a chosen scalarization $\|\cdot\| : V \to [0, \infty]$. The induced extended pseudo-metric on objects is*

$$d_S(a, b) := \|S(a, b)\|.$$

Given V-graphs $M = (X^{\text{in}}, M)$ and $E = (X^{\text{out}}, E)$, a correspondence space *for (M, E) is a V-space S together with maps $i : X^{\text{in}} \to \mathrm{Ob}(S)$ and $e : X^{\text{out}} \to \mathrm{Ob}(S)$, which induce a V-valued correspondence relation*

$$R_S(x, y) := S(i(x), e(y)) \qquad (x \in X^{\text{in}},\, y \in X^{\text{out}}).$$

Concept 174 (Species)**.** *Appendix label: concept:Species.*
Body definition label: hsdef:Species (see § 41.5).

Informal definition. *A species is a "kind" that stays stable through reproduction: if something counts as part of the species, then its offspring (within an agreed tolerance of what counts as "the same kind") also count as part of the species. In other words, the species is closed under the reproduction process. Hyperseed also allows reproduction to be done by groups or composite systems (not only single individuals); that just means the reproduction relation can start from a coalition object instead of a single entity.*

Formal definition. *Fix an observer/context O and tolerance $\epsilon > 0$. Let $\to_O$ be the directed relation on systems given by*

$$S \to_O S' \iff \text{there exists a reproduction event from } S \text{ to } S' \text{ (within tolerance } \epsilon).$$

A nonempty set C of systems is called a species *(for O) if:*

- *(closure) whenever $S \in C$ and $S \to_O S'$, then $S' \in C$; and*
- *(regeneration) for each $S' \in C$, there exists $S \in C$ with $S \to_O S'$ (except possibly for a designated "initial" subset, if one wishes to allow an origin event).*

Concept 175 (Specific Entity)**.** *Appendix label: concept:SpecificEntity.*
Body definition label: hsdef:SpecificEntity (see § 116).

Informal definition. *A specific entity is what you normally mean by "that particular thing" over time: a particular person, a particular dog, a particular company, a particular chair. It is not just one snapshot. Instead, it is a time-ordered stream of occurrences that stay connected and similar enough that we treat them as "the same thing continuing." Hyperseed treats this as a pattern with default rules that can be bent in weird edge cases (so identity can be graded or ambiguous instead of exploding into contradiction).*

Formal definition. *A specific entity in context C is specified by an occurrence stream $\{x_t\}_{t \in T}$ together with a coherence rule R such that:*

1. *(Same-time identity) If $t = t'$ and both x_t and $x_{t'}$ occur, then they are identified: $x_t = x_{t'}$.*
2. *(Near-time similarity) If t and t' are close in proto-time, then the association $\mathrm{assoc}_C(x_t, x_{t'})$ is high (Definition 100), or equivalently the property-sets overlap strongly.*

The strength of "being the same specific entity" is graded by how well the stream satisfies these rules.

Concept 176 (Spiritual and/or Psychedelic Communion)**.** *Appendix label: concept:SpiritualPsychedelicCommunio*
Body definition label: hsdef:SpiritualPsychedelicCommunion (see § 374).

Informal definition. *This concept aims to capture a common kind of report in spiritual or psychedelic contexts: a person feels they are in deep connection or "communion" with something that seems bigger than their usual self. That "something" might be another person, a group-mind, nature, an ecosystem-scale process, or an unusual mind-model accessed in an altered state. Hyperseed does not try to settle what is metaphysically real here; it only gives a structural test for when an experience has this character.*

Formal definition. *Let m, n be minds and consider the dyadic community $C = \{m, n\}$. We say that m has a spiritual experience (spiritual communion) with n on an interval I if:*

1. $\mathrm{Comm}(C, I; w)$ *holds, and*

2. $\mathrm{Scope}(n, I) \geq \mathrm{Scope}(m, I) + \delta$ *for some fixed $\delta > 0$,*

so that n is (in this operational sense) broader-scope than m on I. Psychedelic/entheogenic procedures are modeled as interventions that shift the relevant intensity data w in ways that tend to increase the communion margin and/or the designation of communion episodes (see the entheogen intervention definition following Definition 374 in the main text).

Concept 177 (Spirituality)**.** *Appendix label: concept:Spirituality.*
Body definition label: hsdef:Spirituality (see § 374).

Informal definition. *Spirituality is the ongoing orientation (of a person or a community) toward experiences of deep connection and meaning that feel larger than ordinary everyday self-concern. It includes the habits and practices people use to seek, recognize, integrate, and return to such experiences (for example: meditation, prayer, ritual, moral discipline, contemplative study, and sometimes psychedelics). In Hyperseed terms, spirituality is less about believing a particular theory and more about building reliable ways of entering, stabilizing, and learning from spiritual communion episodes.*

Concept 178 (States of Consciousness)**.** *Appendix label: concept:StatesOfConsciousness.*
Body definition label: hsdef:StatesOfConsciousness (see § 239). ***Informal definition.*** *A state of consciousness is a mode your mind can be in (waking, dreaming, highly focused, spaced out, hallucinating, "oceanic" states, etc.) that changes what you notice, how your thoughts connect, how much you reflect on yourself, and how strongly experiences turn into habits. Hyperseed models these states as different settings of a small "control panel" of parameters: how tightly you are anchored to sensory input, how strongly internal associations take over, how much introspection is amplified, how hard you push for coherence, and how strongly habit and resonance mechanisms couple things together (Hyperseed-Concept 155, Hyperseed-Concept 159).*

Formal definition. *A state-of-consciousness parameter tuple is*

$$\Lambda := (\lambda_{\mathrm{ext}}, \lambda_{\mathrm{int}}, \lambda_{\mathrm{ref}}, \lambda_{\mathrm{coh}}, \rho_{\mathrm{hab}}, \rho_{\mathrm{res}}),$$

where:

- λ_{ext} *controls anchoring to current sensory registration (Section 13);*
- λ_{int} *controls internal completion/association (pattern-web propagation; Section 11);*
- λ_{ref} *controls introspection gain (Section 17.3);*
- λ_{coh} *controls coherence preference (Section 17.4);*

- ρ_{hab} *controls habit reinforcement strength (Section 12);*
- ρ_{res} *controls resonance coupling strength (Sections 3.9 and 12).*

Concept 179 (Stimulate)**.** *Appendix label: concept:Stimulate.*
Body definition label: hsdef:Stimulate (see § 326).

Informal definition. *Think of a "claim" as a statement you might believe (like "it will rain" or "the stove is hot"). An action* stimulates *a claim when doing it tends to give you more evidence that the claim is true than evidence that it is false. An action* inhibits *a claim when it tends to push evidence the other way. This gives a simple, practical meaning to actions: they matter because they tilt what evidence you have for the things you care about.*

Formal definition. *Fix a claim set L (Section 20) and let β be the agent's belief state. Assume that executing an action a in observation context o produces an effect increment*

$$\epsilon_{a,o} : L \to V,$$

so that a belief update step has the form $\beta \leftarrow \beta \oplus \epsilon_{a,o}$ (possibly followed by closure). Write $\epsilon_{a,o}(\phi) = (\epsilon^{+}_{a,o}(\phi), \epsilon^{-}_{a,o}(\phi))$ for $\phi \in L$. Then:

- *a stimulates ϕ at o if $\epsilon^{+}_{a,o}(\phi) > \epsilon^{-}_{a,o}(\phi)$;*
- *a inhibits ϕ at o if $\epsilon^{-}_{a,o}(\phi) > \epsilon^{+}_{a,o}(\phi)$;*
- *a is neutral on ϕ at o if $\epsilon^{+}_{a,o}(\phi) = \epsilon^{-}_{a,o}(\phi)$.*

Concept 180 (Student)**.** *Appendix label: concept:Student.*
Body definition label: hsdef:Student (see § 341).

Informal definition. *A student is someone playing the learning role in an interaction: they seek information, ask questions, pay attention, and then actually update what they believe or can do so they get better at tasks. In Hyperseed this is defined operationally (by observable effects on capability and uncertainty), not by age, enrollment, or credentials. The point is that "student" describes a pattern of behavior and improvement over an episode.*

Formal definition. *Fix a claim language L and an update scheme for messages as in Section 22.5. An agent j plays the role of student relative to an agent i over an episode if it exhibits the complementary pattern to the teacher-role of Definition 341: j performs question acts toward i and updates its beliefs/skills so that its downstream performance on relevant tasks improves (at fixed or reduced effort). (Equivalently: j's question/attention allocation plus sustained assimilation leads to capability gain; see Definition 341 and its remark, and related weakness motivations in [2,3].)*

Concept 181 (Structural Complexity)**.** *Appendix label: concept:StructuralComplexity.*
Body definition label: hsdef:StructuralComplexity (see § 269).

Informal definition. *Structural complexity is a way to say how "complicatedly organized" a system's behavior is over time. Imagine you watch a system interact with its environment and you write down the history of what happens. If the history can be summarized by a short, simple description (a small rulebook, a simple repeating pattern, a compact story), then the structural complexity is low. If any good description has to keep track of many interacting parts, many exceptions, or many nested regularities, then the structural complexity is high. Importantly, this depends on the observer: what the observer can notice and what kind of descriptions the observer is allowed to use (see Sections 8 and 9).*

Formal definition. *Fix an observer/context O and a representational scheme that assigns a description length (or, more generally, a weakness/clarity score) to interaction histories. Let*

$SC_O(h_{0:T})$ denote the structural complexity of an interaction history $h_{0:T}$ as assessed by O (see Sections 8 and 9 for weakness-based and compression-based complexity measures). A system-in-environment is called a complex interactive system (for O) if

$$E\big[\, SC_O(h_{0:T}) \,\big]$$

exceeds a context-dependent threshold over relevant time horizons T (see § 269).

Concept 182 (Subpattern Hierarchy)**.** *Appendix label: concept:SubpatternHierarchy.*
Body definition label: hsdef:SubpatternHierarchy (see § 33.3). ***Informal definition.*** *A subpattern hierarchy is a "part-of" ordering for patterns. One pattern p is below another pattern q if p can show up inside q after you allow yourself to add some extra "remainder" content. This is the pattern version of ideas like "this word is a substring of that longer word" or "this small shape is contained inside that larger picture." The point is to get a usable hierarchy where small patterns can be treated as building blocks for larger ones.*

Formal definition. *Assume $*$ is associative with identity e, and assume $P_{\mathrm{at}}(p * e; p)$ is nontrivial for each pattern-representer p (so $p * e$ is defined and recognized as a pattern in p). Define a binary relation $\preceq_{\mathrm{sub}}$ by*

$$p \preceq_{\mathrm{sub}} q \quad \Longleftrightarrow \quad \exists r \text{ such that } P_{\mathrm{at}}(p * r; q) \text{ is nontrivial.}$$

Then $\preceq_{\mathrm{sub}}$ is a preorder (see § 33.3).

Concept 183 (Submission)**.** *Appendix label: concept:Submission.*
Body definition label: hsdef:Submission (see § 30.2).

Informal definition. *Submission is the "no extra effort" case of going along with a change. In this document, resistance (Hyperseed-Concept 158) is treated as the extra effort demanded by a change (e.g. you have to strain, fight, or spend energy to maintain your old way). Submission is the opposite extreme: the system can accept the change without needing any additional effort beyond what it was already spending. This is an intentionally minimal, behavior-based notion: it does not try to capture the full lived feeling of submission, only an operational invariant that can be used later.*

Formal definition. *For a directed policy change $H \to H'$ in context C:*

- *Resistance is identified with $\Delta\mathrm{Eff}_C(H \to H')$.*
- *Submission (in this minimal operationalization) occurs when the system follows a policy update that does not increase required effort, i.e. when $\Delta\mathrm{Eff}_C(H \to H') = 0$.*

Concept 184 (Symbol)**.** *Appendix label: concept:Symbol.*
Body definition label: hsdef:Symbol (see § 13).

Informal definition. *A symbol is something that stands for something else because of a learned or agreed-upon relationship, not because it looks like the thing. Words, numerals, traffic signs, musical notation, and programming tokens are all symbols: "electron" does not resemble an electron; it gets its meaning from how it connects to other symbols (laws, measurement terms, mathematical operators, etc.). Symbols also usually live inside a larger system (a language, a calculus, a codebase), where the rules for combining symbols matter (Section 9). This is why symbols are tied to representation (Hyperseed-Concept 27) and to relational structure rather than sensory resemblance.*

Formal definition. *An entity A is a symbol for an entity B if there exists a relational context $C \in \mathrm{Ctx}_{\mathrm{rel}}$ such that A represents B in aspect C. In addition, symbolic representations are assumed to participate in a combinational system (Section 9): symbols can be composed and recombined, and their referents are constrained by their relationships to other symbols.*

Concept 185 (Synthetic)**.** *Appendix label: concept:Synthetic.*
Body definition label: hsdef:Synthetic (see § 286).

Informal definition. *"Synthetic" is about how something came to exist. A lifeform is synthetic if an intelligent agent (or group) intentionally guided its design or assembly (for example, engineered organisms, lab-designed microbes, or designed artificial agents). This is different from "biological," which is about what it is made of (organic chemistry), and different from "evolved," which is about arising through unguided evolutionary and self-organization processes. These labels can overlap: a bio-engineered organism is both biological and synthetic.*

Formal definition. *A lifeform S is:*

- *biological if its dominant implementation substrate is organic chemistry (at the relevant descriptive level);*
- *synthetic if its design/assembly was primarily guided by an intelligent engineering process (as opposed to arising via unguided population-level dynamics);*
- *evolved if it arose via evolutionary and self-organization processes without intentional design.*

These labels are not mutually exclusive at all descriptive levels (e.g. bio-engineered organisms), so we allow them to be multi-valued or p-bit-valued when needed (see § 286).

Concept 186 (Tasks)**.** *Appendix label: concept:Tasks.*
Body definition label: hsdef:Tasks (see § 312).

Informal definition. *A task is a structured "do something over time" situation: an agent repeatedly observes the world, chooses an action, and then gets feedback about how well that action went. In real life the feedback is often mixed (helpful in one way, harmful in another), so the task's evaluation is allowed to be conflicted. This matches Hyperseed's value paraconsistency (Section 18) and covers tasks where success is ambiguous, contested, or internally conflicted.*

Formal definition. *A task is a tuple*

$$T = (O, A, P, r, \gamma),$$

where O and A are finite sets, $P : O \times A \to \Delta(O)$ is a transition kernel over observations, $r : O \times A \times O \to V$ is a p-bit-valued immediate evaluation (reward/penalty evidence), and $\gamma \in (0, 1)$ is a discount factor (see § 312).

Concept 187 (Teacher)**.** *Appendix label: concept:Teacher.*
Body definition label: hsdef:Teacher (see § 341). ***Informal definition.*** *A teacher is defined here by effect, not by title. Agent i is acting as a teacher for agent j if, through interaction, j becomes more able to answer task-relevant questions and perform task-relevant actions. In particular, teaching should reduce the student's weakness / uncertainty in a way that improves downstream performance, ideally without increasing the student's required effort. This ties pedagogy to the document's resource-sensitive weakness machinery (see also [2, 3]) and to control: teaching shapes another agent's future capability landscape.*

Formal definition. *Fix a claim language L and an update scheme for messages as in Section 22.5. An agent i plays the role of teacher for an agent j over an episode if:*

- *i repeatedly performs statement/response acts toward j with messages that (when assimilated) reduce j's weakness/uncertainty on some task-relevant question family (Sections 20 and 21); and*
- *j performs question acts toward i and updates its beliefs/skills so that its downstream performance on relevant tasks improves (at fixed or reduced effort).*

An agent j plays the role of student relative to i if it exhibits the complementary pattern: question/attention allocation plus sustained assimilation leading to capability gain (see § 341).

Concept 188 (Tendency to Reverse Habits)**.** *Appendix label: concept:TendencyToReverseHabits. Body definition label: hsdef:TendencyToReverseHabits (see § 34.1).*

Informal definition. *This is a statistical way to say "behaviors are fading rather than getting reinforced." Pick a pattern p and pick a time T that splits the timeline into "before" and "after." Compute how likely (how prone) the system is to express p before T and after T. If, averaged over many patterns and many split-times, the "after" propensity tends to be lower than the "before" propensity, then the context has a tendency to reverse habits: repeated patterns are being undone or washed out over time.*

Formal definition. *Fix a distribution ν over a class P of patterns, a distribution τ over times $T \in \{0, 1, 2, \dots\}$, and a scalarization π. Define, for each $p \in P$ and time T,*

$$\mathrm{Pre}_T(p) := E[\, p_t(p) \mid t < T\,], \qquad \mathrm{Post}_T(p) := E[\, p_t(p) \mid t > T\,],$$

whenever these conditional expectations are defined. The context C manifests the tendency to reverse habits (relative to (P, ν, τ, π)) if

$$E_{p\sim\nu,\, T\sim\tau}\, \pi\big(\mathrm{Post}_T(p) - \mathrm{Pre}_T(p)\big) \;<\; 0$$

(see § 34.1).

Concept 189 (Tendency to Take Habits)**.** *Appendix label: concept:TendencyToTakeHabits. Body definition label: hsdef:TendencyToTakeHabits (see § 34.1).*

Informal definition. *This is the opposite of reversing habits: it is a statistical way to say "practice makes patterns stronger." Using the same idea of splitting time into "before" and "after," the context has a tendency to take habits if, on average, patterns become more likely after the split than before. Not every pattern must increase; the claim is that there is a systematic time-direction bias toward reinforcement, relative to the chosen ensemble of patterns and time windows.*

Formal definition. *Fix a distribution ν over a class P of patterns, a distribution τ over times $T \in \{0, 1, 2, \dots\}$, and a scalarization π. Define, for each $p \in P$ and time T,*

$$\mathrm{Pre}_T(p) := E[\, p_t(p) \mid t < T\,], \qquad \mathrm{Post}_T(p) := E[\, p_t(p) \mid t > T\,],$$

whenever these conditional expectations are defined. The context C manifests the tendency to take habits (relative to (P, ν, τ, π)) if

$$E_{p\sim\nu,\, T\sim\tau}\, \pi\big(\mathrm{Post}_T(p) - \mathrm{Pre}_T(p)\big) \;>\; 0$$

(see § 34.1).

Concept 190 (Third (Peircean Category))**.** *Appendix label: concept:ThirdPeircean. Body definition label: hsdef:ThirdPeircean (see § 46).*

Informal definition. *A Third is a stable rule-like regularity that links many individual interactions. If a Second is a one-off dyadic event ("this interacts with that"), then a Third is the pattern that governs lots of such events ("pairs like this usually behave this way," "treat these kinds of pairs as distinct," "these pairs are interchangeable"). In the simplest crisp case, a Third is just a set of ordered pairs where the rule applies. In the graded case used here, it is a rule that can assign degrees of evidence (possibly with mixed positive/negative components) to each pair.*

Formal definition. *For a context c, a Third is a grouping of Seconds. Concretely, we model a Third as a (possibly fuzzy) relation*

$$R : X_c \times X_c \to V,$$

where V is a commutative quantale as in Section 3.4. In the simplest crisp case, a Third is just a subset $R \subseteq X_c \times X_c$ (see § 46).

Concept 191 (Tools)**.** *Appendix label:* `concept:Tools`*.*
Body definition label: `hsdef:Tools` *(see § 64).* ***Informal definition.*** *A* tool *is something (usually made on purpose) that you can use to reliably make certain things happen. Compared to acting with your bare hands and brain, a tool either lets you do new kinds of actions at all (like using a telescope to see distant things), or it makes an action easier, faster, safer, or more accurate (like using a calculator to avoid arithmetic mistakes). In the Hyperseed view, tools matter because they change what an agent can effectively do: they expand the agent's practical menu of actions and outcomes, or reduce the effort needed to get an outcome. This connects back to agency as closed-loop control (Section 14) and tasks as objective-achievement problems (Section 21).*

Formal definition. *A tool (relative to an agent class and an observer/context O) is an entity T in a reality-system together with an affordance profile Aff_T that is:*

- ***usable:*** *there exists a nontrivial subset $A_T \subseteq A$ and effects $E_T \subseteq E$ such that $\mathrm{Aff}_T(a, e)$ has substantial positive evidence for some $(a, e) \in A_T \times E_T$; and*
- ***purpose-supporting:*** *for some objective functional (Section 18), the availability of T strictly increases expected objective achievement for typical users in the class, via the induced action–effect couplings.*

Concept 192 (Transfer Learning)**.** *Appendix label:* `concept:TransferLearning`*.*
Body definition label: `hsdef:TransferLearning` *(see § 527).*

Informal definition. Transfer learning *is what happens when learning to solve one problem helps you solve a different problem faster or better. For example, once you learn the basic idea of balancing and steering on a bicycle, it is easier to learn a skateboard or a motorcycle. In the math here, the key idea is: two different "ways of representing problems" (two paradigms) support transfer if you can systematically translate the problem-solving dynamics from one representation into the other with only a bounded amount of mismatch. The appearance of γ is about stability: when the underlying update rule is contractive (discounted), small translation errors do not blow up over repeated updates, so you can turn "dynamics mismatch" into a controlled bound on solution mismatch.*

Formal definition. *Two paradigms P and Q are* (ϵ, γ)-commensurable on a class of tasks *if there is an assignment mapping each task $M \in P$ to a task $N \in Q$, together with a TransWeave map (T, T_V) such that*

$$\| T_V \circ B_M \; - \; B_N \circ T_V \|_{\infty \to \infty} \;\leq\; \epsilon,$$

uniformly over the task class (with the interpretation that the relevant Bellman-style operators are in a discounted/contractive regime parameterized by γ).

Concept 193 (Transweave)**.** *Appendix label:* `concept:Transweave`*.*
Body definition label: `hsdef:Transweave` *(see § 527).*

Informal definition. *A* transweave *is a structured "translation" between two different descriptions of a problem, designed so that what counts as a good update step in one description corresponds (as closely as possible) to a good update step in the other. The point is not perfect* *sameness, but controlled loss: after you translate and update, you should end up close to where you would have ended up if you updated first and then translated. When such a translation exists with small error, it explains why skills, strategies, or learned structure can be carried from one domain to another (which is exactly what transfer learning needs).*

Formal definition. *Given two weighted MDPs M_w and $M_{w'}$ with Bellman operators B_w and $B_{w'}$, a* TransWeave map *consists of a state/representation map T together with an induced map T_V on value functions such that*

$$\| T_V \circ B_w \; - \; B_{w'} \circ T_V \|_{\infty \to \infty} \; \leq \; \epsilon.$$

We call ϵ the intertwining error*.*

Concept 194 (Tribe)**.** *Appendix label:* `concept:Tribe`*.*
Body definition label: `hsdef:Tribe` *(see § 334).*

Informal definition. A tribe *is a group of agents who are strongly connected to each other through frequent interaction and strong social ties. Because the same people keep interacting, they tend to reinforce shared habits, shared meanings, and shared norms; this is where cultural patterns can become especially stable. In the Hyperseed framing, tribal-scale structure is where morphic resonance and cultural stabilization become easy to see, and later "mindplex" phenomena naturally appear at about this scale because repeated high-coupling interaction can create noticeable coherence.*

Formal definition. *A tribe (relative to a strong-tie threshold τ) is a subset $T \subseteq A$ such that:*

- *the induced strong-tie subgraph $G_\tau[T]$ is (strongly) connected; and*
- *T satisfies a boundedness condition reflecting finite memory/interaction bandwidth, modeled either as a size bound $|T| \leq N$ or as a density condition such as*

$$\frac{1}{|T|(|T|-1)} \sum_{\substack{i,j \in T \\ i \neq j}} \mathbb{I}\big[(i,j) \in E_\tau\big] \; \geq \; \delta,$$

  for some δ close to 1*.*

Concept 195 (Uncertainty)**.** *Appendix label:* `concept:Uncertainty`*.*
Body definition label: `hsdef:Uncertainty` *(see § 32).* ***Informal definition.*** Uncertainty *is how unsure you are about what is going on or which possibility is true. You are highly uncertain when many different possibilities still seem plausible, and you are not very uncertain when one possibility is clearly expected. One simple everyday check is: if you would not be surprised by many distinct outcomes (because they all "still fit"), then you are in a high-uncertainty state; if most outcomes would feel surprising because one is strongly anticipated, then uncertainty is low. Hyperseed emphasizes that uncertainty is not an absolute property of "the world" all by itself: it depends on the observer and what distinctions the observer can make (Distinction: Hyperseed-Concept 98). In other words, what counts as a different "possibility" is already a modeling choice: coarse distinctions can collapse many fine-grained world-states into one "case," thereby reducing uncertainty as represented by that observer, while finer distinctions can expand the possibility space and thereby increase uncertainty. Once you take that seriously, "information" and "uncertainty" must be indexed by a context/observer (Information: Hyperseed-Concept* **??***; Uncertainty: Hyperseed-Concept 195; see also [1]). This indexing is not merely philosophical: it determines which events are treated as alternatives, which variables are being predicted, and which representational constraints (measurement resolution, vocabulary, attention, memory) are assumed when quantifying uncertainty. This*

part of the document sets up the basic tools to talk about probabilistic belief (Probability: Hyperseed-Concept 139), to relate classical Shannon-style uncertainty to distinction-based measures like logical entropy and graphtropy (Hyperseed-Concepts 105 and **??***; [17]), to explain "ineffability" as a resource limit on what can be clearly said (Hyperseed-Concept* **??***), and to clarify resource-sensitive "limit" ideas like (potential) infinity and infinitesimals (Hyperseed-Concepts* **??** *and* **??***). In particular, the intended connection is that both probabilistic uncertainty and distinction-based uncertainty are ways of tracking "how many live alternatives remain" relative to an observer's representational regime: Shannon entropy emphasizes average uncertainty under a probability distribution, while the distinction-based measures emphasize which pairs of possibilities can or cannot be told apart by the observer's available distinctions.*

Formal definition. *Let X be a finite set of possibilities and let an observer/context O have a belief distribution $p_O : X \to [0,1]$ with $\sum_{x\in X} p_O(x) = 1$. The* Shannon entropy *(a standard uncertainty measure) is*

$$H(p_O) \;:=\; -\sum_{x\in X} p_O(x)\log p_O(x).$$

Here the base of log *fixes the units (e.g. base 2 gives bits, base e gives nats); changing the base rescales H by a constant factor and does not change the ordering of uncertainties. Higher $H(p_O)$ corresponds to greater uncertainty in the sense of greater average surprise. More explicitly, if one defines the (self-)information or "surprisal" of an outcome as $I(x) := -\log p_O(x)$, then $H(p_O) = \mathbb{E}_{x\sim p_O}[I(x)]$ is the expected surprisal under the observer's belief distribution. In the finite case, $H(p_O)$ is minimized at 0 when p_O puts all its mass on a single possibility (complete certainty in the modeled space), and it is maximized when p_O is uniform on X, in which case $H(p_O) = \log|X|$; this makes explicit how the size of the possibility set (and thus the observer's chosen distinctions) constrains the maximum representable uncertainty. (Section § 32 also relates this to distinction-based uncertainty measures such as logical entropy and graphtropy.)*

Concept 196 (Unknowability)**.** *Appendix label:* `concept:Unknowability`*.*
Body definition label: `hsdef:Unknowability` *(see § 366).*

Informal definition. Unknowability *is the idea that something cannot be known (or cannot be made stably expressible) in any absolute sense. This can be read as a claim that no matter how you expand resources, change languages, or refine distinctions, the target cannot be reliably tracked, stated, or settled as "known" in a way that is robust across contexts and observers. Hyperseed's key warning is that this is much stronger than everyday "I can't put it into words right now." In particular,* ineffability *is not the same thing as absolute unknowability: even if some target x is ineffable to an observer O at a particular accuracy/effort budget (ϵ, K), it may become expressible if you (i) increase resources (larger K), (ii) change the representational language $\mathcal{D}_O$, or (iii) change the distinction regime (use a different G). This frames ineffability as a contingent, parameterized limitation (indexed by observer, language, and resources), whereas unknowability is an invariant claim that persists across such changes. One way to keep the notions separate in practice is to ask: are we claiming a permanent impossibility result ("no representation suffices"), or merely a present mismatch between what must be tracked and the current representational apparatus ("this representation does not yet suffice")? The practical point is developmental and cultural: many things become sayable only after people learn new concepts, new vocabulary, or new ways of carving up experience. This includes both individual development (skill learning, perceptual training, mathematical formalization) and collective development (shared terminology, measurement conventions, institutional practices), each of which can expand the set of distinctions that an observer-community can reliably make.*

Concept 197 (Values (Ethical)). *Appendix label:* `concept:ValuesEthical`*.*
Body definition label: `hsdef:ValuesEthical` *(see § 17.9).*

Informal definition. Ethical values *are the things a person or agent treats as important when deciding what to do. They include priorities like truthfulness, compassion, fairness, loyalty, safety, beauty, or personal growth. Values are not the same as momentary feelings: they are more like relatively stable "standards" that guide choices across many situations. They also function as lenses for noticing morally salient features of situations (what counts as harm, what counts as respect, what counts as a promise), so the value structure influences both evaluation and attention. A key point is that values can conflict: an action might support one value while harming another, and real decision-making has to handle that without pretending the conflict is not there. Moreover, even within a single named value (e.g. "fairness"), there may be multiple plausible operationalizations that pull in different directions, so a representation that can carry structured disagreement is often more realistic than a representation that forces a single scalar score.*

Formal definition. *Fix an observer/context O, a set of situations (states) S, a set of actions A, and a finite set $\mathcal{D}$ of ethical value dimensions. A (paraconsistent) evaluative representation of ethical values is given by an evaluative field*

$$E_O : S \times A \times \mathcal{D} \;\to\; [0,1]^2, \qquad E_O(s,a;d) = \big(E_O^+(s,a;d),\, E_O^-(s,a;d)\big),$$

where $E_O^+(s,a;d)$ is evidence that doing a in situation s promotes *value-dimension d, and $E_O^-(s,a;d)$ is evidence that it* opposes *d. The set $\mathcal{D}$ together with E_O constitutes the agent's (observer-relative) ethical value structure. Intuitively, E_O^+ and E_O^- allow the agent to record pro and con considerations separately rather than collapsing them immediately into a single net number; this supports later aggregation methods that are sensitive to conflict, uncertainty, or stakeholder disagreement. The use of $[0,1]^2$ is meant as a simple bounded scale for evidential support and evidential opposition (not necessarily probabilities), so different applications may interpret these coordinates as confidence-weighted arguments, model-based estimates, or learned scores.*

Concept 198 (Value Paraconsistency). *Appendix label:* `concept:ValueParaconsistency`*.*
Body definition label: `hsdef:ValueParaconsistency` *(see § ??).*

Informal definition. Value paraconsistency *means you can honestly represent value conflict without the whole decision system breaking. In real life, you can have strong reasons that an option is good and strong reasons that it is bad at the same time (for different values, or even within one value once you look closely). For example, an action might strongly promote safety while strongly violating autonomy, or it might strongly promote honesty while strongly damaging compassion in a specific context; forcing an immediate collapse to a single score can hide these tensions and produce brittle reasoning. A paraconsistent value representation keeps both sides of that evidence instead of forcing you to pick one prematurely, and it avoids the "anything goes" failure mode where a contradiction would make every action seem acceptable. The intended outcome is not indecision but better-structured deliberation: conflict is recorded explicitly so that later procedures (priority setting, negotiation, reflective equilibrium, constraint satisfaction, or context-sensitive aggregation) can address it.*

Formal definition. *In the evaluative-field formalism, value paraconsistency is modeled by using two-sided evidence values*

$$E_O(s,a;d) = \big(E_O^+(s,a;d),\, E_O^-(s,a;d)\big) \in [0,1]^2$$

without imposing a consistency constraint *such as $E_O^+(s,a;d) + E_O^-(s,a;d) \le 1$. This means the representation treats "there is substantial support for promotion" and "there is substantial support* *for opposition" as separately measurable claims that can both be true in the evidential state of the observer, reflecting genuine moral tension, model misspecification, or heterogeneous stakeholder perspectives. Equivalently, for a chosen threshold $\theta \in (0, 1]$, the representation explicitly permits states with*

$$E_O^+(s, a; d) \geq \theta \quad \text{and} \quad E_O^-(s, a; d) \geq \theta$$

(i.e. strong pro- and anti-evidence simultaneously) while still supporting nontrivial preference and decision rules. Concretely, this leaves open multiple downstream policies: one may treat such cases as triggers for additional information gathering, as signals to seek alternative actions that dominate on both coordinates, or as inputs to a decision rule that trades off values while explicitly accounting for unresolved conflict rather than erasing it at the representation layer.

Concept 199 (Variety)**.** *Appendix label:* `concept:Variety`*.*
Body definition label: `hsdef:Variety` *(see § 28.1).*

Informal definition. *A* variety *is a difference that matters. Two things can be different in a simple sense (two separate footsteps, two separate pencils), but sometimes the difference does not matter for what you are doing: you can swap them without changing anything important. Variety is the opposite case: the two things are not only different, they are* not interchangeable *in the current context or task. For example, the "Enter" key and the "Escape" key are both keys, but swapping them changes what happens in a big way.*

Formal definition. *Fix thresholds $\tau_\delta, \tau_\iota \in (0, 1)$. For $x \neq y$ in X_c, define:*

$$\mathrm{Rep}_c(x, y) \iff \mathrm{Dist}_c(x, y)^+ \geq \tau_\delta \quad \text{and} \quad \iota_c(x, y)^+ \geq \tau_\iota,$$

$$\mathrm{Var}_c(x, y) \iff \mathrm{Dist}_c(x, y)^+ \geq \tau_\delta \quad \text{and} \quad \iota_c(x, y)^- \geq \tau_\iota.$$

Intuitively, a repetition is a pair that is experienced as distinct yet context-substitutable; a variety is distinct and non-substitutable.

Concept 200 (Varieties of Knowledge)**.** *Appendix label:* `concept:VarietiesOfKnowledge`*.*
Body definition label: `hsdef:VarietiesOfKnowledge` *(see § 37.6).*

Informal definition. *"Knowledge" is not just one kind of thing. Knowing a fact (like "Paris is in France"), knowing a skill (like riding a bike), knowing a person, knowing a habit, and knowing a rule are stored, learned, and used in very different ways. Hyperseed treats these as different* types *of stored content, each with its own meaning and its own update method, but still able to interact (for example, facts can shape skills, and habits can shape what facts you pay attention to).*

Formal definition. *A knowledge type T for a system S consists of:*

- *a carrier set (or space) K_T of knowledge items;*
- *a semantics map $\mathrm{Sem}_T : K_T \to S$ that interprets items as constraints on patterns, processes, or goals;*
- *an update operator (or family of operators) Upd_T specifying how items are learned, revised, or forgotten; and*
- *an interface specifying which other types it can exchange information with.*

Concept 201 (Vedantic Strata)**.** *Appendix label: concept:VedanticStrata.*
Body definition label: hsdef:VedanticStrata (see § 17.7.1).

Informal definition. *In many Vedantic traditions, people talk about different "layers" or "stages" of awareness: first you are aware of things in the world, then you notice thoughts and* *feelings, then you notice the act of noticing, and so on. In Hyperseed, "Vedantic strata" names this general idea of stacked levels of reflective awareness. Moving to a higher stratum means that more of your own attention and self-awareness becomes steadily present and stable, instead of being only an occasional flash.*

Formal definition. *Let L_{Ob} be an object-level language of propositions about world and mind, and let $I(\phi)$ denote the introspective proposition "ϕ is present to awareness" (i.e., "I am aware of ϕ"). Define an iterated reflective-language hierarchy by*

$$L_{\mathrm{Ob}}^{\mathrm{ref},0} := L_{\mathrm{Ob}}, \qquad L_{\mathrm{Ob}}^{\mathrm{ref},k+1} := L_{\mathrm{Ob}}^{\mathrm{ref},k} \cup \{I(\psi) : \psi \in L_{\mathrm{Ob}}^{\mathrm{ref},k}\}.$$

A (candidate) Vedantic stratum of order k is a stable reflective-workspace regime whose stable contents and introspective contents live in $L_{\mathrm{Ob}}^{\mathrm{ref},k}$; concretely, this can be modeled as a robust fixed point (or stable attractor) of the reflective closure dynamics on that language, for parameters (notably λ_{ref}) that support the corresponding depth of iterated awareness without destabilizing into trivial paradox.

Concept 202 (Weakness)**.** *Appendix label: concept:Weakness.*
Body definition label: hsdef:Weakness (see § 37.7).

Informal definition. *"Weakness" is a number that measures how general (how non-picky) an explanation is. A weak explanation makes only a few important distinctions, so it can apply to lots of slightly different situations and tends to be robust. A strong explanation makes many fine distinctions; it may fit what you have seen extremely well, but it can be brittle because it depends on lots of details. Hyperseed uses weakness as a proxy for simplicity/generalization (Hyperseed-Concept 202; Hyperseed-Concept 143; Hyperseed-Concept 169; [3, 2]).*

Formal definition. *Fix a behavior (or dataset) b. Let $\mathcal{E}(b)$ be a set of candidate explanations of b (models, hypotheses, plans, proofs, causal graphs, etc.). Assume each explanation $E \in \mathcal{E}(b)$ comes with:*

(a) *an adequacy score* $\mathrm{Fit}(E) \in [0,1]$ *(how well it predicts/explains/controls b);*

(b) *a weakness* $\mathrm{Weak}(E) \in (0,1]$ *(how few distinctions it makes; larger is weaker).*

Define the contrivance cost (description-length proxy)

$$\mathrm{Con}(E) := -\log \mathrm{Weak}(E) \in [0, \infty).$$

Concept 203 (Will (Reflective))**.** *Appendix label: concept:WillReflective.*
Body definition label: hsdef:WillReflective (see § 236). ***Informal definition.*** *Ordinary will is choosing what you do next. Reflective will is one step deeper: it is the ability to notice and change your own way of choosing. For example, you can adopt a new rule like "when I'm stressed, I will slow down and re-check my assumptions," and that rule continues to guide you later. In this sense, reflective will is will that can look at itself, and modify itself, not just pick one action.*

Formal definition. *Let S_{Ob} be the observer's internal state space and let U be a set of interventions (world actions and internal interventions such as attention shifts). Let Π be a space of possible will operators $\pi : S_{\mathrm{Ob}} \to U$. A reflective will state is a pair (π, s) with $\pi \in \Pi$ and $s \in S_{\mathrm{Ob}}$. A reflective will update is a map*

$$RWill : \Pi \times S_{\mathrm{Ob}} \to \Pi \times S_{\mathrm{Ob}},$$

which may change both the internal state and the will operator. A stable reflective will regime corresponds to a fixed point (or slowly drifting orbit) of $RWill$.

Concept 204 (Woe)**.** *Appendix label: concept:Woe.*
Body definition label: hsdef:Woe (see § ??).

Informal definition. *"Woe" is the negative side of evaluation: how bad, painful, threatening, or unwanted a situation is judged (or felt) to be. It is broader than physical pain: it can include fear, grief, shame, frustration, etc. Hyperseed treats woe as an evaluative signal that can attach to internal or external processes (physical, mental, social), and it can coexist with some positive evaluation in the same situation.*

Formal definition. *Given a p-bit $v = (v^+, v^-) \in [0,1]^2$, define*

$$J(v) := v^+ \quad (\textit{joy intensity}), \qquad W(v) := v^- \quad (\textit{woe intensity}).$$

Given an evaluative field E_O, define

$$J_O(s, a; d) := J(E_O(s, a; d)), \qquad W_O(s, a; d) := W(E_O(s, a; d)).$$

Concept 205 (Worker)**.** *Appendix label: concept:Worker.*
Body definition label: hsdef:Worker (see § 342).

Informal definition. *A worker is an agent who repeatedly does tasks as part of a plan or stream of instructions coming from some coordinating structure (a boss, an institution, or a collective policy), and receives resources or other value signals in return. This is a structural role in a coordination network: it describes who is taking direction from whom and how value flows, not whether the arrangement is ethical or unethical.*

Formal definition. *A worker is an agent that repeatedly executes commands or participates in a coordinated plan issued by some coordinating structure (a boss, institution, or collective policy), in exchange for resources or other value signals (Section 18).*

Concept 206 (Wu Wei)**.** *Appendix label: concept:WuWei.*
Body definition label: hsdef:WuWei (see § 1981).

Informal definition. *"Wu wei" (roughly, "effortless action") is the idea of achieving outcomes without unnecessary forcing. You still act, but you try to work with the natural tendencies of the situation instead of constantly fighting them. A simple analogy is surfing: you steer and adjust, but you do not try to overpower the wave. In Hyperseed's math layer, wu wei is modeled by optimizing for task success while explicitly penalizing how much you deviate from a passive/default dynamics. This general principle sits behind the more geometric "wu wei geodesic" notion (Hyperseed-Concept 207) and its applications [21].*

Formal definition. *Let X be a state space with a passive transition kernel $P_0(\cdot \mid x)$. A policy π induces a controlled kernel $P_\pi(\cdot \mid x)$. Fix $\lambda > 0$ and define the forcing cost at state x by*

$$\mathrm{Force}_\lambda(P_\pi \| P_0)(x) := \lambda\, \mathrm{KL}(P_\pi(\cdot \mid x) \,\|\, P_0(\cdot \mid x)).$$

Given a bounded state cost $q : X \to \mathbb{R}$, horizon $T \in \mathbb{N}$, initial distribution $\rho_0 \in \Delta(X)$, and terminal cost q_T, define

$$J_T(\pi) := \mathbb{E}\left[\sum_{t=0}^{T-1} \Big(q(x_t) + \mathrm{Force}_\lambda(P_\pi \| P_0)(x_t)\Big) + q_T(x_T)\right],$$

where $x_0 \sim \rho_0$ and $x_{t+1} \sim P_\pi(\cdot \mid x_t)$. A wu wei policy is any minimizer $\pi^* \in \arg\min_\pi J_T(\pi)$.

Concept 207 (Wu Wei Geodesic)**.** *Appendix label: concept:WuWeiGeodesic.*
Body definition label: hsdef:WuWeiGeodesic (see § 1982).

Informal definition. *A wu wei geodesic is the "least-effort path" for transforming an entire probability distribution from one shape to another while staying as close as possible to a passive* *baseline flow. Imagine a cloud of mist: you want it to start in one shape and end in another. The wu wei geodesic is the way of doing that that uses the least combined "pushing" (moving the cloud around) and "resisting" (fighting what the cloud would naturally do). This is exactly Hyperseed-Concept 207 [21].*

Formal definition. *Let $\Omega \subseteq \mathbb{R}^d$ be a domain and let $\rho(x,t)$ be a density on Ω with a velocity field $v(x,t)$ over $t \in [t_0, t_1]$, subject to the continuity equation*

$$\partial_t \rho + \nabla \cdot (\rho v) = 0.$$

Let $p(x,t)$ be a reference (passive) density and let $\epsilon > 0$. Define the Schrödinger-bridge effort functional

$$W_{SB}[\rho, v] := \int_{t_0}^{t_1} \int_{\Omega} \rho(x,t) \left(\frac{1}{2} \|v(x,t)\|^2 + \epsilon \log \frac{\rho(x,t)}{p(x,t)} \right) dx\, dt.$$

Fix boundary densities $\rho(\cdot, t_0) = \rho_0$ and $\rho(\cdot, t_1) = \rho_1$. A wu wei trajectory (wu wei geodesic) between ρ_0 and ρ_1 (relative to passive prior p) is any minimizer (ρ^*, v^*) of $W_{SB}[\rho, v]$ subject to the continuity constraint and boundary conditions.

Concept 208 (Young)**.** *Appendix label: concept:Young.*
Body definition label: hsdef:Young (see § 2.3).

Informal definition. *"Young" refers to the life stage after infancy and before full maturity: the period when a person or organism is still growing quickly and building basic skills, but is no longer an infant. In Hyperseed's coarse biological lifecycle strata (infant/young/mature/old/elderly), "young" is the second stage and is intentionally broad and context-dependent.*

In particular, "young" is used as a stratification term rather than a precise chronological marker: its boundaries may be indexed to species, environment, and the trait under discussion (e.g., physical growth, neurological development, reproductive capability, social role acquisition, or competence in a learned skill). For example, an organism may be "young" with respect to size and motor coordination while already "mature" with respect to a narrow biological function, and Hyperseed treats this kind of partial ordering between developmental dimensions as compatible with the coarse stage label.

The intended use is also comparative: "young" can function as a default category for entities not yet stabilized into their characteristic adult equilibrium (biological, behavioral, or ecological), but already past the highly fragile and rapidly transitioning infant regime. This makes the term suitable for high-level modeling where only a small number of robust stages are tracked and where fine-grained age classes would be spurious precision.

Listed in the concept inventory without a dedicated formal definition in this version. The absence of a formal definition is deliberate here: the concept serves primarily as a linguistic and modeling convenience to align cross-domain discussions (biology, cognition, and lifecycle-dependent capability) without committing to a single universal threshold rule.

Concept 209 (YVerse)**.** *Appendix label: concept:YVerse.*
Body definition label: hsdef:YVerse (see § ??).

Informal definition. *The Y-verse is a "wider world" concept designed to be self-referential. It is a world-description that already contains its own multiverse inside it: if you take the description Y and apply the operation that forms "the multiverse of Y" (call it* Multi*), you get the same Y back. Intuitively, it is a self-consistent fixed point: expanding it into many worlds does not produce something fundamentally new, it reproduces itself. Hyperseed treats this fixed-point signature as a clue that self-reference and non-well-founded semantics may matter at the "ultimate cosmos" level (Hyperseed-Concept 209).*

Concretely, Multi *is intended to represent whatever construction turns a single "world-description" into a space (or family) of worlds compatible with it—for instance by varying contingent parameters, branching on indeterminacy, or unfolding implicit choices. The Y-verse condition says that Y is already closed under this unfolding: it is descriptively complete in the sense that applying the "multiverse expansion" operation does not change the object. In this reading, the self-referentiality is not merely linguistic; it is structural closure under an operator that would otherwise enlarge the described cosmos.*

This also clarifies why the concept is tied to non-well-founded semantics: if Multi *permits recursive world-containment (worlds that include descriptions of world-families that include themselves), then the resulting structures can naturally be modeled using fixed-point and coalgebraic ideas rather than only well-founded hierarchies. The Y-verse is the special case where this recursion stabilizes exactly, yielding a fixed point rather than an infinite strictly ascending chain.*

The reference "§ ??" is a placeholder for the section where the ambient assumptions on Multi *(its domain, codomain, and any monotonicity or continuity properties) are specified; those details govern which fixed points exist and which are mathematically or conceptually preferred.*

Formal definition. *A Y-verse is a fixed point Y of* Multi*:*

$$Y = \mathrm{Multi}(Y).$$

When multiple fixed points exist, one may select $Y := \mathrm{lfp}(\mathrm{Multi})$ (the least fixed point) or $Y := \mathrm{gfp}(\mathrm{Multi})$ (the greatest fixed point) depending on the intended semantics.

Here, "least" and "greatest" are to be understood relative to an ordering on world-descriptions (e.g., an entailment order, an information order, or a refinement order). Under standard conditions—for example, if the world-descriptions form a complete lattice and Multi *is monotone—the existence of* lfp *and* gfp *follows from the Knaster–Tarski theorem, and they can be characterized as*

$$\mathrm{lfp}(\mathrm{Multi}) = \bigwedge\{X : \mathrm{Multi}(X) \le X\}, \qquad \mathrm{gfp}(\mathrm{Multi}) = \bigvee\{X : X \le \mathrm{Multi}(X)\}.$$

Intuitively, choosing lfp(Multi) *corresponds to the minimal self-consistent closure (the smallest description that is already multiverse-complete), whereas choosing* gfp(Multi) *corresponds to the maximal coinductively consistent solution (the largest description compatible with its own multiverse expansion). Which is appropriate depends on whether one interprets Y inductively (built from finite unfolding) or coinductively (validated by a bisimulation-style consistency criterion).*

C.2 Concepts Regarding General Intelligence

Concept 210 (Reward-summable environment)**.** *Appendix label: concept:RewardSummableEnvironment. Body definition label: hsdef:RewardSummableEnvironment (see §21.11).*

Informal definition. *An environment whose total expected cumulative reward is bounded (here normalized to ≤ 1) no matter what policy is used. This guarantees the universal-intelligence sum uses finite terms.*

Formal definition. *An environment μ is reward-summable iff for every policy π,*

$$V_\mu^\pi \;:=\; \mathbb{E}_{\mu,\pi}\left[\sum_{t=1}^{\infty} r_t\right] \;\le\; 1.$$

Concept 211 (Universal intelligence)**.** *Appendix label: concept:UniversalIntelligence. Body definition label: hsdef:UniversalIntelligence (see §21.11).*

Informal definition. *A Legg–Hutter style measure of intelligence: expected cumulative reward averaged across a broad class of computable environments, weighted by an Occam prior favoring simpler environments.*

Formal definition. *For a chosen set $\mathcal{E}$ of reward-summable environments,*

$$\Upsilon(\pi) \;:=\; \sum_{\mu\in\mathcal{E}} 2^{-K(\mu)}\, V^{\pi}_{\mu},$$

*where $K(\mu)$ is Kolmogorov complexity (Hyperseed-Concept **??**) and $V^{\pi}_{\mu} = \mathbb{E}_{\mu,\pi}[\sum_{t\geq 1} r_t]$.*

Concept 212 (GTGI goal function)**.** *Appendix label: concept:GTGIGoalFunction. Body definition label: hsdef:GTGIGoalFunction (see §21.11).*

Informal definition. *A "goal" is treated as a reward-generating rule: it assigns reward values to finite interaction histories.*

Formal definition. *Fix action/observation sets $\mathcal{A}, \mathcal{O}$ and reward set $\mathcal{R} \subseteq [0,1] \cap \mathbb{Q}$. A GTGI goal function is a map*

$$g : (\mathcal{A}\times\mathcal{O})^* \to \mathcal{R},$$

with goal-induced rewards $r_t := g(a_1, o_1, \ldots, a_t, o_t)$ along a trajectory.

Concept 213 (Natural timescale indicator)**.** *Appendix label: concept:NaturalTimescaleIndicator. Body definition label: hsdef:NaturalTimescaleIndicator (see §21.11).*

Informal definition. *A Boolean function indicating which evaluation horizons are "natural" (meaningful) for a given goal in a given environment.*

Formal definition. *A natural timescale indicator is a map*

$$\tau_{g,\mu} : \mathbb{N}_{>0} \to \{0,1\},$$

where $\tau_{g,\mu}(n) = 1$ means it is meaningful to evaluate goal-achievement for g in μ over n steps.

Concept 214 (GTGI context)**.** *Appendix label: concept:GTGIContext. Body definition label: hsdef:GTGIContext (see §21.11).*

Informal definition. *A "context" packages the environment, the goal, and the time-interval over which the goal is to be evaluated.*

Formal definition. *A GTGI context is a triple (μ, g, T) where μ is an environment, g is a goal function, and $T = \{t_1, \ldots, t_2\}$ is a finite time-interval with $|T| := t_2 - t_1 + 1$. For policy π, expected goal-achievement is*

$$V^{\pi}_{\mu,g,T} \;:=\; \mathbb{E}_{\mu,\pi}\left[\sum_{t=t_1}^{t_2} r_t\right], \qquad r_t := g(a_1, o_1, \ldots, a_t, o_t).$$

Concept 215 (Pragmatic general intelligence)**.** *Appendix label: concept:PragmaticGeneralIntelligence. Body definition label: hsdef:PragmaticGeneralIntelligence (see §21.11).*

Informal definition. *A generalization of universal intelligence that explicitly separates (i) distributions over environments and (ii) distributions over goals in those environments, and averages goal-achievement over goal-appropriate timescales.*

Formal definition. *Given distributions ν over environments and $\gamma(\cdot, \mu)$ over goals conditional on μ,*

$$\Pi(\pi) \;:=\; \sum_{\mu,g,T} \nu(\mu)\,\gamma(g,\mu)\,\tau_{g,\mu}(|T|)\,V^{\pi}_{\mu,g,T},$$

whenever the sum is convergent.

Concept 216 (Resource-consumption distribution)**.** *Appendix label: concept:ResourceConsumptionDistribution. Body definition label: hsdef:ResourceConsumptionDistribution (see §21.11).*

Informal definition. *A probabilistic model of how much computation an agent uses while pursuing a given goal in a given environment over a given interval.*

Formal definition. *Fix a discrete resource scale $\mathcal{Q} \subseteq \mathbb{R}_{>0}$. A resource-consumption distribution for context (μ, g, T) is a probability distribution $\eta_{\mu,g,T} : \mathcal{Q} \to [0, 1]$ with $\sum_{Q\in\mathcal{Q}} \eta_{\mu,g,T}(Q) = 1$.*

Concept 217 (Efficient pragmatic general intelligence)**.** *Appendix label: concept:EfficientPragmaticGeneralIntellig Body definition label: hsdef:EfficientPragmaticGeneralIntelligence (see §21.11).*

Informal definition. *Pragmatic general intelligence adjusted for computational efficiency: goal-achievement is weighted by the inverse of resource usage, so achieving the same goals with less computation scores higher.* ***Formal definition.*** *With $\eta_{\mu,g,T}$ as a distribution over resource usage $Q \in \mathcal{Q}$,*

$$\Pi^{\mathrm{eff}}(\pi) \;:=\; \sum_{\mu,g,T,Q} \nu(\mu)\, \gamma(g, \mu)\, \tau_{g,\mu}(|T|)\, \eta_{\mu,g,T}(Q)\, \frac{V^{\pi}_{\mu,g,T}}{Q},$$

whenever the sum is convergent. In words, $\Pi^{\mathrm{eff}}(\pi)$ aggregates an agent's achieved value across a family of contexts (μ, g, T) while explicitly discounting (or rewarding) the amount of resource usage Q required to obtain that value: the ratio $V^{\pi}_{\mu,g,T}/Q$ is an efficiency-like quantity, and $\eta_{\mu,g,T}(Q)$ averages that quantity over the possible realized resource consumptions in the given context. The factors $\nu(\mu)$, $\gamma(g, \mu)$, and $\tau_{g,\mu}(|T|)$ serve as context weights: $\nu(\mu)$ prioritizes environments, $\gamma(g, \mu)$ prioritizes goal specifications given the environment, and $\tau_{g,\mu}(|T|)$ prioritizes (for example) different horizon lengths or episode durations. The convergence qualifier is substantive: since the index set may be countably infinite, the expression is well-defined only when the weighted series of efficiency-adjusted values is absolutely summable (or otherwise convergent under the intended summation convention). One common sufficient condition is that Q is almost surely bounded away from 0 under $\eta_{\mu,g,T}$ (so the ratio does not blow up), and that $V^{\pi}_{\mu,g,T}$ and the context weights are such that the weighted expectation remains finite.

Concept 218 (Intellectual breadth)**.** *Appendix label: concept:IntellectualBreadth. Body definition label: hsdef:IntellectualBreadth (see §21.11).*

Informal definition. *A diversity measure: not just "how well" an agent performs, but how widely spread the contexts are in which it performs well. Formally, it is the Shannon entropy of a normalized distribution over contexts weighted by the agent's (efficiency-adjusted) performance. Equivalently, the metric treats the agent's overall "competence mass" as something that can be distributed unevenly across contexts: an agent that is extremely strong in a narrow cluster of contexts has low breadth, whereas an agent that allocates substantial competence across many distinct contexts has higher breadth. This also makes breadth sensitive to contextual coverage rather than to raw scale alone: if an agent doubles its performance uniformly in all contexts, the normalization below removes that uniform scaling so that the breadth score reflects the shape of the distribution rather than its magnitude.*

Formal definition. *Define context weights*

$$\chi_{\mathrm{Con}_\pi}(\mu, g, T) \;:=\; \sum_{Q\in\mathcal{Q}} \eta_{\mu,g,T}(Q)\, \frac{V^{\pi}_{\mu,g,T}}{Q}.$$

The quantity $\chi_{\mathrm{Con}_\pi}(\mu, g, T)$ can be read as an efficiency-adjusted expected value in the specific context (μ, g, T), with the expectation taken over the random or variable resource usage Q. In particular, contexts in which π attains high value while consuming little resource produce large

χ_{Con_π}, while contexts that require large Q for modest value are down-weighted. If $V^\pi_{\mu,g,T}$ can be negative in the underlying framework, then χ_{Con_π} may also be negative; in such cases, interpreting $\chi^P_{\mathrm{Con}_\pi}$ as a probability distribution would require additional conventions (e.g. truncation, shifting, or restricting to nonnegative values) to preserve the Shannon-entropy interpretation.

Normalize:

$$\chi^P_{\mathrm{Con}_\pi}(\mu, g, T) := \frac{\nu(\mu)\gamma(g,\mu)\tau_{g,\mu}(|T|)\chi_{\mathrm{Con}_\pi}(\mu, g, T)}{\sum_{\mu',g',T'} \nu(\mu')\gamma(g',\mu')\tau_{g',\mu'}(|T'|)\chi_{\mathrm{Con}_\pi}(\mu', g', T')}.$$

This normalization produces a context-indexed distribution (when the denominator is positive and finite) that answers: "of the agent's total weighted efficiency-adjusted performance, what fraction is contributed by context (μ, g, T)?" The denominator therefore plays the role of a total mass or partition function; it must be nonzero for the normalization to be meaningful, and finiteness parallels the convergence requirements in efficiency-style sums. Because $\nu(\mu)\gamma(g,\mu)\tau_{g,\mu}(|T|)$ appear both here and in $\Pi^{\mathrm{eff}}(\pi)$ above, the breadth measure is aligned with whatever priors or importance weights are used to aggregate performance, differing only in that it focuses on the distributional spread rather than on the aggregate level.

Then

$$B_{\mathrm{int}}(\pi) \;:=\; -\sum_{\mu,g,T} \chi^P_{\mathrm{Con}_\pi}(\mu, g, T)\,\log\bigl(\chi^P_{\mathrm{Con}_\pi}(\mu, g, T)\bigr).$$

This is the Shannon entropy of $\chi^P_{\mathrm{Con}_\pi}$; the choice of logarithm base determines units (e.g. base 2 gives bits, base e gives nats) but does not change the ordering of breadth values across agents. When $\chi^P_{\mathrm{Con}_\pi}$ concentrates on a single context, $B_{\mathrm{int}}(\pi)$ approaches 0, while broader and more uniform allocations across many contexts yield larger entropy. As usual for entropy, contexts with $\chi^P_{\mathrm{Con}_\pi}(\mu, g, T) = 0$ contribute 0 by continuity (interpreting $0 \log 0 := 0$), so only contexts receiving nontrivial performance mass affect the sum.

Concept 219 (Multi-criterion driven general intelligence)**.** *Appendix label: concept:MultiCriterionGeneralIntelliger Body definition label: hsdef:MultiCriterionGeneralIntelligence (see §21.11).*

Informal definition. *A stance that "general intelligence" should not be collapsed to one scalar utility. Instead, one models multiple objectives (e.g. efficiency, breadth, and additional value dimensions) and treats the set of Pareto-optimal tradeoffs as the appropriate "target" rather than a single maximizer. This viewpoint is motivated by the observation that different desiderata can be structurally in tension: for example, increasing intellectual breadth may require allocating time or compute away from maximizing performance in a narrow benchmark, and optimizing worst-case robustness may reduce peak efficiency in easy cases. Accordingly, rather than choosing an arbitrary scalarization (e.g. a fixed weighted sum) up front, one retains the geometry of tradeoffs and regards the frontier itself as the object of interest.*

Formal definition. *Fix Π_{adm} and $\mathbf{J}(\pi) = (J_1(\pi), \ldots, J_k(\pi)) \in \mathbb{R}^k$. Define $\pi' \succ \pi$ iff $(\forall i)\, J_i(\pi') \geq J_i(\pi)$ and $(\exists j)\, J_j(\pi') > J_j(\pi)$. Then the Pareto set is*

$$\mathrm{Pareto}(\mathbf{J}) \;:=\; \{\pi \in \Pi_{\mathrm{adm}} : \nexists \pi' \in \Pi_{\mathrm{adm}} \text{ with } \pi' \succ \pi\}.$$

Here Π_{adm} encodes feasibility constraints (e.g. computability, safety constraints, training budget, interface limitations), ensuring comparisons are made among agents that are considered admissible under the same rules. The dominance relation $\succ$ is the standard (strong) Pareto dominance: π' dominates π if it is at least as good on all criteria and strictly better on at least one; thus, any π outside the Pareto set is unambiguously improvable without sacrificing any objective. Conversely, *elements of* Pareto($\mathbf{J}$) *are precisely those for which improvement in one criterion requires degradation in another (or else leaving* Π_{adm}*), so the set describes the irreducible tradeoff surface among the chosen intelligence-relevant measures. In applications, one often studies not only set membership but also the shape of the frontier (e.g. its convexity or coverage), since different training methods or inductive biases may populate different regions of* Pareto($\mathbf{J}$) *even when they achieve similar scalarized scores.*

C.3 Concepts Regarding Universal Grammar

Concept 220 (Universal Grammar (interface-theoretic))**.** *Appendix label: concept:UniversalGrammarInterfaceThe Body definition labels: hsdef:TraceBasedUniversalGrammar, hsdef:TUGCongruence (see Section 22.6).*

Informal definition. *"Universal Grammar" is treated here not as a list of stipulated constraints, but as the weakest equivalence theory on derivations that preserves a chosen meaning/externalization interface. In Hyperseed terms, UG is a weakness-maximizing collapse of derivational distinctions subject to an interface fidelity constraint (Hyperseed-Concept 202, 98,* **??***).*

This shifts the explanatory burden from "which derivations are allowed" to "which derivational differences can be systematically ignored without changing what the interface can observe." The resulting notion of UG is therefore explicitly observer-relative: changing the observation interface (or changing what counts as a symmetry) changes the induced equivalence, and hence changes which derivational distinctions survive into the theory.

Formal definition. *Fix a grammar LTS G and an observation interface* $(\mathcal{O}, \mathrm{obs}_{\mathcal{O}})$*. Let* $\equiv_{\perp,\Gamma}$ *be the UG core congruence induced by a choice of independence relation* $\perp$ *and symmetry group* Γ *(Definition 364). The interface-theoretic UG core is the quotient of derivations by* $\equiv_{\perp,\Gamma}$*, i.e., the identification of derivations up to independent swaps and declared symmetries, with* τ*-steps ignored.*

Equivalently, UG here is the congruence class semantics of derivations: two derivations count as the same "UG object" when they cannot be told apart by the interface after factoring out (i) swapping of independent actions, (ii) renamings/relabelings declared by Γ*, and (iii) internal bookkeeping steps modeled as* τ*. The quotient perspective makes precise the sense in which UG is a minimal (weakest) theory compatible with the specified interface fidelity constraint.*

Concept 221 (Trace-based Universal Grammar (TUG))**.** *Appendix label: concept:TraceBasedUniversalGrammar. Body definition label: hsdef:TraceBasedUniversalGrammar (see Section 22.6).*

Informal definition. *TUG is the specific formal package from the UG manuscript: a triple consisting of (i) what is observable at the interface, (ii) which actions commute (independence), and (iii) which visible differences are treated as equivalent (symmetries). It is a clean bridge between linguistic UG and Hyperseed's observer-relative weakness program.*

The key point is that TUG separates three logically distinct choices that are often conflated in more informal uses of "UG": the observational granularity (what counts as preservation), the dependency topology (what can be permuted without changing that observation), and the invariances of labeling (what is treated as mere presentational variation). In particular, the same grammar LTS can support multiple TUGs, corresponding to different interface commitments (e.g., semantics-only vs. semantics-plus-externalization).

Formal definition. *A TUG is a triple* $(\mathcal{O}, \perp, \Gamma)$ *as in Definition 364, built over a grammar LTS and observation map.*

Concretely, $\mathcal{O}$ *fixes the codomain of observations (the "interface report"),* $\perp$ *specifies which visible labels in* Lab_V *commute (capturing a trace/partial-order view of derivations), and* Γ *specifies which relabelings preserve the intended interpretation of visible steps. The induced congruence* $\equiv_{\perp,\Gamma}$ *(see also Definition 363) is then the mechanism by which TUG turns raw derivational sequences into equivalence classes that function as UG-level objects.*

Concept 222 (Observation Interface)**.** *Appendix label: concept:ObservationInterface. Body definition label: hsdef:ObservationInterface (see Section 22.6).*

Informal definition. *An observation interface specifies which aspects of a grammar derivation "count" as preserved: e.g., LF-only (semantic commitments) vs LF+PF (semantic plus surface externalization traces). In Hyperseed terms, this is a context/aspect choice that selects which distinctions are active (Hyperseed-Concept 86, 98).*

In practice, the interface is where one decides what a learner, parser, or external evaluator is allowed to "see." For example, an LF-only interface may identify derivations that differ in phonological linearization but agree in scope and binding, whereas an LF+PF interface may keep additional distinctions corresponding to word order, agreement morphology, or prosodic marking, to the extent those are part of $\mathcal{O}$*.*

Formal definition. *An observation interface is a pair* $(\mathcal{O}, \mathrm{obs}_{\mathcal{O}})$ *with* $\mathrm{obs}_{\mathcal{O}} : \mathrm{St} \to \mathcal{O}$ *(Definition 357).*

The map $\mathrm{obs}_{\mathcal{O}}$ *can be read as a projection (or forgetting map) from full grammar states to the information retained at the interface. Because* $\mathrm{obs}_{\mathcal{O}}$ *is defined on states, rather than directly on derivations, interface preservation is naturally expressed in terms of which state components are required to match, and which internal details may vary while remaining observationally equivalent.*

Concept 223 (Canonical Constraint Store)**.** *Appendix label: concept:CanonicalConstraintStore. Body definition label: hsdef:GrammarStateSpace (see Section 22.6).*

Informal definition. *To make interface-equivalence tractable, meaning-bearing choices must leave persistent, canonical "traces in state" (e.g., scope constraints, binding commitments, question operators). This mirrors Hyperseed's treatment of stable representational tokens as the carriers of later inference (Hyperseed-Concept 157, 184).*

The emphasis on canonicity is methodological: if semantically relevant commitments are stored in a normal form, then two derivations that differ only in inessential order or in internal naming choices can still be compared by inspecting the same kind of state object. This is exactly what is needed for quotienting: interface equivalence should reduce to equality (or a simple equivalence) of canonical stores, rather than requiring reconstruction of the full derivational history.

Formal definition. *A canonical constraint store is the* Σ *component of the grammar state space* $\mathrm{St} = \mathcal{T} \times \Sigma$ *(Definition 355), where elements of* Σ *are finite sets (or finite multisets) of interface atoms, presented in a fixed normal form.*

Typical interface atoms (depending on the grammar) may encode scope orderings, variable-binding constraints, agreement requirements, or other commitments that the observation map $\mathrm{obs}_{\mathcal{O}}$ *is designed to preserve. The "fixed normal form" requirement ensures that semantically identical stores do not differ merely by syntactic presentation (e.g., ordering of constraints, choice of fresh names), which in turn supports the intended identification of derivations under* Γ*-symmetries and* $\perp$*-commutations.*

Concept 224 (Rely Footprint)**.** *Appendix label: concept:RelyFootprint. Body definition label: hsdef:ResourcesAndRelyFootprints (see Section 22.6).*

Informal definition. *A rely footprint records which semantic/interface resources a grammatical action touches. It is the bridge between (i) linguistic locality/economy constraints and (ii) concurrency-style dependency topology.*

Intuitively, resources are the "places" where actions could interfere: if two steps both modify or consult the same resource, they can create an ordering dependency that the interface can detect. Conversely, if their rely footprints are disjoint, the steps are candidates for commuting without changing what is ultimately observed. This makes the rely footprint a compact static summary of potential interaction, analogous to read/write sets in program logics.

Formal definition. *Given a resource set* Res*, a rely footprint is a map* rely : $\mathrm{Lab}_V \to 2^{\mathrm{Res}}$ *(Definition 359).*

The choice of Res *is part of the modeling commitment: it may include, for example, features, indices, discourse referents, scope sites, phase-bounded domains, or other interface relevant loci. The point is not that* all *such structure must be enumerated, but that enough is tracked to justify the intended independence relation* $\perp$ *and the induced trace-based identifications.*

Concept 225 (Grammatical Independence)**.** *Appendix label: concept:GrammaticalIndependence. Body definition label: hsdef:GrammaticalIndependence (see Section 22.6).*

Informal definition. *Two meaning-bearing grammatical actions are independent if they act on disjoint parts of structure and disjoint semantic resources, so their order does not matter to the interface. Independence is the formal source of the "trace monoid" viewpoint and, later, of economy/locality results.*

In this setting, independence is not merely a claim about derivational convenience; it is the mechanism that licenses collapsing sequential histories into partial orders. When two steps are independent, the interface-theoretic UG core treats the two possible orders as the same derivation up to $\equiv_{\perp,\Gamma}$*, reflecting the idea that any ordering difference is an artifact of the derivation strategy rather than a difference in linguistic outcome.*

Formal definition. *Grammatical independence is the relation* $\perp$ *on* Lab_V *defined in Definition 361.*

Typically (and depending on the specific instantiation), $\ell_1 \perp \ell_2$ *is justified by a combination of (i) disjointness of their rely footprints and (ii) non-overlap of the structural regions they update, ensuring that swapping the corresponding steps preserves* $\mathrm{obs}_{\mathcal{O}}$ *up to the intended symmetries. This is the precise locus where locality/economy intuitions are translated into a concurrency-style commutation criterion.*

Concept 226 (Label Symmetry Group)**.** *Appendix label: concept:LabelSymmetryGroup. Body definition label: hsdef:LabelSymmetryGroup (see Section 22.6).*

Informal definition. *A label symmetry group specifies which systematic relabelings of visible grammatical actions are treated as inessential for interface purposes. Examples include renaming of indices, uniform permutation of feature names within an agreed schema, or alternative but equivalent encodings of the same interface commitment. Declaring such symmetries makes explicit which differences are regarded as representational artifacts rather than genuine grammatical distinctions, aligning with the Hyperseed idea that a theory may quotient by a chosen invariance (Hyperseed-Concept* **??***, 98).*

In the TUG package, Γ *complements independence:* $\perp$ *identifies differences due to ordering of commuting steps, while* Γ *identifies differences due to alternative naming or presentation of the* same *kind of step. Both are needed if the goal is to capture interface preservation rather than derivational idiosyncrasy.*

Formal definition. *A label symmetry group is the group* Γ *acting on the visible label set* Lab_V *as in Definition 362. The induced action is used inside the congruence* $\equiv_{\perp,\Gamma}$ *to identify derivations whose visible steps differ only by application of elements of* Γ*.*

In particular, Γ *provides the formal vehicle for factoring out uniform renamings (e.g., of freshly introduced symbols) that do not alter the interface observation once the canonical constraint store and observation map are taken into account. This ensures that the UG quotient is sensitive to meaning and externalization choices, but insensitive to arbitrary representational conventions.*

Concept 227 (Trace Quotient)**.** *Appendix label: concept:TraceQuotient. Body definition label: hsdef:TUGCongruence (see Section 22.6).*

Informal definition. *The trace quotient is what you get when you collapse derivational differences that are not distinguished by the interface: reorderings of independent actions and symmetry-equivalent labels. It is an explicit, algebraic representation of Hyperseed weakness applied to derivations.*

Formal definition. *The trace quotient is the quotient monoid* $\mathrm{Lab}_V^*/{\approx_{\perp,\Gamma}}$ *where* $\approx_{\perp,\Gamma}$ *is the TUG congruence (Definition 363).*

Concept 228 (Principles and Parameters (as invariants and symmetries))**.** *Appendix label: concept:PrinciplesParametersAsInvariants.*
Body reference: Remark 1230 (see Section 22.6).

Informal definition. *"Parameters" correspond to choices about what is observed and which surface differences are declared equivalent; "principles" are the invariants that remain once these choices are made. This reframes P&P as an invariance/quotienting story rather than a hard-coded axiom list.*

Formal definition. *Fix a family of grammars over a shared operational substrate. A* parameterization *is a choice of observation interface* $\mathcal{O}$ *and symmetry group* Γ *(and possibly a change in the visible label inventory). A* principle *is any property invariant under the induced UG core congruence* $\equiv_{\perp,\Gamma}$ *across the family.*
